TUNNELLING FOR A BETTER LIFE

Tunnelling for a Better Life contains the contributions presented at the ITA-AITES World Tunnel Congress 2024, which was held from 19-25 April 2024 in Shenzhen, China. As urbanization accelerates, the pivotal role of tunnels and underground spaces in fostering environmental sustainability and improving quality of life becomes ever more pronounced. These underground structures serve as sustainable solutions to the challenges posed by rapid urban growth. By seamlessly integrating into urban landscapes, they alleviate congestion, reduce pollution, and enhance overall mobility, thus contributing to a greener and more sustainable urban environment. Moreover, tunnels and underground works provide vital support for various urban functions, such as accommodating economic activities, providing safe shelters during emergencies or disasters, and facilitating efficient utility management. They address immediate urban needs and lay the foundation for a better and more resilient future.

By focusing on the latest trends in tunnelling and underground engineering, and looking ahead to the era of low-carbon and intelligent technology, the papers in this book illustrate the transformative potential of tunnels and underground works in shaping a better life for present and future generations. The contributions cover a comprehensive range of topics on tunnel engineering, showcasing the latest advancements, insights, and innovations across the following areas:

1. Planning and General Aspects
2. Design and Methodology
3. Geotechnics, Geology and Geophysical Prospecting
4. Ground Stability and Consolidation
5. Support and Lining
6. Conventional Tunnelling
7. Mechanized Tunnelling (TBM, shield)
8. Immersed Tunnels
9. Waterproofing and Drainage
10. Instrumentation and Monitoring/Testing and Inspection
11. Digital and Information Technology
12. Machine Learning
13. Underground Caverns/Underground Space Use
14. Operational Safety, Maintenance and Repair
15. Contractual Practices and Risk Management

Tunnelling for a Better Life is a must-read for professionals, engineers, owners, and other stakeholders worldwide in tunnelling and underground engineering.

Table of contents

Preface	xxxvii
Acknowledgements	xxxix
WTC 2024 Organization	xli
<i>Planning and general aspects</i>	
Multilateral institutions and governance of urban underground space <i>N. Bobylev, Y.-K. Qiao & F.-L. Peng</i>	3
Forecast and trends related to key personnel for mechanised excavation with TBMs <i>F. Bove</i>	8
The common duct in New Taipei City <i>H.C. Chao, C. Song, T. Ko, I.K. Chiu & Y.C. Lin</i>	13
Progress and prospect of urban tunnel engineering in China <i>X. Chen</i>	20
New chemicals with reduced carbon footprint <i>F. Couturier, D. Matioszek & T. Boursier</i>	28
City Rail Link – City Rail Link: Managing challenges on the pioneer underground metro project in New Zealand <i>F. Dudouit</i>	33
Nuclear decommissioning in the UK: Cross-sector collaboration and learning with the tunnelling and underground space sector investigating alternative approaches to reactor dismantling and graphite retrievals <i>D. Garbutt & M. Knights</i>	41
Planning of alignment & proposed actions for tunnel collapse in diverse ground conditions on the steepest railway curves in the Eastern Ghats, India <i>R. Gupta, L. Kumar & A. Kumar</i>	47
Comparison of carbon footprint emissions in tunneling projects using innovative methods <i>P. Jarast & V. Nasri</i>	57
Collaboration in Moscow Metro development: Analysis of joint construction efforts by Russian and Chinese builders <i>V.P. Kivlyuk, A.I. Paschenko, D.S. Konyukhov, L. Xue, J. Zhou, S.N. Vinogradov, K.V. Orlov, Y. Song, J. Huo, Y. Lyu, Z. Gu & T. Wang</i>	65

The application of technology for resource utilization, reduction, and harmless treatment of subway shield tunneling waste soil	72
<i>J. Lei, H. Long, K. Jia, T. Song & H. Pan</i>	
Development and prospects of railway tunnels in China	78
<i>X. Li, S. Tian, W. Wang, J. Gong & H. Wang</i>	
Differentiated driving effects of China's green transportation facilities assessment policy	87
<i>Y. Liu & W. Qiu</i>	
Planning and execution of horizontal directional coring method for future tunnelling works	96
<i>F. Mahony, K. Goh & C. Veeresh</i>	
Theory meets practice: Evaluating discrepancies between theoretical settlement projections and actual measurements in tunnelling projects with tunnel boring machines	101
<i>E. Navarro, E. Salvador & F. Diez</i>	
Geotechnical and tunnel engineer's role on the success of major tunnel projects delivery	109
<i>J. Pan, D. Och, A. Kuras & G. Bateman</i>	
TBM traffic tunnels for sustainable infrastructure	116
<i>S. Pompeu-Santos</i>	
Underground space use layout planning using multi-source spatial data	125
<i>Y.K. Qiao, Z.Y. Li, N. Bobylev & F.L. Peng</i>	
Tunnelling in a green country – Brenner Base Tunnel study case: Decision and solutions in construction lot H41 Sill Gorge-Pfons	132
<i>I. Zamberlan & C. Schwarz</i>	
Technical challenges and countermeasures of plateau railway tunnels	139
<i>Y. Zhao, T. Zhu & G. Yan</i>	
<i>Design and methodology</i>	
Observational method and calibration of design safety factors to optimize technical-economical solutions in tunnelling projects	149
<i>A. Antiga, M. Lorenzi & A. Lucia</i>	
Design of Ontario Line South Tunnel	158
<i>M. Bakhshi, V. Nasri, T. Maalouf</i>	
Design challenges in conventional tunnelling on the Sotra Link Project in Norway	164
<i>G. Barbieri, G. Bella, E. Trivellato, S. Agrillo & M. Giani</i>	
(I)-TM: I-System's tunnelling method – four years of application in most challenging ground in India	173
<i>H. Bineshian</i>	
Segment design for Australia's largest diameter TBM tunnel	182
<i>S.F. Chau, H. Asche, D. Oliveira, J. Shepherd & C. D'Hondt</i>	
Review of key technologies for design of Dalian Bay Undersea Tunnel	193
<i>Z. Chen, H. Chen & M. Lu</i>	
Design of tunnel brace and retaining structure on East Artificial Island of Shenzhen-Zhongshan Link	200
<i>H. Chen, C.N. He, X.D. Lai & L. Yu</i>	

Sustainability of Shihmen reservoir by desilting tunnel in Taiwan <i>C.E. Chiang, P.S. Kuo, H.T. Chiang & Y.J. Lin</i>	209
Advanced countermeasure for encountering heavy gas influx in new Wu-shan-ling divert water tunnel <i>K.H. Chou, S.H. Wang, C.H. Chen & T.H. Chen</i>	214
The “hybrid” tunnel. An innovative solution for urban tunnel in soils. The case of Américo Vespucio Oriente AVO1, in Santiago de Chile <i>J.M. Galera, M. de Cabo & G. Ibarra</i>	220
The effect of the movement joint on the seismic response of the cross-passage intersection in segmental tunnel lining <i>G. Giordano, D. L’Amante & G. Fantauzzi</i>	228
Development of sustainable criteria for the Italian railway tunnel design <i>F. Iacobini & A. Pranno</i>	235
Analysis on applicability of seismic calculation methods for shield tunnel in Shanghai area <i>X.X. Li & H. Chen</i>	240
Validation of joint non-linear numerical analysis with large-scale physical testing for arched cut and cover tunnels at HS2 project (UK) <i>M. Li, S. Psomas & N. Al Haddid</i>	247
Innovative application of low-carbon and energy-saving technology in underground space: A case study of erlangshan tunnel on Sichuan-Tibet expressway <i>G. Lin, J. Zheng, J. Wang & F. Yang</i>	256
Low carbon emission design concept and method for tunnels and underground engineering <i>G. Lu, J. Liu, Y. Zhao, S. Shi & Z. Zhang</i>	261
Design of the REM Aéroport de Montreal’s P5 ventilation shaft <i>M. Mains, J. Lee & V. Nasri</i>	270
Tunnels and stations design of Montreal Blue Line <i>V. Nasri</i>	277
Influence of calculation method on the design of the secondary lining <i>J. Ortuta & M. Bakoš</i>	285
Research on smart design and innovation of Jiaozhou bay second tunnel <i>L. Qu, X. Li, M. Tan, H. Jiang, M. Xiao & W. Sun</i>	292
Application of a confinement-dependent spalling criterion for tunnels in highly stressed brittle rock <i>M. Rahjoo & E. Eberhardt</i>	300
Practical considerations of shale swelling impact on underground structures liner design for Ontario Line transit project in Toronto, Canada <i>M. Rahjoo & V. Nasri</i>	308
How to consider the effects of longitudinal joint imperfections on internal forces in segmental tunnel linings <i>F. Rauch & O. Fischer</i>	315
Athens metro “Piraeus” station: Numerical analysis versus observational method <i>K. Sampakis-Bakopoulos & N. Gerolymos</i>	323

Karanga-a-Hape Station MC21 Junction – Collaborative solutions for complex geology and geometrical constraints - Tackling the challenges at Karanga-a-Hape Station caverns	329
<i>A. Sarathchandran, G. Charlesworth & R. Graafhuis</i>	
Design of temporary cofferdam and deep excavation for cofferdam tunnel of Shenzhen-Zhongshan Link	337
<i>Z. Shi, C.N. He, L. Yu & Q.W. Xia</i>	
Comparative effects of twin-stacked tunnel excavation on adjacent structure using different simulation models	345
<i>N. Sittiamornporn, P. Jongpradist, C. Phutthananon, A. Chayaroon & P. Malaisree</i>	
Key technology of Submarine railway tunnel in complex environment and high-water pressure	352
<i>C. Song, W. He, S. Lv & Y. Yu</i>	
Development and innovation of design method for railway tunnel support system in China	360
<i>S. Tian, D. Liu, Y. Zhang & X. Li</i>	
Maungawhau mined tunnels - Collaborative design – Management of design amendments for Maungawhau mined tunnels for improved construction schedule outcomes	368
<i>H. Toi, R. Gong, D. Wang & G. Charlesworth</i>	
“SINTEF-TriPOD” in underground design – A demonstration for two projects in Norway	377
<i>N. Trinh & E. Grøv</i>	
Automatic computation for design of tunnel shafts	385
<i>C.K. Tsang, A. Koay & T. Sia</i>	
Case study about adjacent three-arch tunnel	390
<i>H. Tseng, K. Kuo & T. Chu</i>	
Optimizing the tunnel ventilation design related to respirable dust in tunnelling by using CFD	396
<i>R. Wei, R. Galler & C. Weiß</i>	
Study on the mechanism of tunnel structure damage under the combined effects of fault creep and earthquakes	402
<i>Z. Xia, S. Jia, J. Wang & Q. Wang</i>	
Theory and practice of total safety factor method for tunnel support structure design	406
<i>M. Xiao, B. Xie, C. Xu, K. Wang & Z. Deng</i>	
Considerations of the coefficient of subgrade reaction forces on seismic response displacement method of a double-circular shield tunnel	416
<i>M. Xu & T. Manabe</i>	
Analysis of key technologies in structural design of prefabricated station of Shenzhen Metro	424
<i>Z. Xu, D. Meng, R. Liu & M. Li</i>	
Addressing design challenges in large diameter tunnels with big openings in deep soft ground: Innovative solutions and analysis techniques	432
<i>J. Yuan, V.C.S. Goh & C. Maxcia</i>	
Aseismic mechanism of laminated shear energy dissipation structure in tunnels during an earthquake	441
<i>X. Zhang, A. Cao, Y. Jiang & X. Wang</i>	

Geotechnics, geology and geophysical prospecting

An improved simplified solution for the characteristic line of tunnels in strain-softening rocks <i>M. Anthi, Th. Pferdekämper & G. Anagnostou</i>	451
Estimation of tunnel support loads due to large deformation in squeezing ground conditions <i>K. Arora & M. Gutierrez</i>	457
Tunnelling in weak sandstone: A case study of Subansiri Lower Hydroelectric Project (2000 MW) <i>M.S. Chouhan & S. Potnis</i>	467
Correlation of empirical classification systems in squeezing anisotropic environment and optimisation of underground supports in a headrace tunnel; a case study from Tanahu Hydropower, Nepal <i>E. Christakis, B. Parajuli, P. Yao & R.K. Adhikari</i>	476
Hydro-geo-mechanical properties for water flow prediction in tunnelling <i>M. Coli & R.E. Rizzo</i>	485
3D Geological reconstruction and application of tunnel face <i>D. Duan, H. Bai, W. Li & W. Qiu</i>	493
Study of microgravity survey to predict the Bukit Timah rock head for tunnelling in Singapore <i>T.E.S. Ernest, C. Veeresh, J. Kumarasamy & K.H. Goh</i>	501
Rock drilling aerosol deslagging technology and CFD-DEM two-way coupling numerical simulation of weak surrounding rock geology <i>S. Guo</i>	509
Uninterrupted continuous forecasting in mechanized tunnelling in rock <i>J. Hecht-Méndez, T. Dickmann & D. Krueger</i>	517
Limits on the estimation of the EPB face pressure. A concrete example based on Kalman filter approach <i>C. Iasiello, A. Flor & P. Fantini</i>	523
Experimental study of rheological characteristics of bentonite-based drilling fluids <i>S. Javarone, M. Palombini, M. Cinelli, I. Bavasso & D. Sebastiani</i>	529
Optimized electrical exploration for predicting geological transitions ahead of a tunnel based on harmony search algorithm <i>M. Kang, K. Kwon, S. Park, Y. Choe & H. Choi</i>	536
High resolution resistivity imaging for assessment of geological conditions ahead of tunnel face in a complex geology <i>S.L. Kapil</i>	542
Tunnel engineering application of assessment technology of karst development degree based on hydrochemical kinetics and fractal theory <i>C. Li, J. Wu, Q. Li, W. Yu & S. Lu</i>	548
Model test and analysis of failure mechanism of deep high sidewall tunnel from splitting failure to zonal disintegration <i>F. Li, Q. Zhang, G. Xin & G. Long</i>	556
Development and test of directional coring drilling system for advanced geological exploration <i>J. Liu</i>	565

Geological risks in TBM tunneling and its prediction by HSP method <i>S. Lu, Y. Xiao & X. Wang</i>	572
Rock abrasiveness in the studies of são paulo metro: Tests, classification systems, parameters obtained from various lithotypes and their relationship with weathering degree <i>M.D. Monteiro, H C. Rocha, G.B. Robbe & A.M. de Almeida</i>	579
Phased prediction method for construction period of secondary lining construction time of tunnel in squeezed rocks <i>L. Ning</i>	584
Ground characterisation of the Sydney Basin for tunnelling works <i>D.J. Och, J. Pan, I.T. Graham, N. Walker, A. Kuras & G. Alvarado</i>	591
Chengdu-Guiyang High-speed railway—Yujingshan Mountain Tunnel crossing giant karst cave and underground river <i>W. Qing, Y. Yu, J. Zheng, Y. Zhu & Y. Wang</i>	598
Tunnel behavior in soft soils subjected to pore water pressure drawdown <i>A. Santos, R. Pérez-Léon, J. Rodríguez-Rebolledo & B. Caicedo</i>	608
The deformation characteristics of soft soil layers with different sand content and the time and space effects of foundation pit excavation on the tunnels below <i>C. Shen, M. Miao, C. Huang, Y. Dong & J. Fan</i>	616
Non-invasive tunnelling investigations using muon tomography <i>C. Steer & L.F. Thompson</i>	625
Empirical correlations between ground's mechanical properties and I-system <i>C. Upadhye, S. Potnis & B. Hoss</i>	629
Research on key technology of design of long tunnel in water-rich karst platform of compound syncline basin <i>H. Wang, M. Wang, H. Fu, P. Li & Z. Li</i>	638
Numerical simulation of the mechanism of strain rockburst under true triaxial loading and unloading conditions <i>Y. Xue & H. Tian</i>	647
Sequential 3D geological information system using re-grid of voxel model based on exploration data ahead of the tunnel face <i>S. Yoshikawa, Y. Aono, K. Saito & T. Nishi</i>	655
HSP Method-based advanced geological prediction and tunneling parameter pre-control technology for super-large diameter pipe-jacking project <i>Z. Zhao, F. Lan, B. Wang, L. Meng, X. Wang & S. Lu</i>	660
<i>Ground stability and consolidation</i>	
Excavation induced settlement in Sydney area <i>G. Alvarado, S. Sadeghian & Y. Dong</i>	671
A modified approach to assess tunnel excavation stability <i>S. Anwar & G. Charlesworth</i>	678
Study on crosslink-induced Xanthan Gum biopolymer treated soil as a subsea tunnel backfill grout for saline condition permeability control <i>J. Bang, D.-Y. Park, J. Kim, S. Im & G.-C. Cho</i>	685

Fixing of unstable water-saturated soils by artificial freezing for construction of inter-tunnel joints during metro construction	689
<i>E.A. Deplagni, V.P. Kivliuk & D.S. Konyukhov</i>	
Factors impacting thawing-refreezing around tunnels in permafrost soils	695
<i>S. Gavhane & S. Potnis</i>	
Deformation characteristics of long and narrow deep foundation pit with partition walls	705
<i>H. Geng, S. Guan, Z. Chen, G. Dai & Z. Li</i>	
Disturbance effect and surrounding rock pressure characteristics of loess shield tunnels	711
<i>X. Han, P. Wang, Z. Chen, H. Feng, H. Cui & F. Ye</i>	
Numerical simulation of polymer grouting for rock fracture: Influence of isocyanate index on grout propagation	718
<i>M. Hao, J. Zhang, L. Zou & X. Li</i>	
Dynamic soil response around a shallow rectangular tunnel and adjacent building	726
<i>Z. He & S.P. Gopal Madabhushi</i>	
Chemical-combined jet grouting for mass treatment of break-in area in Vietnamese urban underground construction	732
<i>H.Q. Le, H. Oyama & P.N. Do</i>	
A systematic deformation control methodology for underground space construction in close proximity to an existing metro station	740
<i>J. Li, R. Wen, W.W. Yang & W.F. Mou</i>	
Study on diffusion mechanism of backfill grouting in sand and clay stratum	747
<i>S. Li, F. Ye, T. Xia, K. Ying & X. Han</i>	
Influences of stress-dilatancy rule on the derivation of ground response curve for deep-buried tunnels	755
<i>J. Liang, J. Chen, J. Ma, H. Yang & L. Huang</i>	
The use of jet grouting technology: An overview of the different applications in tunnelling	760
<i>P. Lunardi, G. Lunardi, G. Cassani, M. Gatti, L. Bellardo & C.L. Zenti</i>	
Stability analysis of surrounding rock in a highway tunnel crossing a Water-Rich fault fracture zone	769
<i>S. Luo, X. Xie & D. Zhu</i>	
Selection of an ontological model for phyllite tunnel based on on-site measured	777
<i>J. Ma & J. Zhang</i>	
Analysis of stability of rock column between cut & cover metro station and NATM tunnels	783
<i>S. Maiti, M. Khare & S. Potnis</i>	
The freezing technique for the world's longest railway tunnel	789
<i>A. Marottoli, M. Ianeselli, R. Marrazzo, A. Gallotto, G. Vecchione, M. Cavolo & F. Gallo</i>	
Stability of portal slopes of a diversion tunnel after the Kahramanmaraş, Turkey (Türkiye) February 6, 2023 Earthquakes	798
<i>A.A. Mert & F. Caliskan</i>	
Numerical analysis of the deformation of undersea tunnel crossing fault zone	806
<i>J. Ni, J. Zhang, H. Huang, D. Zhang, & L. Zhang</i>	

Research on surrounding rock by shallow tunnelling in Boulder-Cobble Mixed formation: Instability characteristics and control strategies	813
<i>Y. Qin</i>	
Practical approach for the control of surface settlements due to TBM tunnelling during excavation by following up of monitoring	822
<i>V. Rattia, H. Rocha, A. Dantas, T. Mendes & A. Assis</i>	
Jet grouting soil improvement to excavate a tunnel under passing the A4 Milano-Venezia motorway for the extension of the line 1 of the Milan metro	828
<i>M. Silvestri, D. Chirulli, A. Antiga & P. Coppola</i>	
Study on the mechanical behavior of the vertical pre-reinforcement	836
<i>Y. Tatebayashi, N. Tamura, T. Amemiya, K. Kawata & N. Isago</i>	
Marble sludge in two-component grout applications	842
<i>C. Todaro, A. Carigi, M. Cardu & D. Peila</i>	
Study of support design and construction results of unconsolidated in Aso Caldera	848
<i>T. Tomita, T. Ano, H. Nagamatsu, H. Hirano & H. Tabata</i>	
State of the art of soil conditioning technology for earth pressure balance shield tunnelling	857
<i>Z. Wan, S. Li, S. Zhao, K. Qiu & S. Hao</i>	
Numerical prediction of tunnelling-induced displacement field in large and very shallow tunnels	865
<i>W. Yang, D. Zhang & D. Boldini</i>	
Stability numerical investigation of laminated and randomly discontinuous flat roof	871
<i>P. Yiouta-Mitra & E. Vougioukas</i>	
Responses of a shallow tunnel in liquefiable ground subject to multiple shakings	877
<i>J. Zhang, E. Bilotta, Y. Yang & Y. Yuan</i>	
Failure mechanism of reinforced faces and design method of advanced supports for tunnels excavated by the full-face mechanized method	882
<i>X. Zhang, M. Wang & L. Yu</i>	
Key technologies and safety analysis of deep foundation pit construction in a sea area	890
<i>Z. Zhao & S. Gao</i>	
Data-driven stability analysis and uncertainty quantification of surrounding rock mass for tunnel	897
<i>H. Zhao & L. Zhang</i>	
Study on settlement deformation of existing structures under ultra-large diameter shield tunnel	906
<i>M. Zou, C.L. Zhen & X. Xie</i>	
<i>Support and lining</i>	
Rock bolt design, A numerical parametric study	917
<i>S. Anwar, A. Mann & S. Sadeghian</i>	
The effect of a frictional interface in a preliminary yielding support for a deep tunnel	926
<i>L. Batocchioni, V. González & S. Miliziano</i>	
Numerical calculation approach for the design of segmental tunnel lining equipped with inflatable O-ring sealing	932
<i>M. Bazzani, F.D. Santis, P. Fantini, M. Daniele & S. Pesa</i>	

The mechanism, functioning and installation of reinforced ribs of shotcrete in Norwegian Method of Tunnelling (NMT)	941
<i>R. Bhasin & M. Shabanimashcool</i>	
Shotcrete structural behaviours as tunnel support in hard jointed rocks – Swedish state of the art	946
<i>Y. Chang & C. Höök</i>	
Study on the influence of cracks on mechanical behaviors of tunnel lining of high speed railway with a speed of 400 km/h	953
<i>P. Chen, K. Liu & C. Yan</i>	
Design and verification of shear key support system for segmental lining openings at cross passages using non-linear finite element model	962
<i>J.T. Chong</i>	
Environmental and economic advantages in using HPFRSCC in tunnelling	969
<i>M. Coli, M. Francini, L. Martelli & M. Tanzini</i>	
Structural and sustainability requirement with high performance fibre reinforced precast segment carbon counting example	977
<i>B. de Rivaz</i>	
Research on reinforcement measures for soft plastic loess tunnel base	983
<i>Q. Deng</i>	
Analytical solution to failure history of segment joint with inclined steel bolt	991
<i>X. Dong, B. Du & X. Chen</i>	
Numerical analysis of two deep circular shafts at a former gas works site on the London Power Tunnels Phase 2 scheme	1000
<i>J. Ellis, O. Brown, A. Simic, R. Kundan & J. Coupland</i>	
Comparative analysis of simplified solutions for the radial joint behaviour of segmental tunnel linings with finite element numerical modelling	1008
<i>A. Emadi & A.R. Gomes</i>	
Steel lining support in headrace tunnel of Uma Oya Project, Sri Lanka	1015
<i>A.R. Farshbar, A. Noorzad, P.V. Yuvaraju & B. Rejith Kumar</i>	
Durability of two-component backfill grout: An experimental study	1021
<i>M.D. Felice, A.D. Giulio & N. Valiante</i>	
Tangential resistance between primary and secondary lining with PVC waterproofing sheet membrane	1027

Analysis of composite shell lining based on laminated theory <i>W. Shuyi</i>	1183
Singapore's land transport authority: 25 years of sprayed concrete lining tunnelling <i>A. Sim, K.B. Chang, M. Marotta, C.K. Poh & M. Mohiadeen</i>	1189
Design of precast bolted universal segmental tunnel lining for the London Power Tunnels phase 2 scheme <i>A. Simic, O. Brown & J. Ellis</i>	1199
Value engineering of concrete mix to save 230 tonnes of steel fibre for the west section of the Thames Tideway Tunnel <i>J. Su, S. Sheth, A. Ellison & C. Barret</i>	1207
Dynamic response characteristics of ultra-shallow buried metro station structures under surface vibration load <i>L. Tao, L. Deng, Y. Zhang & Z. Jia</i>	1216
Mechanical response and fault-resistant design of urban shallow subway tunnel under normal fault <i>L. Tao, J. Liu, Z. Wang & M. Shi</i>	1224
Analytical solution for longitudinal response of cross-fault mountain tunnels based on foundation beam model <i>L. Tao, M. Qiu, H. Zhang, Z. Jia, C. Shi</i>	1231
Experimental study on mechanical properties of grouted π -type SCCS arch <i>Z. Wang, W. Li & Y. Cai</i>	1238
Study on deformation joint width of mining tunnel under the operation of a normal fault <i>Q. Wang, D. He, J. Chen, P. Geng & H. Shen</i>	1244
Analysis of issues in the theory and calculation methods of composite lining for hard rock tunnels <i>N. Wang & X. Yang</i>	1250
Analysis of mechanical behavior and engineering suggestions for double-arch tunnel without middle drift <i>C. Wang, D. Zhang & Y. Li</i>	1258
A mechanical analysis model for tunnels crossing active fault zones <i>M. Wang, X. Zhang & L. Yu</i>	1267
Study on mechanical characteristics of a DDCI connection structure for longitudinal joints <i>M. Xiao, J. Chen, G. Xue, Z. Yan & S. Wang</i>	1276
Research on support parameters of the second Jiaozhou Bay Subsea tunnel based on the total safety factor method <i>M. Xiao, W. Sun, L. Chen & L. Jin</i>	1282
Research on the airproof performance of shield tunnel segment sealing gasket based on laser surface microstructure <i>M. Xiao, G. Xue, J. Chen, C. Zhang & S. Wang</i>	1291
Research on the application of marine engineering mass concrete with anti-cracking agent <i>B. Xie, W. Xu, Y.J. Wang, J. Zhang, W. Jin & J. Liu</i>	1297

Development and application of wall-climbing grinding robot for tunnel lining steel formwork	1303
<i>K. Yan</i>	
Retrospective analysis of the design and manufacture of a case of steel fibre reinforced segmental lining in view of the actual behaviour of some rings on site	1312
<i>Z. Yang, Z. Gu & P. García de Haro</i>	
Robustness evaluation on non-circular segmental tunnel linings: Case study on quasi-rectangular shield tunnel	1321
<i>Y. Ye, Z. Liu & X. Liu</i>	
The effect of polypropylene fiber on the strength and crack propagation of foam concrete	1326
<i>R. Yin, Q. Li, X. Zeng & W. Qiao</i>	
Research on construction technology of drilling and blasting tunnel based on load adjustment control technology	1333
<i>G. Ying, R. Zheng, Y. Xing & W. Chen</i>	
Construction and applicability of using double supports in a large overburden ground conditions as a countermeasure to suppress displacements	1340
<i>S. Zhai, D. Abeyawardena, H. Aoki, S. Ohmori & N. Isago</i>	
Mechanical evolution mechanism of primary support under steel arch frame corrosion in subsea tunnel	1347
<i>Y. Zhang, S. Tian, M. Wang & L. Yu</i>	
Effect of excavation on the pipe roof deformation under the action of the pipe roof-beam support system	1356
<i>W. Zhao, Q. Bai & D. Pi</i>	
Study on horizontal earth pressure of segment considering the influence of backfill grouting pressure	1365
<i>J.-L. Zhong, X.-C. Zhong, Y.-Z. Jian & F.-D. Li</i>	
Impact of base rock deterioration on the mechanical characteristics of loess-expansive mudstone tunnel lining structure	1373
<i>H. Zhu</i>	
 <i>Conventional tunnelling</i>	
Crystalline silica exposure in tunnel construction: Identifying barriers to safe practices	1383
<i>F. Anlimah, V. Gopaldasani, C. MacPhail & B. Davies</i>	
Design and construction optimisation of the Karanga-a-Hape Station mined tunnels and bored tunnel cross passages on the City Rail Link project	1390
<i>V. Balakumarasingham, P. Daudibertières, E. Chatoux & W. Okada</i>	
Experiences during tunnelling in extreme ground conditions in the Himalayas - Excavation of Rohtang Tunnel, India	1399
<i>R. Bernard</i>	
The impact of ramp width on tunnel face stability during ramp excavation	1405
<i>Q. Chen & Y. Cui</i>	
Deep underground mined cavern excavations in Auckland city centre, New Zealand	1412
<i>T. Cheung, W. Okada & S.F. Chau</i>	

Construction of Girgaon Station of Mumbai metro line – 3, a combination of cut & cover and conventional tunnelling and mix of social and technical challenges in congested urban environment	1418
<i>S.G. Dalvi, R.R. Kumar, S.K. Gupta & A. Rawat</i>	
Challenges in the conventional tunnel mixed-face execution	1424
<i>T. de Sá Lima, B. Scodeler & E.P. Filho</i>	
Research on key technologies for the construction of extra long tunnels on green roads in karst peak cluster areas	1429
<i>Z. Dong, B. Guo, Y. Zhou, Mengyan & S. Xing</i>	
Challenges and lessons learned from 100 km of major hydropower tunnels in Bhutan	1437
<i>T. Dorji, D. Brox & S. Wangdi</i>	
Design and construction considerations for cross passages in Bangkok subsoil	1446
<i>O. Duangsano, A. Sramoon, A. Asanprakit, A. Chayaroorn & N. Phienwej</i>	
Construction of underground rail tunnel above deep tunnel sewerage system	1455
<i>H.M. Fong, Q. Li & C. Veeresh</i>	
A study of merits and demerits of steel decking verses concrete decking for traffic management and construction logistics during construction of underground metro stations for Colaba-bandra-seepz (line 3) in Mumbai, India	1461
<i>S.K. Gupta, R.R. Kumar, D. Binnar & S. Vishwakarma</i>	
Automatic blasting design and construction system optimized for geological conditions	1469
<i>R. Hemmi, Y. Ide, K. Kakimi, T. Shizawa & F. Ito</i>	
Effect of focusing tube geometry and abrasive flow rate on rock drilling width	1475
<i>H.-J. Hwang, Y. Cha, J. Kim, C. Park & G.-C. Cho</i>	
Development of advanced tunnel blasting and shotcrete as automated tunnel construction system	1479
<i>K. Iwano, T. Aoyagi, T. Yamagishi, T. Mega & T. Inuzuka</i>	
Unforeseen excavation of mixed face soil conditions in a hard rock drill and blast road tunnel	1486
<i>P.D. Jakobsen, H. Nilsen & A.K. Lund</i>	
Evaluation of removable time of tunnel lining formworks using surface wave techniques	1492
<i>K. Kato, C. Kuroda, N. Utagawa & K. Ohno</i>	
Construction of desilting chambers and connecting tunnels for Vishnugad Pipalkoti He Project (444mw) in adverse geological conditions and very remote location - A case study	1499
<i>R.K. Khali</i>	
Construction of tunnel T-49A on Dharam – Qazigund section of Udampur-Srinagar-Baramulla New BG railway line project in highly adverse geological conditions- A case study	1507
<i>R.K. Khali & S. Yalal</i>	
Construction of a new tunnel in proximity to an in-service tunnel by implementing measures to control blasting vibration and ground displacement	1517
<i>Y. Kobayashi, T. Ishii, T. Koma, K. Nakano & Y. Kinomura</i>	
Cross passage tunnel excavation by core cutting machine (Stitching) and hydraulic rock splitters in hard rock at Mumbai Metro Station Line-03 (Aqua Line)	1526
<i>A. Kumar Saw, S. Potnis, M.J.C. & M. Roy</i>	

Test and research on load spectrum of tunnel drill jumbo <i>X. Liu</i>	1532
Experimental study of step method construction in soft and broken surrounding rock section of super-long and large section tunnels <i>Y. Liu, Y. Wang, T. Zhu, M. Tian & Q. Cheng</i>	1540
Innovative practice of mechanized and intelligent construction technology for railway mountain tunnel drilling and blasting method <i>K. Liu, Y. Yu, Y. Li & X. Liu</i>	1549
The Brenner Base Tunnel: An overview of the excavation types used in the project <i>D. Marini, G. Venditti, D. Unteregger, R. Insam & R. Marazzo</i>	1561
Key construction technologies for high-speed railway tunnels that with shallow buried depth and gentle slope in loess platform <i>W. Mi, Y. Wang, H. Zhang, X. Miao, J. Zhang & M. Zhang</i>	1569
Construction procedures of the tunnel for the extension works of Madrid Metro Line 3 from Villaverde Alto to El Casar <i>M. Núñez & J. Zurdo</i>	1579
Deformation failure characteristics and control measures of shallow loess tunnel of water-rich stratum: A case study <i>K. Tang & J. Qiu</i>	1586
Impacts of the February 2023 Kahramanmaraş, Turkey earthquakes on outlet works in rock formations <i>P. Uygur, Ö. Öztürk, E. Dumlu & F. Çalışkan</i>	1594
Research and development support for the construction of the big circle line on the example of the line's intersection with the existing facilities of the Moscow metro <i>V.V. Viazovoi, R.A. Evtushenko, D.S. Konyukhov & D.S. Petunina</i>	1602
Evaluation of impacts on existing structures induced by deep excavations in Bangkok MWA project <i>P. Vonghirunyika, W. Kroehong, T. Yonjoho, K. Kandavorawong, A. Chayaroon, O. Duangsano & P. Jongpradist</i>	1610
 <i>Mechanized tunnelling (TBM, shield)</i>	
Investigation of vibration patterns generated during rock cutting tests <i>U. Ates, H. Copur & A. Shaterpour-Mamaghani</i>	1621
Bio-polymer sodium alginate application as an eco-friendly additive in slurry TBM excavation <i>A. Bae, Y.J. Shin, Y. Choe, S. Kim & H. Choi</i>	1630
More efficient, cost-effective and reliable Slurry Treatment Plants (STPs) for mechanized tunnelling operations in the Asia-Pacific region <i>K. Bai & G. Vogt</i>	1634
An evaluation of using different excavation methods related to specific geologic conditions in the Istanbul area <i>C. Balci & N. Bilgin</i>	1641

Critical issues in selecting conventional and mechanized tunnelling methods, lessons learned from the past	1648
<i>N. Bilgin & C. Balci</i>	
Computational modeling of cutting disc-rock interaction in mixed ground conditions	1654
<i>S.N. Butt, J. Rostami & G. Meschke</i>	
Pumice mineral using as a backfill grout injection in TBM excavations	1663
<i>U.C. Çalışkan, S. Beyhan & H. Ergin</i>	
Performance analysis of TBM excavation parameters related to small-diameter horizontal and inclined tunnels	1669
<i>M. Cardu, C. Todaro, O. Farzay, A.D. Giovanni & S. Saltarin</i>	
Wear prediction of disc cutter tools during shield tunnelling in composite stratum based on improved deep learning method	1675
<i>J. Chang, D. Zhang & H. Huang</i>	
A modified foam half-life time test method for EPB shield tunnelling	1682
<i>Z. Chen, A. Bezuijen & Y. Fang</i>	
Automatic excavation system for directional control in shield tunneling using machine learning techniques	1687
<i>J. Chen, H. Kamada, N. Takamoto, H. Sugiyama, S. Yamamoto & T. Aoyama</i>	
Influence analysis and control measures of super-large diameter shield tunnel undercrossing the existing tunnel in upper-soft and lower-hard composite stratum	1694
<i>J. Chen, Z. Lv & H. Lou</i>	
Influence of TBM cutter configurations on gravel excavation characteristics revealed by discrete element method	1698
<i>Y.-F. Chen, T.-T. Wang & F.-S. Jeng</i>	
Research on the application of high-strength burn-free building blocks made from shield muck	1705

<i>G. Bomben</i>	

Analysis of cement grout hydraulic erosion in a homogeneous fracture <i>H. Duan & L. Zou</i>	2522
Seepage and drainage study of underwater tunnel connecting section with combined method <i>H. Fu, K. Hu, Y. Wu, Y. Yu & W. Liu</i>	2529
Comparison of double shell and sprayed single shell waterproofing methods in tunneling <i>I.U. Gök, E. Karahan & B. Ünver</i>	2539
Constitutive model of aged EPDM rubber in subsea shield tunnel <i>C. Gong, C. Xie, Y. Ge & J. Song</i>	2548
Research and application of joint waterproofing technology for prefabricated metro station structures <i>M. Huang, Q. Fan, X. Yang & L. Fang</i>	2554
Innovative waterproofing system for shallow underground structures <i>D.S. Konyukhov, T.E. Kobidze & O.B. Krymov</i>	2561
Tunnel drainage system and the possibility of non-destructive remediation <i>J. Ortuta & V. Tóth</i>	2567
Step effects of hydraulic pressure of tunnels in loess under high-pressure seepage <i>J. Qiu, K. Tang, Z. Zhao, Y. Bai, N. Zhang, Y. Chen & S. Ding</i>	2575
ITAtch design guidance chapter for composite Sprayed Concrete Lined (SCL) tunnels waterproofed with sprayed membranes <i>J. Su</i>	2584
Self healing materials for preventing tunnel crystalline damage: Anti-calcium leaching, mechanical performance, self-healing mechanism <i>Y. Tong, F. Ye, C. Tian, Y. Jiang, J. Zhang, H. Wang, B. Wu & X. Han</i>	2593
Analysis of viscous fingering between water and cement-based grout in tunnels <i>S. Zhang, F. Johansson & L. Zou</i>	2602
Analysis of cement grout propagation with varying fracture apertures <i>L. Zou, G. Zirgulis, A.N. Ghafar, U. Håkansson & V. Cvetkovic</i>	2610
<i>Instrumentation and monitoring/testing and inspection</i>	
Design and development of tunnel liner void detection system <i>A. An, W. Luo, G. Tian, Y. Xu, L. Gao & J. Zheng</i>	2619
Tunnel condition assessment: State-of-the-art <i>S. Behbahani, J. Steinkuehler, J. Rostami, X. Wang & T. Iseley</i>	2624
Ground movement due to shaft construction and dewatering at Bengeworth road for the London Power Tunnels 2 scheme <i>O. Brown, A. Simic & J. Ellis</i>	2630
Application of Acoustic signal to quantify the damage of the lesser Himalayan sandstone under unconfined compression loading and its implementation in the micromechanical damage-plasticity model <i>S. Chajed & A. Singh</i>	2639
Tunnel detection and monitoring technology based on terrestrial laser scanning <i>Y.-J. Cheng, C. Wang & W.-G. Qiu</i>	2644

Bored tunnels: Automated extraction of segment edge location from scan data <i>J. Douglas, O. Côté & S. Jain</i>	2650
Cavity detection model from GPR images considering reinforcing bars in tunnel segment lining <i>C. Hwang, S. Yang, S. park, H. Kim & H. Choi</i>	2658
Combination of modelling and monitoring in assessing stability of a tunnel constructed in highly deformable rock and fragilized by fire <i>T. Kazerani & E. Garin</i>	2664
Field measurement of pile transient lateral response to advancing tunnel <i>C.M. Khoo, H. Mohamad, B.P. Tee & M.F. Ghazali</i>	2672
Model experiment on load-bearing performance and failure process of newly proposed invert to reduce volume of excavation <i>Y. Koizumi, A. Kusaka, N. Isago, K. Kawata, T. Otsu & N. Mikami</i>	2681
A noncontact mobil system using camera module for tunnel inspection <i>C. Lee, D. Kim & D. Kim</i>	2689
Tunnel indirect monitoring and damage identification method based on SET-Swin transformer <i>Q. Li, X. Xie & K. Zeng</i>	2696
Effectual approach to characterize rock fracture: Insight from calculating method of fractal dimension <i>B. Li, W. Zhang, Y. Xue, K. Li, J. Zhao, Y. Chen, R. Kong & G. Wang</i>	2702
Research on integrated monitoring platform of composite steel-concrete immersed tunnel <i>X. Mao, Z. Zhang & L. Li</i>	2717
Study for health monitoring of mountain tunnels operation using distributed fiber optic sensing technology <i>H. Nonaka, Y. Miyajima, N. Sakamoto, Y. Taira, T. Yamamoto, M. Imai, K. Koike, K. Kishida, H. Shinbo & J. Kawabata</i>	2724
Development of wear detection device using dye <i>Y. Omae, Y. Imaoka, H. Ueda, A. Nakamoto & R. Fukui</i>	2731
Structure health sensing network layout and monitoring based on wireless sensor network in undersea tunnel <i>L. Ouyang, H. Huang, D. Zhang, C. Wang & S. Zhu</i>	2737
Innovative shaft inspection system for the Gotthard Base Tunnel <i>M. Puglia, P. Spohn, K. Wachter, L. Chelini & S. Xiao</i>	2745
Fault diagnosis system for tunnel boring machines based on electrical energy monitoring <i>Y. Qin, C. Zhang, S. Huang, Z. Wu, H. Shen & J. Sun</i>	2751
Pivotal role of instrumentation & monitoring in construction of Mumbai Metro Line 3 in an urban setting <i>A. Rawat, R.R. Kumar & S.K. Gupta</i>	2757
Geotechnical instrumentation for road tunnels: Success cases in Colombia <i>V. Restrepo, H. Salazar & J. Piedrahita</i>	2763

Analysis of laboratory tests for the determination of the clogging risk in mechanized tunnel excavation in fine-grained soils	2771
<i>D. Sebastiani, S. Mangifesta, A. de Lillis & S. Miliziano</i>	
Information entropy based Robust Sensor Placement (RSP) method for wireless sensing of shield tunnel deformation	2778
<i>J. Shi, H. Huang & Z. Guan</i>	
Design and key features of shaft and tunnel excavation monitoring system implemented in Singapore's Deep Tunnel Sewerage System Phase 2 Project	2784
<i>A.K.K. Soe, L.L. Woo, K. Khin, P.C. Koh, A. Maxwell & E. Valdez Jr</i>	
Research on concrete strength detection method based on digital drilling and machine learning	2792
<i>R. Wu</i>	
Development and application of similar materials to cobble stratum for solid-fluid coupling model test	2800
<i>W. Zan, W. Zhang & Q. Yang</i>	
Study on the deformation and stress law of single shell lining in subsea rock tunnels	2809
<i>W. Zhang</i>	
Using the acoustic emission and infrared thermal imager to identify the precursor of rock violent failure	2817
<i>S. Zhu, D. Zhang, H. Huang, C. Wang & L. Ouyang</i>	
 <i>Digital and information technology</i>	
BIM Modelling & reality capture in underground drill and blast caverns	2825
<i>P.R. Antón, I.J.F. Teixeira, A. Barbetta, B.B. Vieira & F. Abreu</i>	
The Sotra Link Project (Norway): An application of the BIM methodology in tunneling design and construction	2834
<i>G. Barbieri, E.D. Panicis, G. Bella, D.D. Femina, A. Biagi & M. Giani</i>	
INFRA-BIM interoperability for Tunnel Renewal	2841
<i>M. Catapano, A. Poli, R. Roncoroni & A. Reis</i>	
Design and implementation of a mobile welding robot for TBM cutterhead: Enhancing efficiency, precision, and safety	2848
<i>P. Chen, J. Chen, J. Mao, J. Shu, M. Yang & S. Guo</i>	
Enhancing management and construction quality for a 5km long sandwich immersed tunnel through digital and intelligent methods	2857
<i>W. Chen & J. Liu</i>	
Digital strategies-driven optimization of infrastructure maintenance: The case study of the rehabilitation of a disused tunnel in northern Italy	2863
<i>F. Foria, E. Moschetti, M. Calicchio, V. Grigoras & B. Boyaci</i>	
Intelligent technologies and applications on TBM tunnel construction	2868
<i>W. Guo, K. Hong, P. Gao & F. Li</i>	
Research and application of the bim-based fine management in shield tunnelling construction of rail transit engineering	2876
<i>Y. Huang, Z. Zhang, K. Jia, H. Lai & Y. Li</i>	

Innovative design and practice of full life cycle of complex underground engineering equipment based on digital twin <i>F. Liu</i>	2885
Research on intelligent construction technology and grading method of railway shield tunnel <i>G. Lu, T. Wang, J. Liu & W. Wang</i>	2893
The interface between construction site and Tunnel Information Model: The case of the Brenner Base Tunnel <i>D. Marini & G. Venditti</i>	2902
Integrated design of precast concrete linings for mechanized tunnels <i>A. Menozzi, B. Tiberi, D. Maturi & R. Comini</i>	2910
Data-driven underground construction management: a case study of the Big Circle Metro Line in Moscow <i>M.D. Nadot, V.V. Vyazovoy, M.A. Lvovskaya & A.G. Polyankin</i>	2917
Research on construction collaborative control method based on drilling and blasting tunnel equipment <i>Q. Nianwen, Z. Miaojun, J. Weiliang</i>	2920
Trusted elements in the digital model of the tunnel <i>G. Paskaleva, P. Beronneau & T. Bednar</i>	2927
Why is it worth using BIM in tunnelling? <i>F. Robert & N. Dias</i>	2935
Digital automation in the structural modelling process for tunnel linings – A digital tool-based case study <i>A. Shivasami & G. Heath</i>	2944
Demonstration of parametric analyses in ground models by applying programming logics using a digital tool named ParaRanger <i>A. Shivasami, R. Nair & L. Dunbar</i>	2951
Streamline field management processes to improve labor productivity and reduce material loss <i>H. Umeyama, S. Kitagawa, T. Arai, T. Fukuda, S. Taniguchi, F. Ito & H. Nagamatsu</i>	2959
Research on integrated management platform of shield construction based on digital twin and application in subway engineering <i>X. Wang, J. Wang, Y. Zhang & S. Jiang</i>	2965
A study of digital quantitative evaluation system for the safety risk management in the construction activities of transportation hubs <i>R. Wen, D. Gao, W. Yang & W. Mou</i>	2972
Research on data management and analysis of BIM technology <i>Y. Zhaofeng</i>	2980
A study on 3D reconstruction of tunnel based on NeRf: A case study of Shanghai Metro Line 18 Tunnel <i>Z. Zheng, Y. Xue, Y. Guo, J. Liu & L. Zhao</i>	2985

Machine learning

- Development of a hard rock TBM performance prediction model using RMR input parameters 2995
A. Dardashti, J. Rostami, R. Ajalloeian, J. Hassanpour & A. Salimi
- Performance analysis of supervised algorithms on encoded data for predicting tunnel strain classes 3005
A. Dewangan, D.R. Sahoo & J. Karlovsek
- Automatic classification and segmentation of tunnel cracks based on deep learning and visual explanations 3014
Y. Feng, X. Zhang, S. Feng, Y. Zhao & Y. Chen
- TBM machine parameters estimation: From design approach to on-field results. A concrete example based on Kalman Filter approach 3023
C. Iasiello & J. Rodríguez-Sánchez
- An intelligent decision support system for tunnel structural defects maintenance with combining knowledge graph and deep learning 3029
F. Jia, Y. Xue, Q. Zhang & L. Qu
- Prediction of disc cutter wear considering ground conditions and TBM operating parameters 3037
Y.S. Kang, S.J. Park, J.H. Hwang, J.P. Hong & T.Y. Ko
- Leakage prediction and post-grouting assessment in headrace tunnel of a hydropower project 3044
T.B. Katuwal, K.K. Panthi, C.B. Basnet & S. Adhikari
- A novel machine-learning model for estimating disc cutter life in TBMs considering individual cutter travel lengths 3053
D. Kim, Y. Shin, D. Kim, C. Lee, K. Kwon & H. Choi
- Segment segmentation of tunnel ring point clouds using 3D deep learning 3059
W. Lin, B. Sheil, X. Xie, K. Li & G. Niu
- Forecasting the driving speed of the TBM using machine learning algorithms 3067
M. Miller, Y. Fang, H. Luo, Y. Wang, G. Xu, B. Leng, S. Kharitonov, V. Akulich, Y. Ma & F. Zou
- Intelligent tunnel asset management of CERN underground facilities 3073

Preface

The World Tunnel Congress 2024 and the 50th ITA-AITES General Assembly are held in Shenzhen, China, from 19–25 April, 2024. The China Civil Engineering Society (CCES) is honoured to host this prestigious and significant event which is not only a milestone in the history of the ITA, marking its 50th anniversary but also a testament to the enduring commitment and collaboration within the international tunnelling community.

With the visionary theme of “Tunnelling for a Better Life,” WTC2024 is set to spotlight the pivotal role of tunnelling and underground works in creating sustainable, efficient, and resilient environments. This theme is a call to the global community to leverage the latest in innovation and technology, addressing the era’s most pressing challenges, including climate change, urbanization, and the quest for low-carbon, intelligent infrastructure solutions.

The proceedings encompass a wide array of critical topics in tunnelling and underground space, reflecting the latest trends, insights, and innovations. WTC2024 has received more than 1,000 abstracts and 540 full papers from authors of 46 different countries. After the peer review by the Scientific Committee which was composed of 145 experts from 39 countries, 486 papers from 40 countries were accepted for publication in the WTC2024 Proceedings. From integrating low-carbon technologies to applying intelligent systems in the design, construction, and management of tunnelling and underground works, the contributions within these pages showcase a forward-looking approach to tackling the complexities of modern urban development. The sustainable solutions presented within the proceedings illuminate a path toward resilient, low-carbon, and eco-friendly practices, reflecting our commitment to minimizing environmental impact and underscoring our dedication to efficiency and progress in the intelligent and digital era. The WTC2024 proceedings will inspire and guide our community toward realizing the potential of underground spaces to create a better, more sustainable life for present and future generations.

As we gather in Shenzhen, a city renowned for its dynamic innovation and rapid growth, we are reminded of the power of collaboration and the importance of knowledge exchange in advancing our field. The WTC2024 serves as a platform for experts, practitioners, and stakeholders from across the globe to come together, share insights, and forge partnerships that will drive the future of tunnelling and underground space development.

On behalf of the organizing committee and the CCES, we express our deepest gratitude to all participants, contributors, and sponsors who have made this event possible. As we celebrate the 50th ITA-AITES anniversary, WTC2024 in Shenzhen will provide invaluable opportunities for the international tunnelling community to explore the depths beneath our cities and the heights of our aspirations for a sustainable future and a better life.

Yi Jun
Chair of the WTC2024 Organizing Committee
President of the China Civil Engineering Society (CCES)
Shenzhen, April 2024

Acknowledgements

Reviewers

The Editors wish to extend their gratitude to all the members of the Scientific Committee for their unwavering dedication and invaluable contributions.

Sponsors

The Organizing Committee and the Editors wish to extend their gratitude to the congress sponsors for their help and support.

Multilateral institutions and governance of urban underground space

Nikolai Bobylev*

Saint Petersburg State University, Saint Petersburg, Russia

Herzen State Pedagogical University of Russia, Saint Petersburg, Russia

Yong-Kang Qiao & Fang-Le Peng

Tongji University, Shanghai, China

ABSTRACT: Multilateral institutions are the international organizations that are formed by three or more countries. These institutions usually work on development issues addressing global agenda. Urban underground space, traditionally and predominantly being a responsibility of a city government, is fast becoming an issue of global importance and co-operation. Globalization of urban underground space has been facilitated by technological complexities and innovation. Tunnelling and underground space development has been increasingly executed by global businesses, operating across countries and continents. In response to this “globalisation” trend of urban underground space development, this research is looking into the work that has been already done by variety of multilateral institutions and international organisations, setting out agenda and needs for further discussion on urban underground space at a global level.

Keywords: Globalization, Governance, Institutions, Planning, Urban Underground Space

1 INTRODUCTION

The term *Governance* refers to the set of formal and informal institutions, government, business, civil society that influence a decision-making processes (Rhodes, 1996, 1997, Tretter, 2008, Berggruen & Gardels, 2012). A sustainable governance can be understood as binding political decisions to the benefit of future generations that include state and non-state actors through steering mechanisms, cooperation, and coordination (Driessen et al, 2012, UN Habitat, 2002).

Multilateral institutions are the international organizations that are formed by three or more countries. These institutions usually work on development issues addressing global agenda. The present global agenda is set out by the United Nations via Agenda 2030 and the Sustainable Development Goals (United Nations, 2023). Global development agenda addresses most pressing contemporary problems planet Earth is facing: climate change, biodiversity loss, sustainable and resilient urbanization. This formal and informal agenda reflects international consensus on major challenges, and is supported by the overwhelming majority of national governments, public and private sector, the latter via gaining prominence ESG (Environmental and Social Governance) campaign.

Numerous institutions work on global challenges agenda. Many international institutions set to address a planetary perspective, and aim to align current governance systems with the contemporary global challenges, such as global environmental change and earth-system transformations.

It has been argued that major global challenges can and should be addressed at a global level of governance (e.g. Earth System Governance research alliance, 2023). While it seems obvious, that challenges like climate change and ocean plastic should be addressed at a global level via multilateral agreements, it is less obvious that more localised problems, like urbanisation, should have any global governance framework.

In this paper, we will explore the case of urban underground space as a part of urbanisation process, investigate associated levels of governance, and specific issues that are relevant at the global level.

2 URBAN UNDERGROUND SPACE AS A PART OF GLOBAL AGENDA

Urban areas are at the forefront in driving global environmental change, and these areas are themselves heavily affected by global change, namely

*Corresponding author: n.bobylev@spbu.ru

climate change, land degradation, biodiversity loss. There has been a growing understanding in the recent decades that cities must become greener, smarter, more resilient, energy efficient and compact to address the above challenges. Urban underground space is widely accepted as an important asset for a sustainable urban development, primarily addressing resiliency, energy efficiency, and land use (Peng et al, 2021, Volchko et al, 2020, ITA Working Group 20, 2023, Bobylev et al, 2023).

Construction sector has been accounting for nearly 40% of global CO₂ emissions (for large cities the figure is about 70%) (OECD, 2022), hence, buildings and structures are central to the low-carbon global transition. Climate strategies have been already developed in many cities. Climate change adaptation requires addressing floods and flash floods in urban areas, which tops agenda in many cities. The flood protection infrastructure, including subsurface infrastructure, has been the key element of adaptation plans (Tianming, et al, 2021). Sustainability and resilience has been a part of most cities' development strategies, and urban underground space is an important dimension to these policies (Qiao et al, 2019).

Urban underground space is a part of the global environment and development agenda. Firstly, urban underground space is indispensable for a compact, sustainable urbanisation and a three-dimensional city. Secondly, urban underground space is important in addressing climate change adaptation and mitigation agendas. Thirdly, urban underground space is relevant to a few Sustainable Development Goals, it is interlinked with many issues like energy and environment, that eventually affect global progress on the goals. Fourthly, underground space is a big player in energy sector, which impacts many globally important issues, from climate to economy, equality, poverty, human-wellbeing, ecosystems health. Underground space provides geothermal energy, allows energy storage and transit, is a part of urban energy efficiency agenda via transport infrastructure and buildings thermal performance (Akhmetzyanov et al, 2021, Lin et al, 2022).

3 MULTILATERAL INSTITUTIONS

This section presents state-of-the-art and briefly describes international multilateral institutions that are relevant to urban underground space. We start with global international organisations that are focused on urban underground space.

The International Tunnelling and Underground Space Association is a non-governmental, non-profit organization founded in 1974, comprising currently 78 member nations (International Tunnelling and Underground Space Association, 2023), the Association has a Special Consultative Status with the Economic and Social Council of the United Nations.

The Associated Research Centers for Urban Underground Space is an international, non-governmental

organization founded in 1996, the organisation has been holding biannual professional conferences focused on urban underground space planning and development (Associated Research Centers for Urban Underground Space, 2023).

We continue with the major international organisations where countries are members, we pick the most relevant ones to the urban underground space.

The United Nations Human Settlements Programme (UN-Habitat) is the United Nations designated agency that leads and co-ordinates implementation of the sustainable urban development agenda (UN-Habitat, 2023). Urban underground space has been regularly mentioned in its programmatic documents like Habitat III and New Urban Agenda, however there has not yet been any specific action, guide, or policy campaign focused on subsurface use.

The World Bank is an international financial institution with 189 member countries, it leads several affiliated organisations that are working on reducing poverty and building prosperity in developing countries (World Bank, 2023). The World Bank has been financing projects and producing analytical reports that involve discussions on urban underground space.

The Organisation for Economic Co-operation and Development is an intergovernmental organisation with 38 member countries, founded in 1961 to stimulate economic progress and world trade (Organisation for Economic Co-operation and Development, 2023). Urban underground space has been a part of the Organisation urban policy, as well as some regional and country reports.

The United Nations Office for Disaster Risk Reduction was created in 1999, in 2020 it has published *Words into Action: Implementation Guide for Land Use and Urban Planning* (United Nations Office for Disaster Risk Reduction, 2020) a series of guidelines, based on global expertise, communities of practice, and networks of Disaster Risk Reduction practitioners. The guidelines provide practical, specific advice on implementing the Sendai Framework for Disaster Risk Reduction 2015-2030, it includes a substantial part on urban underground space focusing on combatting floods.

The International Energy Agency is an autonomous intergovernmental organization, established in 1974, that works on policy and data on the global energy sector; it is governed by the 31 member countries and affiliates 13 associated countries (International Energy Agency, 2023). Urban underground space and subsurface features in the reports by this Agency on District energy networks, Geothermal energy, and CO₂ storage.

We move further to a lower, but more focused level of specific multilateral projects and ad-hoc initiatives that significantly contributed to the knowledge on urban underground space.

The European Cooperation in Science and Technology project named "SUB-URBAN – A European network to improve understanding and use of the

ground beneath our cities” has published city surveys of 29 European countries to reflect the state-of-the-art in suburban planning (Campbell et al., 2017).

The NeTTUN project financed by the seventh Framework Programme for the European Commission united 23 industrial, research and development organisations across 9 countries in Europe to investigate the construction, management and maintenance of tunnels (NeTTUN, 2016).

4 CURRENT AGENDA OF THE MULTILATERAL INSTITUTIONS

The current agenda of the above named multilateral institutions related to urban underground space is formed as a response to major global challenges and issues on which those institutions have been working. Thus, urban underground space itself has been yet not on the global institutions agenda, but rather features as one of the issues, tools, options, items of attention, or responses to well-known global challenges like climate, energy, poverty, etc. Professional associations and specific projects dealing directly with subsurface use and tunnelling represent the only international institutions that feature urban underground space as a distinct global agenda item.

Major global interdisciplinary institutions, like World Bank, has been gradually increasing presence of urban underground space in their reports. Now it is very clear that urban underground space not just has been mentioned, but have a detailed description and a clear link to the problem solution or phenomenon which a particular report is discussing. This observation can be interpreted as urban underground space gradually moving towards becoming of one of the distinct issues on global agenda as presented by major international development institutions.

For now, urban underground space has been mentioned as a secondary topical item in the reports, the primarily items of those reports are listed below. The list below was obtained by screening, reading, and interpreting reports of the above named organisations as presented on their websites, the reports issued during and after 2020 were read and analysed (only major development organisations, International Tunnelling and Underground Space Association, Associated Research Centers for Urban Underground Space were excluded). The list below includes themes that urban underground space addresses, and it was sufficiently detailed and explained how in a particular report. The themes are listed alphabetically:

- Advancing Climate Action
- CO₂ storage resources and their development
- District energy networks and engineering infrastructure
- Emergency Response
- Geothermal energy
- Livable city
- Thermal energy storage

- Transformative climate adaptation action
- Transforming cities
- Transforming the urban space
- Transit-oriented development
- Underground hydrogen storage
- Urban development (guides, best practices)
- Urban development overview (regional, national)
- Urban public spaces
- Urban regeneration
- Urban resilience
- Urban transit

It can be observed that this themes indeed include some major global challenges, as well as some specific responses to them, like transit-oriented development. However, some major global agenda issues are missing, like climate change mitigation. The latter example suggests that there is a lot of room and a certain urgency that underground space professional community make aware global policy players of high relevance of urban underground space to (in this example) climate change mitigation by providing renewable energy and energy efficient buildings and structures.

5 GLOBAL AGENDA FOR URBAN UNDERGROUND SPACE

Global agenda for urban underground space has been evolving in the recent decade, based on conceptualising subsurface and urban underground space as asset (Maring & Blauw 2018), partially renewable resource (Parriaux, 2006), and an origin of geosystem services (van Ree, & van Beukering, 2016). This has been quite different from actual absence of any concept of subsurface use in prior decades, and the use of underground space on the first come first served basis (Admiraal & Cornaro, 2016, Grecksch, 2021).

Still evolving concept of geosystem services is focusing on abiotic components and services of the environment (Gray, 2018; Fox et al, 2020). Nature-based solutions are a concept for integrating a range of ecosystem-based approaches in order to address a range of societal challenges (Busha & Doyon, 2019). Both concepts are very relevant to the global agenda for urban underground space, which can be defined as a sustainable, frugal and rational use of urban underground space resources, recognising the limits of their renewability and current and future value to humankind.

Figure 1 Illustrates the value of subsurface defined through geosystem services. The main categories of geosystem services are: 1 – biotic services directly supporting ecosystems; 2 – abiotic services directly supporting ecosystems; 3 – abiotic services supporting man-made infrastructure and indirectly influencing ecosystems; and 4 – abiotic services supporting man-made infrastructure and not related to ecosystems (i.e. to specific types of biomes and distinct living environments (Bobylyev, et al, 2022).

Figure 1. Categorization and visualization of geosystem services (from Bobylev, et al, 2022).

6 GOVERNANCE OF URBAN UNDERGROUND SPACE

Governance of urban underground space is relevant primarily at a national and regional (city) levels. National level provides building codes, planning laws, technology norms. Regional and city level regulates spatial plans, environmental permissions, buildings, structure, and infrastructure design approvals, as well as energy and groundwater use permissions and quotes.

Global governance of urban underground space might be required to (1) archive progress on global challenges where urban underground space supports this progress, (2) governance of urban underground space itself, conceptualising it as a global challenge or an important asset. The first avenue was detailed in sub section “4. Current agenda of the multilateral institutions”, and it is obvious that this part of the urban underground space governance agenda has already gain some attention and policy documents. The second avenue, global governance of urban underground space has not been yet addressed by international policy community, except of occasional mentioning by underground space professionals.

Global governance of urban underground space should be based on the global agenda for urban underground space (section 4), and address potential conflicts and competing interests by stakeholders. Agenda for these interests and stakeholders themselves could have regional and geographical specifics, this agenda has not been yet conceptualised.

We offer some more insights in competing interests and potential conflicts in urban underground space at a global level. Firstly, urban underground space has some non-renewable resources (section 4), and, therefore, general sustainability approach based on the rights of future generation would apply at a global

level. Secondly, urban underground space use impacts a number of the Sustainable Development Goals, and thus affects global progress towards their implementation. Thirdly, urban underground space use (and subsurface use in general) in one particular area might impact its use in another area. Urban underground heat island, groundwater depletion, groundwater barrage effects are good examples. Here we can mention environmental risks, associated with e.g. nuclear waste storage, carbon dioxide deposition, deep geothermal energy use. All these potential conflicts and impacts might have transboundary context in particular locations, and hence quite relevant to global governance. In this regard, Convention on Environmental Impact Assessment in a Transboundary Context (United Nations Economic Commission for Europe, 1991) is quite relevant and to certain extend represent a blueprint to one of the aspects of urban underground space global governance. The Convention was signed in Espoo in 1991 and entered into force in 1997, so far it has been mainly used in the air pollution context.

7 CONCLUSIONS

Urban underground space has been emerging as one of the themes on the global development agenda. Our research has shown that urban underground space has been gaining increasing attention and traction by the global multilateral institutions and international organizations. We have reviewed activities and reports by five major global intragovernmental organizations and have listed prime thematic areas of their work that feature urban underground space. Urban underground space has not been yet a subject of global governance, but rather an important component of many solutions to contemporary global problems, predominantly climate change, sustainable and resilient urbanization, energy.

Governance of urban underground space has been placed on national, regional, and municipal agendas. Global governance agenda for urban underground space has been steadily emerging, mainly based on a need for a rational use of subsurface resources, accompanied by a forming vision for underground space as a global asset for groundwater and carbon dioxide storage.

Urban underground space has been a part of the global environment and development agenda, we expect that in the years to come its presence in a wider dialogue on major global challenges will increase.

Forecast and trends related to key personnel for mechanised excavation with TBMs

Fabrizio Bove*

Seli Overseas, Rome, Italy

ABSTRACT: Some of the crucial questions in order to carry out a proper planning of a new tunnel boring machine (TBM) project, as well as budgeting, are “how many experienced positions do we need to cover a complete TBM bore? Do we need all at once? What could be a rule of thumb’s ratio between highly experienced (key personnel) and unexperienced?”.

In order to proceed with an adequate management of a TBM project, an analysis of the key positions needed at different stages is proposed, starting from the acceptance of the TBM in factory up to the last phase, i.e. the final disassembly of the machine on site. Additionally, a differentiation of the highly skilled and experienced critical positions needed according to the various types of available TBMs in the market is highlighted.

Eventually, a career path in order to optimise the continuous supervision and goals is suggested, as well as the impact on personnel of the increasing automatizations, data analysis, robotics and remote controlling is also discussed.

Keywords: key personnel, planning, key position, career, management, budget

1 INTRODUCTION

In every organization or company, the importance of personnel is commonly emphasised with the same words, i.e. *human capital* and, more often, *human resources*, which in the last decades has been universally adopted.

Concurrently, the sharp distinction between white and blue collars is going to lose practical meaning within the tunnelling industry. Regardless of what we can nowadays address as an old-fashioned differentiation, a new approach is needed to achieve the expected results within a lean management perspective.

Moreover, considering that physiological oscillations and peaks related to the demand of personnel are cyclical in the market of infrastructures and tunnels, a temporary shortage of it needs to be properly addressed and managed.

It is also worth to point out that, within a TBM project, the overall cost of personnel (labour and staff) can be estimated to be around 40%-50% of the whole construction costs. This value is greater than the same cost of TBM, usually being around 15%-20%.

Eventually, a new perspective focusing on the key personnel, intended as the minimum “core” specialized technicians needed to achieve the goals, can both reduce the costs and allow to better manage the

project. Indeed, a proper choice as well as management of the staff that “makes the difference”, being able to properly lead the ongoing tasks in every phase, is demanded.

2 KEY POSITIONS RELATED TO TBM

An assessment of the core number of qualified personnel in order to properly execute a TBM drive since the beginning, i.e. starting with the factory acceptance test (FAT) up to the termination of the TBM project, usually being the disassembly of the same machine, is carried out in this paragraph.

It is worth to point out that the current trend leads to present in tender phase also the resumes of some key positions, being a paramount parameter for the project’s award: in certain cases it can be a contractual requirement not only for the managers, but also for some critical technicians, like tunnel superintendents, TBM operators etc. and, additionally, a list of minimum requirements should be fulfilled, like years of experience in a certain role as well as specific experience related to the proposed TBM type, that for this purpose can be grouped in earth pressure balance (EPB), slurry, shielded TBMs for hard rock (simple shield and double shield) and open TBMs.

*Corresponding author: f.bove@selitunnelling.com

Hence, what is a key position within a TBM project? First and foremost, it is a role with qualified experience in a specific field of TBM excavation, whose skills are mandatory to properly carry out the project. For the sake of clarity, also a project manager, a safety manager or a senior accountant are key positions; nevertheless, they are not necessarily needed with a dedicated focus and consolidated experience in TBMs, although a previous experience in this field will surely enhance value to the ongoing project.

Eventually, a general summary of these key positions is presented hereby:

- TBM senior engineer: usually he's a civil engineer with overall experience in TBM and general helicopter view of all phases of the project. A dedicated focus is needed for the driving parameters, soil conditioning, grouting and interaction between the TBM, the soil or rock mass as well as the surface and any interface.
- Plant manager: this position is usually covered by a mechanical engineer with overall experience in TBM assembly, disassembly, maintenance, and spare parts management. Moreover, a general overview of conveyors, locomotives or multiservice vehicles (MSVs) and equipment is also needed.
- TBM superintendent: he's the leader of the ongoing process of excavation, with sound knowledge of all internal processes, machineries and TBM operations. An attention to the logistics and general arrangement and organization of the site is also needed.
- Shift supervisor: he's in charge of the shift into the tunnel, with sound knowledge of all internal processes, machineries and TBM operations.
- Chief electrician: he's supervising any electrical equipment in TBM, with sound experience in high and medium voltage cables and junctions.
- Programmable Logic Controller (PLC) electronic: usually he's an electronic engineer able to properly set the parameters into the PLC as well as troubleshooting.
- Chief mechanic: he's supervising any mechanical work in TBM as well as the daily and weekly maintenance, highly experienced in the various components of the machine and, usually, also in hydraulics.
- TBM operator: he's the driver of the machine. Further to have clear the concepts of alignment, pressures, thrust, rotation of the cutterhead, penetration rate, surface settlements, soil conditioning etc., he's able to fine tune the advance according to the geology in situ.
- Erector operator: he's in charge of assembling the ring according to the tolerances (gaps and offsets), giving as result of his task the final and permanent product of the project, i.e. the lining, entirely visible.
- Grouting operator: is the person in charge of the injection of the backfilling, coping with the

expected quality of cement as well as entirely filling the volume of the gap between excavation and lining. Although the cement injection is not visible like the lining, this is the other final product of the excavation.

- Mud engineer: this position is requested only for slurry machines. Usually, he's in charge for the adjustment of the slurry fluid as well as for the supervision of the slurry treatment plant (STP).
- Conveyor mechanic: he's a mechanic with specific experience in the alignment, extension, maintenance, vulcanization, junction and repair of continuous conveyors.
- Cutterhead mechanic: he's a mechanic in charge of the cutters or rippers replacements and the check of the buckets, to prevent any possible wear of the surface of the cutterhead and, concurrently, optimizing the dressing of the cutting tools. A long experience with different TBMs as well as with many types of soils and rocks is needed.
- TBM surveyor: an experienced land surveyor able to connect the external benchmarks and open traverse with the guidance systems of the TBM and any possible articulation of the same machine.
- TBM senior electrician: he's an experienced electrician able to deal with the majority of routinary electric tasks into the machine.
- TBM senior mechanic: as for the senior electrician, he's an experienced mechanic able to deal with the majority of mechanical parts into the machine.

3 THE VARIOUS STAGES OF THE PROJECT

If one considers the evolution of a whole project with one TBM, the personnel needed at different phases can vary both in terms of total number as well as related to the key positions (see Figure 1).

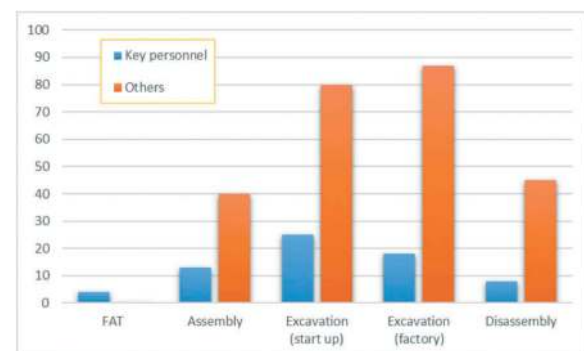

Figure 1. No. of personnel (key and others) at different stages.

For example, during the assembly phase, roughly ten key personnel will be needed to manage the entire process, especially mechanics and electricians. Once the TBM will be ready to bore, the same whole team also guarantees a smooth transition to

the excavation phase, with some “additions” during the learning curve that is usually identified with the first 200 m of excavation.

Once that TBM has started a regular advance, i.e. similar to an underground factory, the number of key personnel can be reduced and, thus, replaced with less experienced and trainee workers. This is possible because, during this factory phase, the attention is more focused towards a proper scheduling and refurbishment instead of troubleshooting, optimization, training etc. thus allowing a slight reduction of personnel.

Moreover, it is worth noting that the number of key personnel in every phase can be adjusted according to the customized TBM itself as well as the whole context of the project (logistic, critical tasks, “reaction” of the machine to the excavation etc.), as shown in Figure 2.

Additionally, some optimizations can be carried out in case of twin TBMs or more than one TBM located in the same area, for example using the same chief mechanic, PLC electronic, chief electrician and plant manager for both machines instead of one per TBM.

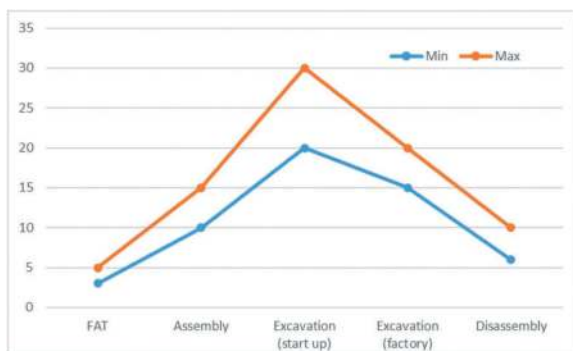

Figure 2. Estimation of possible ranges of key personnel at different stages.

4 DIFFERENT POSITIONS ACCORDING TO TBM TYPES

Looking to the different types of TBM available in the market and, although the TBM customization is still impacting the market, a sort of “common floor” with a forecast for key personnel needed according to the different type of TBM can be listed (see Table 1). Usually, EPBs and Slurry TBMs need a little bit more units of key personnel than hard rock TBMs, shielded or open, especially regarding the lining and grouting operations.

Obviously, regardless the type of TBM, some positions can be “overlapped” by the same person if this same technician has more than one skill and, concurrently, the TBM does not have critical issues to be fixed in that peculiar field. Some examples that are worth to be highlighted in terms of optimization and lean management are shown hereby:

- PLC electronic and chief electrician can be covered by the same technician.
- Experienced mechanics and electricians can be reduced if the TBM has no major and continuous failures. Moreover, it is worth to point out that current industrialization process regarding the TBM production, less customized and more industrial if compared to some decades ago, has the result of less adjustments needed as well as a reduction of breakdown occurred during the excavation, enhancing again the idea that less mechanics and electricians are needed.
- The number of cutterhead mechanics needed depend on the geology: it is heavily related to the hardness of the rock mass as well as the abrasiveness of the soil itself (quartz content) and it can be adjusted according to the different geological formations foreseen (or directly experienced) along the TBM axis.

5 THE CAREER PATH

In this paragraph a possible and “theoretically perfect” evolution for a trainee is proposed since the beginning of his activity in TBM, as shown in Figure 3.

It is quite straightforward that, according to a progressive increasing experience, a general overview of the different tasks allows a better understanding and control of the entire process of excavation day by day. Hence, a deep and direct knowledge of the majority of the most critical TBM tasks, acquired by actual experience in the different roles, plus the needed soft skills for a leading position, can bring a technician to lead the whole excavation process as TBM superintendent.

To better focus on the choice of these roles, it is worth considering that the suggested steps at the beginning, i.e. grouting operator and erector operator, have been included because they generate the output of a TBM ride, i.e. the permanent and visible result of the work of excavation, as already mentioned. Hence, a proper injection of the void between the lining and excavation and, moreover, the installation of the concrete rings without gaps and offsets are essential to achieve the expected results in terms of quality.

After having been trained in these tasks, a long-term experience as TBM operator is suggested, since the position needs a deep knowledge of the majority of TBM technique, in terms of guidance parameters (thrust, torque, rotation etc.), cutterhead dressing, alignment to the theoretical axis, earth pressure, muck removal, over-excavation and so on.

6 MANAGEMENT, REWARDS AND COMMITMENT

A proper management of the personnel should be carried out also using some rewards, that usually can

Table 1. Key positions related to TBM type.

Position	EPB	Slurry	Shielded TBM	Open TBM
TBM Senior Eng.	1	1	1	1
Plant Manager	1	1	1	1
TBM Superintendent	1	1	1	1
Chief electrician	1	1	1	1
PLC electronic	1	1	1	1
TBM senior electrician	2-4	2-4	2-4	2-4
Chief mechanic	1	1	1	1
TBM senior mechanic	2-4	2-4	2-4	2-4
Shift supervisor	1 per shift	1 per shift	1 per shift	1 per shift
TBM operator	1 per shift	1 per shift	1 per shift	1 per shift
Erector operator	1 per shift	1 per shift	1 per shift	
Grouting operator	1 per shift	1 per shift		
Mud engineer		1		
Conveyor mechanic	1	1	1	1
Cutterhead mechanic	1	1	1	1
TBM surveyor	1	1	1	1

have a financial impact roughly estimated being around 10%-20% of the total cost of personnel.

In any case it has to be considered within a bigger context of optimization of the project, i.e. a sound reduction in terms of time for completion. It is straightforward that the anticipation of the termination can positively impact in the rental costs as well as in the reduction of the whole cost of personnel.

Some measures that can be implemented are listed hereby:

- Bonus on milestones (TBM ready to bore, final disassembly, station crossing etc.).
- Bonus related to the meters excavated beyond the contractual minimum requirements.
- Final reward at breakthrough.

To avoid any possible jeopardization of the project, any reward applied should be connected to the

fulfilment and accomplishment of any quality, safety and environmental requirement and regulation.

Eventually, a higher level of key personnel management also needs bonds and adjustments ad personam as well as a strong commitment with the company, sharing the passion of carrying out any task to create value for all the stakeholders and the community.

7 THE FUTURE

Looking to the future, it is clear and straightforward that also the TBM market is oriented toward an increasing automatization, thus progressively reducing the manual and physical work: it means that the human action will be switched day-by-day toward a direction of control and supervision. Some of the ongoing and possible evolutions are listed as follow:

- robotic inspection of the cutterhead,
- remote guidance of the multiservice vehicle (MSV),
- automatization of the TBM driving,
- transportation into the back-up automatized and erection of the segments semi-automatic,
- semi-automatic analysis of “big data” regarding excavation, monitoring, environmental and safety parameters with automatic alerts.

Finally, according to these incoming changes, a reduction of the total number of personnel mainly carrying out manual works inside the tunnel can be expected because of automatization. Conversely, further checks in terms of maintenance, control and analysis of data will be needed, thus bringing to a renewal and adjustment of key personnel’s skills toward data analysis and control.

8 CONCLUSIONS

After a general overview of different aspects, like type of machines, phases of the project, implementation of an optimized career, current trends and future expectations it is worth to note that a proper forecast and management of the key personnel is one of the core aspects of a successful project.

Moreover, because of this analysis, the number of key personnel can be properly set and adjusted according to two parameters mainly:

Figure 3. A proposal of career path.

- the different stages of the project,
- the TBM type,

Additionally, some additional adjustments can be also carried out according to the logistics.

Eventually, for a better management of the projects, a career path for key personnel is needed, as well as a strong commitment and shared values between the company and the human capital.

The common duct in New Taipei City

Hsiao-chou Chao*, Chihkuang Song & Tsean Ko
Moh and Associates, Inc., Chinese Taipei

I-Kung Chiu & Yu-Chun Lin
Public Works Department, Chinese Taipei

ABSTRACT: Conventionally, underground utility lines are installed separately and are managed by different authorities. This approach can sometimes lead to challenges in coordination, communication, and efficiency, as different entities or organizations may have their own procedures, standards, and timelines. Renewal, relocation, and maintenance of various pipelines would involve repetitive excavations, frequent traffic interruption, and inevitably shorten the lifetime of the roads. The common duct, as an underground structure that accommodates two or more types of public utilities such as power transmission lines, telecommunication lines, storm sewers, sanitary sewers, tap water pipes, natural gas pipes, and oil pipes, was introduced to Taiwan in the late 1990s. The common duct system offers a solution for constructing a more resilient and sustainable urban environment. With more than twenty years of persistent endeavors, all major cities in Taiwan have successfully developed their common duct network plans and initiated the construction of these systems. As the completion of a common duct system network in a complex urban environment is anticipated to take a substantial amount of time, any change in urban development during the period has the potential to impact the objectives or functions of the planned common duct system network. To adapt to changes, ensure relevance, and maintain the effectiveness of the system network plan over time, it is necessary to conduct a consistent and diligent process of review and revision subsequent to its initial announcement. In New Taipei City, the phase I and phase II initial plans of common duct system network was announced in 2008 and 2012, respectively. The first comprehensive review was carried out and completed in 2016 and the second began in 2021. Methods and results of the comprehensive reviews that meet the public demand, quality of road service, and align with major infrastructural projects are summarized in this article.

Keywords: Resilient City, Common Duct, Main Duct, Supplier Duct, Expert Questionnaire, Analytic Hierarchy Process

1 OVERVIEW

The common duct is an underground structure designed to house and protect multiple types of public utility lines, such as water pipes, power cables, gas main, and telecommunication cables. In general, there are two types of common duct: the main duct and the supplier duct. The main duct serves as a pathway for regional public utility lines. The supplier duct, which can further be divided into branch duct, cable trough, and duct bank, is used to accommodate the public utility lines that deliver the services to the users.

Common duct is an essential part of modern city infrastructure. As maintenance, renewal, and expansion of utility lines can be conducted within the common duct, adverse impacts such as construction noises, traffic interference, and the need for pavement repair resulting from excavation can be significantly reduced or even avoided. Furthermore, the

resilience of a city can be enhanced significantly by establishing a common duct network. The experience of the Kobe earthquake in 1995 demonstrates that common ducts can offer effective protection for utility lines, with power supply recovering in 14 days, telecommunication in 7 days, and tap water supply in 42 days in the aftermath.

As shown in Figure 1, located on the northern part of the island, New Taipei City comprises a total area of about 2,053 km². As a city that has undergone intensive development, building new common duct network in the congested and limited underground space poses challenges for all parties involved. This paper introduces the background for development of the common duct network in New Taipei City, the current status, the method for reviewing and updating the planned network, and critical design and construction issues.

2.3 The second comprehensive review

In response to the change of urban development after 2016, the second comprehensive review commenced in 2021. As illustrated in Figure 4, three target schemes and five functional indexes were specified as the baseline criteria for scoring and selection of the routes for updating the common duct network. The five functional indexes are (a) level of road service, (b) level of repetitive excavation occurrence, (c) level of demand for pipelines, (d) number of major infrastructural projects to be implemented along the candidate routes in the future, and (e) level of road width. The three target schemes required to be met include (1) the demand for various types of pipeline, (2) build the common duct in association with the to be implemented infrastructure projects, and (3) promote the quality of road service.

Development of the common duct system network follows the two-stage procedures outlined in Figure 5. In the first stage, the roads with width greater than 20m were identified and selected, followed by generation of a preliminary system network as shown in Figure 6. In the second stage, expert questionnaire and Analytic

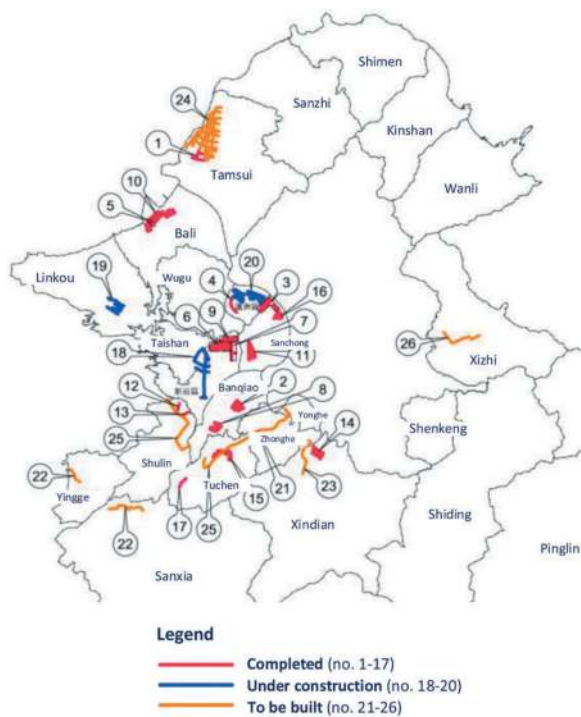

Figure 3. Common Duct System Network updated after the first comprehensive review.

Hierarchy Process (AHP) were applied to determine the relative importance in terms of weights among the five functional indexes and three target schemes for each of the road sections in the preliminary system network.

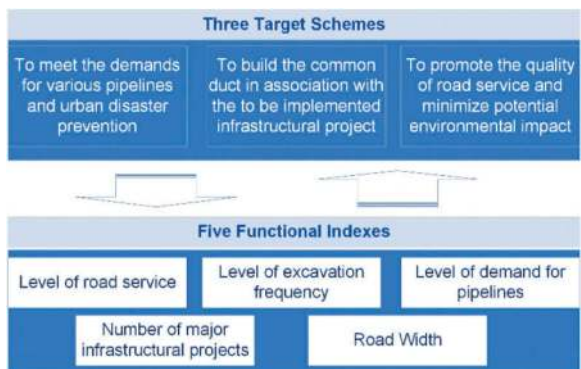

Figure 4. The baseline criteria for selection of the routes for common duct system network.

The weights of the three target schemes and five functional indexes determined by expert questionnaire and AHP method are listed in Tables 3 and 4, respectively. The weighted score for each of the road sections can be calculated by summing the product of the weight and the index value corresponding to each of the five functional indexes. Calculation of the weighted score is demonstrated by examples of three road sections listed in Table 5. It is expected that road section with weighted score greater than zero should be incorporated into the common duct network.

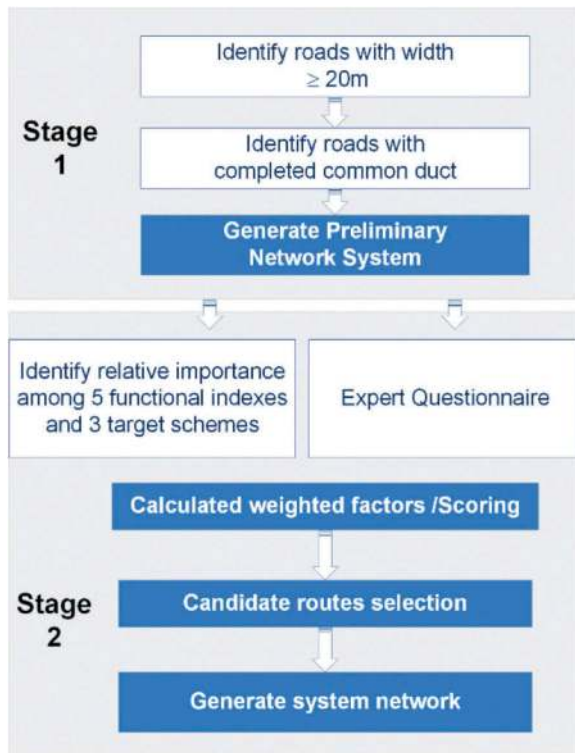

Figure 5. The two-stage procedures for developing the common duct system network.

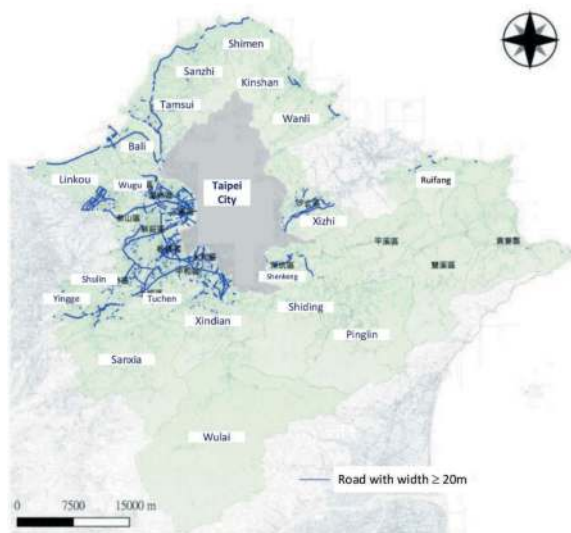

Figure 6. Preliminary common duct system network developed in the second comprehensive review.

Results of the revision for common duct system network in New Taipei City are demonstrated by the tentatively developed sub-network in Xinchung, Luzhou, Wugu, and Taishan districts as shown in Figure 7. The solid black line and red line represent existing and planned routes, respectively, in the common duct network that has been announced at the completion of the first comprehensive review. The solid purple line and blue line represent the routes of common ducts that

Table 3. Relative importance among three target schemes.

Target Scheme	Description	Weight
1	To meet the demands for various pipelines and urban disaster prevention	0.415
2	To build the common duct in association with the to-be constructed major infrastructural project	0.244
3	To promote the quality of the road service and minimize potential environmental impact	0.341

Table 4. Relative importance among 5 functional factors.

Functional index	Description	Weight
1	Level of road service	0.191
2	Level of excavation frequency in recent years	0.217
3	Level of demand for various types of pipelines	0.201
4	Number of major infrastructural project to be implemented in the future	0.216
5	Road width	0.175

would be added after the second comprehensive review (mid-term report, 2023).

3 ALIGNMENT OF COMMON DUCT NETWORK

In principle, main common duct shall be placed under median strip with its horizontal alignment consistent with the road. Horizontal alignment is allowed to be adjusted under the circumstance such as crossing over existing underground facilities. In consideration of the space required for installation of retaining structure for excavation work, the clearance between the main duct and adjacent structures shall be no less than 2m.

Branch duct shall be placed under sidewalk or mixed lane. To provide sufficient space for construction of retaining structures and connection of pipelines to the user end, the clearance between the branch duct and the border of private land shall be no less than 1m. The radius of curvature of the branch duct shall not exceed the allowable radius of curvature of the pipelines to be incorporated.

Cable trough also shall be installed under sidewalk or mixed lane. To provide sufficient space for connecting pipelines to the user end, the clearance between the cable trough and the border of private land shall be no less than 30cm.

For main duct constructed by cut and cover method, the overlying depth of soils shall be no less

Table 5. An example of calculation for weighted score.

No.		24	25	26
Road Section		Sanchung Sanhe rd. sec. 2	Sanchung Sanhe rd. sec. 3	Sanchung Sanhe rd. sec. 4
Level of road service	Original value	NA	NA	NA
	Index value	0	0	0
Level of excavation frequency (each/year)	Original value	9	14	25
	Index value	-1	-1	0
Level of demand for pipelines (number of types)	Original value	7	8	10
	Index value	1	1	2
Major infrastructures to be built (number)	Original value	1	1	1
	Index value	1	1	1
Road width	Original value	21	27	25
	Index value	0	1	0
Has the common duct been built already?		No	No	No
Weighted Score		0.20	0.38	0.62

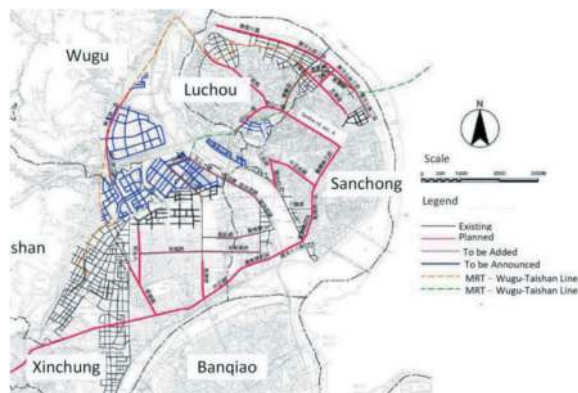

Figure 7. Tentatively developed common duct system network in Xinchung, Luzhou, Wugu, and Taishan districts.

than 2.5m and 1.0m for standard section and special section, respectively. The special section of common duct refers to the entrance, ventilation port, material input port, and diversion section. The clearance height shall be no less than 220cm. For main duct constructed by bored tunnelling method, the overlying depth of soils shall be no less than the diameter of the tunnel. The clearance to the adjacent underground structure shall be no less than 1.0m.

For branch duct, the allowable minimum slope is no less than 0.2% for the purpose of drainage. In consideration of cable installation or maintenance, the slope of a branch duct shall not exceed 1:3 (vertical to horizontal) when the vertical alignment is required to go up or go down to avoid crossing paths with another underground facilities. In general, the height clearance of branch duct shall not exceed

150cm. Nevertheless, this limitation can be eased under circumstances such as change of road alignment, varied width of sidewalk, or extra demand for pipeline capacity.

4 SELECTION OF THE TYPE OF COMMON DUCT

The type of common duct can be selected based on (1) the properties of pipelines to be incorporated, (2) the structural type, and (3) the widths of road and sidewalk.

For main duct, the box shaped structure will be selected when it would be constructed by cut and cover method. The circular shaped structure will be selected if the alignment of main duct crosses features such as underpass, large size box culvert, river, or underground rapid transit and is required to be constructed by bored tunnelling or pipe jacking methods.

The supplier common ducts with the type of branch duct, cable trough, or duct band usually are installed under the sidewalk or mixed lane. The criteria for selection of the type of supplier duct is demonstrated by Figure 8. For road with width less than 15m, a cable bank would be selected and installed on one side. For road with width greater than 15m, the type of supplier duct would be determined based on the width of sidewalk. The common duct can be installed on both sides of the road under the sidewalk or mixed lane.

For roads with existing pipelines, such as water main, telecommunication cable, or storm sewer, it is required to develop a scheme for allocating the common ducts in a congested underground space,

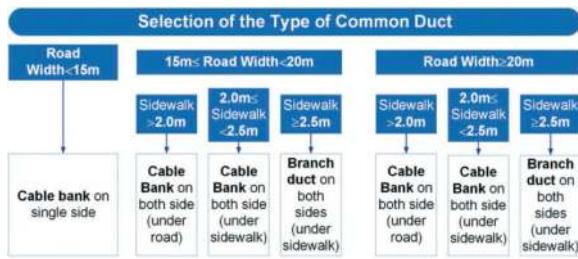

Figure 8. The criteria for selection of the type of supplier duct.

considering the issues involving constructability, future inspection and maintenance. Figure 9 illustrated an example where the layout of common ducts and other types of pipelines are integrated under a 20m-wide road with 1.5m-wide sidewalks. In Taiwan, the BIM and Smart technology are commonly used in the design, construction and maintenance for common duct. Detailed introduction to the application of BIM can be found in the work of Yu et.al. (2021, 2022).

Figure 9. An example demonstrating the integrated layout of common duct and other types of pipelines for road with width 20m.

5 CONSTRUCTION SCHEME

Main common duct is usually constructed by cut and cover method, bored tunnelling method, and pipe jacking method. The box-shaped main ducts with the depth ranges from 5m to 8m as shown in Figure 10(a), (b), (c) and (d) can be constructed by cut and cover method. The circular-shaped main ducts as shown in Figure 11(a) and (b) can be constructed by bored tunnelling or pipe jacking methods. The

supplier ducts such as branch duct or cable trough as shown in Figure 12(a) and (b) are usually installed under sidewalk or mixed lane and constructed by open cut and cast in place method. To ensure construction quality and safety, the underground works need to follow the practice of geotechnical engineering with comprehensive geotechnical investigation, analysis, design, and instrumentation and monitoring. Auxiliary measures such as ground improvement for protection of the buildings in the proximity would be required as per the results of analysis and design.

Figure 11. The configuration of main duct with circular shape.

Figure 12. The configuration of branch duct and cable trough.

6 CONCLUSIONS

The initial plans of common duct system network for New Taipei City were announced and released in 2008 and 2012, respectively, as the blueprint for future

development. To adapt to changes of urban development, ensure relevance, and maintain the effectiveness of the system network over time, the announced plan is subject to periodic review and revision. In New Taipei City, the first comprehensive review and revision was completed in 2016, and the second are expected to be completed in early 2024.

The development of an integrated common duct system network in limited underground space and a congested urban environment is a challenging task. The planning and design must be able to address the public demand for pipelines, align with the construction schedule of major infrastructure projects on the routes of network, and meet the requirements for high-quality road services. Five functional indexes, including level of road service, level of repetitive excavation occurrence, level of demand for pipelines, number of major infrastructural projects to be implemented along the candidate routes in the future, and level of road width were selected as the criteria for evaluation. The AHP method was implemented to evaluate the relative importance for each of the indexes and based on which to develop the system network. The persistent effort invested in this endeavor is expected to contribute to the creation of a more resilient and sustainable urban

environment, and ultimately leading to an improved quality of life for all.

ACKNOWLEDGMENTS

The authors are grateful to Dr. Za-Chieh Moh for his support in preparation of the manuscript and to all the colleagues who have contributed their efforts to this project.

ABSTRACT: Since the beginning of the new century, with the continuous progress of China's urbanization, China's urban tunnel engineering has achieved rapid development. This paper firstly summarizes the challenges faced by the current urban tunnel engineering in China, and introduces the relevant key technologies of tunnel construction according to the above challenges. For example, mechanized metro's under-excavated station, a prefabricated subway station technology and double carbon resource utilization technology of urban tunnel. The engineering applications of these technologies are introduced in China. Among them, Shasan Station is the first mechanized metro's under-excavated station with double-hole combination pipe jacking at home and abroad. It adopts a construction method of transforming large into small and dividing into parts, ultimately forming an integrated underground space. Then, the key technologies of dual-carbon resource utilization and low-carbon operation and maintenance of urban tunnels are mainly introduced, including waste soil/slurry resource utilization. The intelligent, integrated and modular muck resource equipment technology is developed, and the muck is separated into coarse aggregate, fine sand, mud cake and water for recycling by using the processes of mud and sand separation and solid and liquid separation. The technology has been used on a large scale in Shenzhen subway. Finally, some suggestions are given for the future development direction of urban tunnel engineering in China.

Keywords: Underground Space Development, Intelligent, Review, Technical equipment

1 INTRODUCTION

With the rapid development of the economy, cities are facing "urban diseases" such as traffic congestion and environmental pollution. The development of underground space is an important approach to addressing these issues. Urban tunnel projects are a vital component of underground space development, significantly improving the city's surface traffic conditions, enhancing traffic efficiency, and alleviating road congestion. Therefore, many construction methods and technologies have been developed for the construction of urban tunnel projects.

The pipe jacking method, recognized for its fully mechanized excavation and trenchless construction advantages, has experienced rapid development in recent years (Sterling, 2020). It has found extensive applications in the construction of urban underground infrastructure (Chen et al., 2021; Sun et al., 2019; Zhang et al., 2016). However, the utilization of the pipe-jacking method in subway station construction

is infrequent due to the limited size of the pipe-jacking machine, which fails to meet the spatial requirements of the station structure (Yang et al., 2022). The possibility of using a smaller-sized pipe-jacking machine for constructing an integral underground structure has been considered, although the impending construction of tunnels presents considerable challenges (Gao et al., 2019; Wang et al., 2023).

As the core component of the subway system, the prefabricated subway station has many advantages such as rapid construction, flexible layout and sustainable development (Luo et al., 2022; Yang and Lin, 2021). However, with the rapid construction and expansion of prefabricated subway stations, how to ensure their safety, reliability and operation efficiency has become an urgent problem to be solved (Tao et al., 2022). In this context, the prefabricated subway station monitoring has become a key task. Through the comprehensive monitoring of the prefabricated subway station, the status information of the station structure, including the key parameters such as vibration,

*Corresponding author: xschen@szu.edu.cn

deformation and stress, can be obtained in real time (Qiu et al., 2023). This not only helps to ensure the structural safety of prefabricated subway stations, but also provides important data support to help subway operators in operation and maintenance management and decision-making.

The issue of ecological efficiency in construction processes is a major challenge in Urban Tunnel Engineering. Currently, over 5000 km of urban tunnels are under construction in China (Ding et al., 2014; Zhang et al., 2020), leading to a significant increase in the emission of waste spoils from urban underground spaces, tunnels, and building foundations (de et al., 2017). Severe environmental, resource, and safety issues are generated because of the increase (Mao et al., 2021; Xue et al., 2015). Statistics indicate that several billion cubic meters of these waste spoils were emitted annually in China, making them one of the most difficult types of solid waste to dispose of and recycle (Xiao et al., 2021). Taking Shenzhen as an example, the city generates over 100 million cubic meters of construction waste each year, of which waste spoils account for more than 70%. Despite this, the bulk of this waste is predominantly managed through external landfilling, with a low recycling rate (Chen et al., 2022; Qiu et al., 2020).

This paper first summarizes the challenges faced by current urban tunnel engineering in China, and then introduces the relevant key technologies of tunnel construction based on the mentioned challenges. For example, the under-excavated station of mechanized metro, prefabricated subway station technology, and the double carbon resource utilization technology of urban tunnels. The aim is to provide reference for future urban tunnel engineering construction.

2 PRESENT CHALLENGES OF URBAN TUNNEL ENGINEERING

2.1 *Challenge of tunnel construction adjacent to existing structure*

The intensive development of underground spaces has become a crucial strategy for addressing issues like the scarcity of urban land resources and road traffic congestion. However, the construction of urban tunnels faces constraints due to existing structures and underground pipelines, leading to a reduction in safety distances. Additionally, a subway station in Shenzhen (Wang et al., 2023 and 2024) and an underground parking in Zhengzhou (Gao et al., 2019) are being constructed using small-section rectangular pipe-jacking tunnels, requiring the construction of multiple tunnels with zero spacing. The primary challenge in constructing tunnels in close proximity to existing structures lies in the intelligent control of construction machinery. The insufficient intelligence in existing construction machinery hinders the timely acquisition of critical

data, such as geological conditions and the responses of existing structures, needed to guide construction. This limitation impedes effective control of construction disturbances, thereby increasing construction risks.

2.2 *Challenge of prefabricated underground structure construction*

Prefabricated underground structures face various challenges owing to the special environmental and functional requirements of underground structures, especially in terms of waterproofing and seismic resistance. There are waterproofing challenges for prefabricated underground structures. Prefabricated underground structures are assembled from precast components, and the joints are prone to be weak links in waterproofing. In addition, compatibility and durability degradation between different materials may lead to leakage. Finally, the complex hydrogeological environment that underground structures have to cope with increases the difficulty of waterproofing. Seismic performance challenges exist for prefabricated underground structures. The joint stiffness between precast components may be lower than that of conventional cast-in-place structures, affecting the overall seismic performance. Due to the special characteristics of prefabricated structures, the uncertainty of their seismic response increases and requires special analysis and design. During earthquakes, the joints between precast components may fail, affecting the overall structural stability. The joint design should be optimized so as to improve the seismic performance. Finally, a long-term monitoring and maintenance mechanism for prefabricated underground structures should be established to ensure their safety and durability.

2.3 *Challenge of the utilization of urban tunnel waste for low-carbon and large-scale resource recovery*

The utilization of urban tunnel waste for low-carbon and large-scale resource recovery presents a host of challenges. First and foremost, there's a need to develop resource recovery methods specifically tailored for urban tunnel waste, facilitating the separation and targeted utilization of multi-phase spoil. Moreover, traditional stabilizing materials like cement have significant drawbacks, including high energy consumption and substantial pollution (Yang et al., 2022). The challenge is exacerbated by the low-value, difficult-to-utilize clay content in the spoil, which makes cement-based stabilization not only energy-intensive but also less effective and costly, thus impeding its widespread adoption. Consequently, this necessitates the innovation of new, low-carbon functional materials for extensive application. Furthermore, the current lack of viable resource recovery methods for waste spoil impedes the large-scale use of processed materials. The

complexity and variability of the spoil also present difficulties in equipment adaptability, particularly with the clay content. This issue is compounded by the limited space at construction sites, where traditional resource recovery equipment, often bulky and inefficient, becomes impractical. Addressing these challenges is crucial for advancing sustainable urban tunnel construction.

3 KEY CONSTRUCTION TECHNOLOGY

3.1 Construction of a subway station using the pipe-jacking method

3.1.1 Construction scheme

Taking the Shasan Station of Shenzhen Metro Line 12 as a case study, this paper introduces the pipe-jacking construction scheme employed for this subway station. The station has a width of 22.6 meters, a height of 13.53 meters, and a buried depth of 7 meters. Notably, the middle section of the station traverses beneath a large rainwater box culvert, extending 70 meters, which was constructed using the pipe jacking method. However, challenges emerged due to a mismatch in geometrical dimensions between the existing rectangular pipe-jacking machine and the requirements for the station's structural cross-sections. To address this issue, a transformative approach is proposed, involving the division of the cross-section of the subway station into two smaller sections representing the left and right substructures of the station, as illustrated in Figure 1. Subsequently, suitably sized rectangular pipe-jacking machines are employed to sequentially construct the left- and right-line tunnels, maintaining a clearance of about 5 to 10 cm. Finally, a structural transformation is applied to the left- and right-line tunnel, making them to form an integral subway station space.

The pipe-jacking section of the station was constructed using a customized super-large rectangular pipe-jacking machine, which excavated the left- and right-line tunnels sequentially. Following tunnel excavation, temporary sidewalls between the left- and right-line tunnels were removed, and middle pillars, transverse beams, and longitudinal beams were retained to form the integral structure of the subway station, as depicted in Figure 2.

Figure 1. Construction scheme of the Shasan station.

Figure 2. Construction procedure. (a) Left-line substructure, (b) right-line substructure, (c) permanent structure.

The construction sequence using the pipe-jacking method involves the following steps:

- (a) Assemble the left-line substructure in the launching shaft, synchronously jack each ring of the substructure using the pipe-jacking machine, and excavate the soil until reaching the receiving shaft.
- (b) Lift the machine from the receiving shaft, transport it back to the launching shaft, and repeat the process until the right-line substructure is completed.
- (c) Insert four I-steels into the reserved steel box of both the left- and right-line substructures. Pour post-cast concrete into the box to complete the construction of the longitudinal beam. Cut and remove the temporary sidewalls, replacing them with the longitudinal beams and middle plate. Post-cast the upper and lower U-beams after removing the remaining temporary sidewalls and steel supports.

3.1.2 Key techniques

- 1) Jacking super-large rectangular tunnel with shallow buried depth underpass near a box culvert
The Shasan station is situated beneath an urban main road and a large rainwater box culvert. The jacking construction of super-large section rectangular left- and right-line substructures inevitably causes ground surface deformation and differential settlement of the culvert. To mitigate the environmental impact, the following measures can be implemented. Firstly, optimizing the construction sequence by jacking the twin rectangular boxes successively in the same direction proves effective in minimizing ground deformation (Wu et al., 2020). Additionally, employing a horizontal isolation pipe roof and a vertical isolation wall proves to be beneficial in alleviating the environmental impact (Wu et al., 2017; Gao et al., 2022).

- 2) Jacking the right-line tunnel in close proximity to the left-line tunnel

Precise control of the pipe-jacking machine's attitude during the jacking process is crucial for the approaching construction, achievable through several measures. Firstly, implementing a longitudinal screw connection between the machine and the three-ring tunnels enhances both longitudinal stiffness and facilitates balance by providing counterweights for the machine. Secondly, the hinge-jointed hydraulic cylinder between the front and rear shields assists in adjusting the attitude during construction. Lastly, grouting holes designed on the machine's side allow the injection of high-pressure bentonite into the soil, enhancing control over the horizontal clearance of the left- and right-line tunnels. Moreover, adjusting the grouting pressure difference in these holes can further contribute to controlling the machine's roll angle.

- 3) Structural transition

The left- and right-line tunnels are separated from each other, which are needed to be integrated into a whole station structure through structural transition. The structural transition encompasses both vertical and horizontal mechanical transformations. Critical elements for the vertical mechanical transition include pre-buried steel boxes on the top and bottom plates of the left- and right-line tunnels, columns integrated into temporary side walls, and inserted I-steels within the steel boxes. Following the vertical structural transition, continuous longitudinal beams and supporting columns replace temporary side walls to bear vertical loads. Horizontal mechanical transition involves the removal of temporary steel beams after constructing the middle plate of the station.

3.2 A multi-scale monitoring and safety assessment of a prefabricated subway station

Assembling process of large and heavy prefabricated structures may lead to significant strain/stress concentration, and hence may damage these prefabricated components in the form of cracks presented in concrete structures. In this study, we have established a multi-scale monitoring and safety assessment of a prefabricated subway station integrating internal distributed fiber optic sensors and machine vision technologies. A number of prefabricated subway stations including Shapu station, Longxing station, and Pingxi station were monitored using the above-mentioned sensing technologies. Typical distributed fiber optic sensor-based monitoring system is shown in Figure 3(a), where the sensor cables were mounted along steel rebars of prefabricated structures.

Continuous distributed strain field inside prefabricated structures can be directly obtained from fiber optic sensors. Monitored strain distributed in continuous space is shown in Figure 4 and the related spatial resolution of collected strain is 1 mm. Strain change of vault (as shown in Figure 3a) at the different

Figure 3. Application of distributed fiber optic sensors for monitoring large scale prefabricated structures inside subway station (a) position and installation of distributed fiber optic sensors, and (b) transportation and assembling process of vault structures.

assembling steps can be clearly obtained and the potential positions with high stress/strain concentration are also very clear. Therefore, the distributed fiber optic sensors can be used for detecting potential defective positions of prefabricated structures.

The monitoring system also include machine vision equipment and a number of single planar targets as

Figure 4. Monitored strain distribution of internal surface inside vault structures.

shown in Figure 5, which were used for tracking the lateral and vertical movement of the whole prefabricated subway stations automatically. The monitoring system is wireless and the monitoring frequency is 50 Hz. The maximum measurement error is less than 0.4 mm within a monitoring distance of 50 m.

Figure 5. Machine vision-based displacement filed monitoring system in prefabricated subway stations.

Typical monitored settlement of Shapu station during construction process is shown in Figure 6. All obtained settlement data are in continuous, as the machine vision equipment is real-time online automatic monitoring system. It is also seen that the settlement data of different prefabricated structures present slightly difference (less than 5 mm), which is resulted from the difference in overburden pressure of upper soil during backfilling process.

Figure 6. Typical settlement data of prefabricated subway station in construction process.

3.3 Double carbon resource utilization of urban tunnel

3.3.1 Resource utilization methods of solidified tunnel waste

To facilitate the large-scale application and absorption of tunnel waste, multiple types of solidification and resource utilization methods have been developed.

(1) Utilization of geopolymeric flocculation-solidification soil and flowable fill materials

In the construction of shield tunnels, the direct on-site reduction and solidification of engineering spoil with low sand content and no value for sand-mud separation can significantly reduce the volume of material that needs to be transported off-site. This allows the spoil to be efficiently transformed into fill material in a single step, as shown in Figure 7. Additionally, after flocculating and concentrating the original tunnel waste slurry, further flocculation-solidification processing can be applied to produce flowable fill materials.

Figure 7. Schematic diagram of the process for producing mud flocculation-solidification soil (Sun et al., 2023).

By adding geopolymeric-based flocculation-solidification agents directly into the waste mud ponds, it is possible to swiftly create flocculated and solidified soil. Throughout this process, the

negative charges of slurry particles are neutralized by $Al(OH)_3$ colloid from flocculants, causing the slurry system to become unstable. Simultaneously, CPAM, characterized by its long-chain structure, captures slurry particles and forms flocs in the solution. Flocculation enhances the growth of the strength of solidified sediments by densifying the sediment. Upon hydration of geopolymeric particles, the hydrates fill the gaps within the flocs, leading to decreased fluidity and further strengthening. Figure 8 illustrates the mechanism of the combined effect of geopolymeric flocculation-solidification.

Figure 8. Mechanism of geopolymeric flocculation-solidification (Sun et al., 2023).

(2) Underwater anti-dispersal(lightweight) fill material

To enhance the performance of existing conventional grouting backfill material slurries, the development of underwater anti-dispersion fill materials aims to address issues caused by conventional grout backfill material slurries, such as separation, loss of cementitious materials, insufficient compactness, voids, and inadequate durability, especially in water-rich geological conditions. The process involves using an anti-dispersion agent, which is a high-dose coagulant, to fully encapsulate geomaterials and tunnel waste particles. This ensures that the slurry does not disperse during underwater casting and that the strength of the solidified body is successfully formed. By introducing high polymer bubbles, the weight of the solidified waste can be effectively reduced, while also decreasing the amount of material used. This approach aims to achieve the goal of large-scale, low-carbon utilization.

(3) One-step building material

The current method of mechanically dehydrating slurry and utilizing the resultant filter cake for

Figure 9. Underwater anti-dispersion mud slurry filler for underwater casting.

roller-compacted fillers or as building materials — through processes like further crushing, water addition, solidifying agent incorporation, and stirring — is energy-intensive, costly, and highly inefficient. However, integrating the processes of flocculation, pressure filtration, and solidification can significantly enhance the resource utilization efficiency of the filter cake. The solidified filter cake can then be directly extruded to form building materials or fillers. Research has demonstrated that a geomaterial-based method combining flocculation, pressure filtration, and solidification notably improves the dewatering performance of tunnel waste slurry. Under low-pressure filtration conditions, the volume of dewatered slurry treated with geomaterial flocculation-solidification agents increases by 25%, and the drainage rate by 40%. Additionally, geomaterials display superior solidification efficiency, resulting in stronger solidified soil. Employing high-pressure filtration further aids in expelling water from the solidified soil, thereby densifying its structure. Tests indicate that tunnel waste slurry treated with this geomaterial-based flocculation-pressure filtration-solidification method can achieve a strength of 10 MPa, satisfying the standards required for conventional building material blocks.

Figure 10. One-step building material (Sun et al., 2023).

(4) Road construction filling disposal

A substantial amount of tunnel waste requires more extensive disposal methods. It is estimated that road construction filling applications can accommodate over 50% of shield tunnelling spoil. Due to the modification and cutting effects on soil bodies during the shield tunnelling process, the properties of the spoil are weakened, making it unsuitable for direct use in road subgrade construction. The use of a flocculation - pressure filtration-solidification method can rapidly improve the quality of tunnel waste spoil, bringing it up to the standards required for subgrade applications. Additionally, by integrating the use of geosynthetic materials, the performance of road subgrades filled with tunnel waste spoil can be further enhanced. Theoretical derivations and calculations required for filling applications are conducted to obtain analytical solutions, thereby guiding practical engineering applications (Sun et al., 2020; Sun et al., 2015).

3.3.2 Tunnel waste treatment equipment

Tunnel waste, influenced by construction methods and geological types, displays considerable variability in its slurry and spoil characteristics. For efficient and low-carbon resource utilization of shield waste, it is crucial to identify its unique properties and match them with suitable low-carbon resource utilization technologies. This strategy can significantly enhance the efficiency of tunnel waste resource utilization. The phase separation equipment traditionally used in engineering construction for processing surplus mud and spoil characterized by a large footprint, low reliability, high noise levels, poor adaptability to various spoil types, low automation, complex operation, and substantial labor requirements urgently requires an upgrade to intelligent control systems. The upgrading and retrofitting of this equipment entail the modularization of the resource utilization process for shield construction spoil. This modularization includes developing distinct modules for screening, sand washing, flocculation concentration, and pressure filtration. Through model optimization, pipeline design, and other measures, the processing efficiency of surplus mud and spoil can be greatly improved.

Figure 11. Integrated tunnel waste resource utilization equipment.

4 CONCLUSIONS

In the realms of construction technology of a subway station using the pipe-jacking method, prefabricated station technology, and tunnel muck recycling technology, the prospective developmental pathways in China unfold as follows:

- (1) Intelligent Construction. With the relentless progression of technology, the integration of artificial intelligence, big data, and the internet of things in subway construction is poised to gain widespread adoption. The utilization of these technologies holds the promise of boosting construction efficiency, cutting down costs, and ensuring safety—a pivotal trajectory for the forthcoming evolution of subway construction.
- (2) Green Construction. As environmental consciousness reaches new heights, the paradigm of green construction emerges as a pivotal trend in the future of subway construction. This

encompasses the adoption of eco-friendly construction materials, the minimization of environmental impacts during construction, and the optimization of construction organization to realize objectives such as energy reduction, pollution mitigation, and environmental protection.

- (3) Information Management. Given the diverse specialties and trades involved in subway construction, information management assumes paramount importance in ensuring construction safety and efficiency. Moving forward, information management will be an indispensable tool in subway construction, involving real-time monitoring of construction sites, live collection and analysis of construction data, and remote control and management of the construction process.

In conclusion, the developmental trends in subway station pipe-jacking construction technology, prefabricated station technology, and tunnel muck recycling technology encompass intelligent construction, green construction, and information management. The progression of these technologies holds the promise of enhancing the safety, reliability, and efficiency of subway construction, thereby propelling the rapid development of urban underground space in China.

New chemicals with reduced carbon footprint

Francois Couturier*, Dimitri Matioszek & Thomas Boursier
SNF, Andrezieux, France

ABSTRACT: Chemicals are widely used in any tunnelling projects for many purposes and benefits. One recent challenge, quite common across many industries, is the reduction of carbon footprint of chemicals. The ISCC+ certification (International Sustainability and Carbon Certification) was set up some years ago and is now well recognized and adopted by chemical manufacturers. ISCC+ is based on traceability of biobased or recycled feedstocks used by chemical manufacturers. As a side benefit of ISCC+ certification, it is possible for chemical manufacturers to provide data about emission factor reduction for each chemical. Suppliers of feedstocks are more and more proposing alternatives to fossil resources, and these alternatives are derived from virgin biomass, circular materials, or renewable ones. Some chemicals for tunnelling having reduced carbon footprint are already commercially available. The reduction can be even more than 100%, depending on feedstocks. The paper also provides detailed explanations on ISCC+ certification.

Keywords: Bio-based chemicals, Tunneling additives, Carbon footprint

1 USE OF CHEMICALS IN TUNNELING PROJECTS

Tunnel Boring Machines (TBM) are high technical equipment that can not work without chemicals, whatever the TBM type. The following cases illustrate the benefit of chemicals in 2 closed shield TBM types, Earth Pressure Balance (EPB) and slurry machines.

1.1 *Chemicals for EPB machines*

Ground treatment in EPB is essential for safety and use of foaming agent to control pressure is necessary. By reducing permeability of excavated material, operational conditions become safe and work goes faster. The foaming agent dosing depends on soil conditions and can be as high as 80%. Foaming agent provides more benefits like reduced abrasion and less clogging. During transport to the surface level, the soil and foam blend has to be conditioned with polymers that bring viscosity control and water absorption to cope with water spills. Efficient lubricants are required since loss of lubricant leads to failure. Technical greases are provided for lubrication and they can withstand wash out, water and dust presence. Sealants are necessary at several TBM locations to make sure that water, soil and backfilling material do not enter in the TBM inner space.

1.2 *Chemicals for slurry machines*

Bentonite mud is permanently injected through nozzles in the excavation chamber, making a slurry once mixed with soil particles. In order to cope with slurry viscosity variation, chemicals are added to the slurry. Presence of groundwater requires viscosification with polymer additives, and presence of swelling clays requires fluidification. Another drawback of clays is that they stick to the tools, and fluidifiers will help detach and suspend them in the circulating slurry.

At the slurry treatment plant, chemicals are used to treat and recycle water. Typically, coagulants and flocculants provide fast settling of soil and bentonite particles, leaving clear water ready for reuse and preparation of fresh bentonite mud.

The list of chemicals above mentioned is not exhaustive and many other chemicals are used at some other locations on the tunnel jobsite.

1.3 *Some other uses of chemicals*

Whether it is during tunnel boring or during repair sessions, waterproofing grouts are necessary to prevent water from flowing to the work zone. During tunnel life, some cracks are appearing, from millimeter to centimeter size, and require various injection material. Chemist have been able to set up specific formulations able to penetrate the crack with

*Corresponding author: fcouturier@snf.com

adjustable parameters like setting times, depth penetration, adherence, mechanical strength and resistance to incoming waterflow.

Concrete for segment is a material made mainly of mineral components, but it contains also chemical additives, such as superplasticizers. These specialty chemicals are specifically designed to decrease water demand, enhance cement hydration during curing, reduce shrinkage, improve workability, and achieve the requested plasticity.

Upstream, the sand that is used in concrete may not be from 100% natural origin. Indeed, sand aggregates in construction formulations are more and more “manufactured sands”, due to depletion of natural sand deposits. While the crushing process drives grading and shape, clay mineralogy of source rock dictates fines properties and additives adsorption. Some specific chemicals provide solutions to overcome fines and swelling clays deleterious impacts on concrete and mortar performance.

Backfilling materials are necessary to fill the void between concrete segments and the ground, in order that ground pressure is equally distributed over the external segment surface. Chemicals known as stabilizers and retarders are used to improve the backfilling material properties: the final mix has to get the same strength as the surrounding ground and it shall fill every void before the setting time is reached.

Soil consolidation is sometimes necessary to prevent ground collapse when TBM is entering weak zones, and several options are available, including use of specific chemicals able to bring mechanical properties. These chemicals can also be used when TBM meets fractured areas with many cavities to fill.

Ultimately, tunnel boring is not just a mechanical action, but also a series of chemical reactions.

2 TOWARDS MORE SUSTAINABLE CHEMICALS

The chemical industry is still a recent industry with many new processes to be invented. Over the past 100 years it has supplied chemicals to various downstream industries, and today any manufactured good needs some chemicals in its manufacturing process, as catalyst or upstream component. The role of chemical industry will be even more critical in solving modern challenges, like energy transition, or feeding more people, or coping with growing urbanization. Extracting minerals for batteries, like lithium and nickel, is not possible without mining chemicals, feeding the world population is not possible without fertilizers and pesticides, treating wastewaters or producing potable water is not possible without coagulants, flocculants and disinfection agents.

2.1 *Transition to sustainable chemistry*

A massive move towards sustainable chemicals is on its way. Use of fossil resources for chemical

production will significantly decrease in the next decade. Alternatives like use of agriculture or forestry biomass, use of biogenic wastes and residues to make feedstock chemicals are already existing. Many processes have been developed over the past 10 years to move from a linear economy to a circular one, leaving less waste and maximising reuse. Successful processes have led to pilot plant, and now full size plants. This is a large scale approach, and here are some examples taken from various countries and industries.

2.2 *Some recent moves to sustainable chemicals*

2.2.1 *Sustainable Aviation Fuels (SAF)*

The aviation industry has set up goal of carbon footprint reduction, in order to keep growing without increasing its carbon emissions. Options like electric or hybrid vehicles are not yet available like in the car industry or limited to small aircrafts. Biomass-derived jet fuel is one option that comes now into reality. Some routes to sustainable fuels are ethanol to olefins route, and synthetic gas-based kerosene. The 3 key points are as follows: feedstock shall be largely available, given the size of the market; in the same time feedstock supply shall not reduce land surfaces currently in use for food production; and new SAF shall work with the existing petro-based fuel infrastructures. Ethanol route is currently having the lead in the USA, since ethanol can be produced from sugar feedstocks like molasses, but also from cellulosic sources like bagasse (a waste from cane sugar process), or forestry waste, or rice straws. In the UK one project is moving fast using ethanol route, with ethanol made from residual gases coming from surrounding industries, like a nearby steel manufacturing plant. SAF are also a reality in Asia, with Singapore hosting the world’s largest manufacturing SAF plant in terms of capacity.

2.2.2 *Bionaphta in Europe*

One of the biggest biorefinery in Europe is located in Rotterdam. It produces sustainable fuel for road transport and aviation, but also bionaphta to reduce the carbon footprint of plastic industry. The Rotterdam plant is processing wasted cooking oils and fats from animal origin, some of these arriving directly by boat. After a pretreatment step, purified oils are sent to a reactor producing biodiesel, biopropane and bionaphta. There is another biorefinery in Finland producing bionaphta from crude tall oil, a waste from paper pulp production.

2.2.3 *Bio-based polypropylene in Japan*

On its path to carbon neutrality, the Japanese chemical industry has to address the issue of the fragmentation of its main petrochemical complex that are operated by several chemical companies which makes decision for change and investments

more complicated. Despite this, decarbonation of the chemical industry has started in Japan, pushed by the Green Growth Strategy initiated at government level. Naphta from fossil origin can be replaced by naphta from biomass, waste plastic and residual gases containing carbon dioxide. There are many forests near Shunan city, where a large petrochemical facility is located. Fast growing trees are planted to provide cost competitive biomass. Biomass naphta is produced and used near Osaka to make polypropylene.

2.2.4 Bio and recycled plastics in France

One start-up in France started in 2014 to study casein as a possible source for making plastics. After years of research, a pilot plant has been made to finetune the manufacturing process. An industrial plant has started in 2022, now producing a 100% bio-based and biodegradable plastic, targeting single-use plastics and water-soluble plastics. Another French company has found and patented a technique to turn polyethylene terephthalate (PET) from packagings or textiles to new plastics, using enzymes in specific reactors to degrade PET. The new plastics have the same properties as the ones from fossil origin.

2.2.5 Practical case at SNF

SNF is a 40-year-old company headquartered in France and operating 23 plants worldwide. Figure 1 illustrates the very recent changes in its supply chain. With more and more raw materials now available from bio or recycled sources, SNF is now able to manufacture most of its end products, known as water soluble polymers, with reduced carbon footprint.

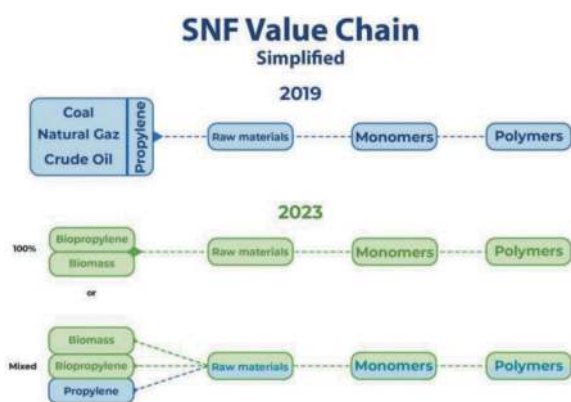

Figure 1. SNF value chain in 2019 and 2023. Most of raw materials and finished goods are now available with some part of biomass or recycled sources.

Whether managed by start-ups or large chemical companies, there are hundreds of new chemicals coming every year in industrial quantities to fuel the

sustainable growth of the chemical industry, in its effort to help reduce carbon dioxide emissions.

3 MEASURING SUSTAINABILITY IN CHEMICALS

International Sustainability and Carbon Certification (ISCC+) is a certification for counting carbon emission and it is currently used by many industries across the globe. It covers all sustainable feedstocks, including agricultural and forestry biomass, biogenic waste and residues, circular materials and renewables. With currently over 8000 valid certificates in more than 120 countries, ISCC is among the world's largest certification systems.¹ Industries like food, plastics, packaging, textiles, chemicals are using ISCC certification.

3.1 ISCC+ in the chemical industry

ISCC+ certification in the chemical industry does not require a physical separation of flows coming from biomass or recycled sources and flows from fossil origin. It is not necessary to duplicate storage tanks for raw materials and finished goods or having specific reactors and feeding and discharging lines. ISCC+ certification can be implemented with no significant investment. In case the company has already traceability in place, like ISO 9001 is requesting, implementation of ISCC+ certification is light. Most of chemical manufacturers having ISCC+ certification have chosen the mass balance approach: certified and non-certified raw materials, having same chemical and physical properties, can be mixed during the manufacturing process but have to be separated in the bookkeeping. Final products are made from mixed raw materials, and it is possible to allocate some parts of the certified raw materials in the final products. Through the certification, certified raw materials cannot be allocated twice. Final products may have from 0 to 100% certified sustainable share.

3.2 Emissions from cradle to gate

Manufacturers of chemicals have first figured out their own emissions, with a split between direct emissions, known as scope 1, encompassing emissions from company activities, and undirect emissions, known as scope 2, related to emissions coming from consumption of electricity, steam and gas. At the company level, scope 1 and 2 emissions can be monitored and reduced. They are already at a low level since they often go along with operating cost reduction.

Scope 1 and 2 count was not satisfactory for end user, because indirect emissions upstream or downstream in the company value chain were not taken into account.

Progressively data on scope 3, dealing with these indirect emissions out of company scope, have been made available.

It is then now common to communicate data from cradle to gate, which counts emission from raw materials extraction to the shipment at the gate of the company. This approach gives a partial life cycle assessment, since upstream transport to user and end of life steps (like waste management) are not counted. But it can be taken as a reliable data by the next user, who can then add its own emission count and pass it downstream to the next customer.

3.3 Practical cases on 3 tunneling additives

Some chemicals used in tunnelling are already available with certified raw materials, proving that decarbonation in the chemical industry is not anymore at the stage of white papers and company announcements. Three examples of tunnelling additives having certified raw materials are reported below. All three are manufactured by SNF in Andrezieux, France. For each, Product Carbon Footprint (PCF) is calculated separately with either fossil raw materials (PCF1) or certified raw materials, when available (PCF2). PCF is expressed in kilogram of carbon dioxide equivalent per metric ton of finished product (kg CO₂e/mt), on a cradle to gate basis.

3.3.1 Soil conditioner

FLOSET CE 630 N is a soil conditioner used in EPB machine providing stabilization of the mix made of soil particles and foaming agent. It comes as a liquid, known as inverse emulsion since the polymer itself is dispersed in oil. The main raw materials are acrylamide, acrylic acid, caustic soda and oil and all four are now available as ISCC+ certified origin. PCF1 is 946, PCF2 is slightly negative, at -71. The negative value for PCF2 is possible since certified raw materials either contained biogenic carbon dioxide (when from biomass) or prevented carbon dioxide emission (when recycled).

3.3.2 Mud fluidifier

FLOSET CT 39 is a fluidifier used in slurry TBM in presence of clays. It has dispersive and deflocculating properties, and can easily be dosed in the bentonite mud. It comes as a liquid, with 44% solid content. The balance is water, since water is used as a solvent in the polymerization step. Its main raw materials, acrylic acid and caustic soda, are both available as ISCC+ certified origin. PCF1 is 512 and PCF2 -456. With such a negative value, the product itself can be considered as a carbon sink.

3.3.3 Flocculant at the slurry treatment plant

FLOPAM AN 923 SH is a flocculant that is dosed at the slurry treatment plant to help settle bentonite and ground particles, leaving clear water for recycling. PCF1 is 2000 and PCF2 is 203. As a powder, its manufacturing process requires more energy than for

the 2 products above, since it includes drying and grinding steps, using gas and electricity. However, PCF1 is kept at reasonable level because product is made in France, where electricity is mainly from nuclear origin, having a low carbon footprint.

As we can see from Figure 2, results for carbon footprint reduction are not the same between products: in the case of FLOSET CE 630 N and FLOPAM AN 923 SH, it is possible to fully offset the carbon emission when moving from fossil to biomass or recycled sources. For FLOSET CT 39, the use of sustainable resources allows to go well beyond offsetting carbon footprint.

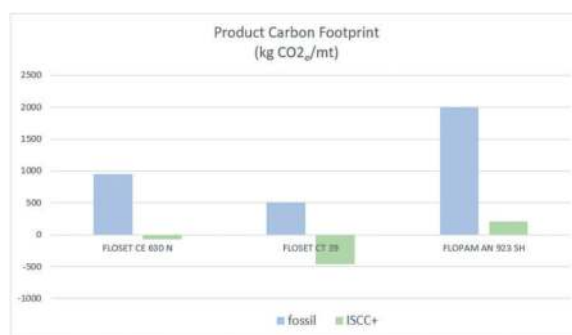

Figure 2. Product carbon footprints with fossil and ISCC+ certified sources, as of July 2023.

In Europe, these 3 chemical products are already available for sale in their reduced carbon footprint version. There is an extra cost for raw materials from biomass or recycled sources, mainly because the availability of biomass or recycled feedstock is low. Arable land is kept first for human and cattle feeding. In a second priority, arable land is used to provide feedstocks to make biofuels, like in countries importing crude oil. Forestry biomass is also competing with other uses, like wood pellets for home heating. As for recycled sources, collection networks are not yet developed enough, and the manufacturing units processing recycled feedstocks are recent (higher depreciation) and designed with a smaller capacity. Some of these units are located next to their source of raw materials (like the bionaphta plant in Finland using tall oil from the local pulp mills) but far from their customers, making overall logistics more expensive, unlike the petrochemical platforms built decades ago and well optimized. Extra costs passed on to the end user for the 3 chemicals listed above are currently in the order of 50% to 100%, and we believe that they will gradually decrease in the short term, at the same time as upstream capacities increase. However, in the medium term, it is likely that some extra costs will persist since fossil resources remain the cheapest ever found so far.

In a broader perspective, it is very likely that by 2030, most of the chemicals used directly at the tunnel construction site will be available from biomass or recycled sources.

4 CONCLUSIONS

The chemical industry has already achieved good results in its way to decarbonation. As early adopter of ISCC+ certification, it is now able to supply chemicals having some parts of raw materials from biomass or from recycled origin. Despite chemicals play an essential role in tunnels construction, their contribution to the total carbon dioxide emission

during project's life is probably not the major one. The effective reduction of the global carbon footprint in tunnel construction will first come from the use of low carbon cement, given the vast quantities of concrete used in tunneling and their high contribution to the global carbon dioxide count. Since zero carbon cement will not be largely available soon, use of chemicals having a low or negative carbon footprint is a way to reduce immediately the project carbon footprint.

City Rail Link – City Rail Link: Managing challenges on the pioneer underground metro project in New Zealand

Francois Dudouit*

Alliance Project Director; Link Alliance, Auckland, New Zealand

ABSTRACT: City Rail Link (CRL) is New Zealand's first underground metro. It is a turnkey project which will be a game-changer for Auckland by doubling the number of people who live within 30-minutes of the city centre. In mid-2019, the Link Alliance, an alliance comprised of the client City Rail Link Ltd and six other New Zealand-based and international constructors and designers, was chosen to deliver the stations, tunnels, and systems. An alliance delivery model with strong integration with the future asset owners, Auckland Transport and KiwiRail, was chosen because of the challenges associated to the size of the project, its complexity, and the risks. The scope of the alliance works includes designing and building two new underground stations and one redeveloped aboveground station, 1.6km twin underground running tunnels, electrical and mechanical equipment and rail systems, as well as testing and commissioning. The technical and engineering feats required so far have been significant, as has the focus on risk management.

Link Alliance is building in the centre of busy Auckland, using a variety of construction methodology including TBM excavation through anchors and large underground excavation in East Coast Formation Bay soil. All of this while in close proximity to live rail infrastructure surrounded by people who live and work in the area. While the alliance has needed to be innovative and adaptable, we have remained clear that people are at the heart of what are doing. We are a culturally diverse team and have developed a unique and inclusive culture which embraces Māori values, looking after our team and stakeholders, and reaching clear sustainability goals.

Decarbonisation in a growing city like Auckland requires continued and focused improvement of urban transport, as well as a commitment to sustainability goals during construction and operational phases of large-scale infrastructure projects like the one we're building. From the design stage of the CRL, decarbonisation was prioritised and formally integrated across management systems so that all decisions considered carbon footprint implications.

Keywords: Alliance, Risks, Mining, TBM, Sustainability

1 GENERAL DESCRIPTION OF THE PROJECT

City Rail Link (CRL) is a railway project which will be a game changer for Auckland's transport network when it opens to the public. It is a 3.45km long railway link that will connect the existing Waitemata Station (Britomart) to the North Auckland Line at Maungawhau Station (formerly Mount Eden).

CRL will fundamentally change the dynamics of the existing railway network towards a metro-type operation. Waitemata Station (Britomart) is located close to Auckland's seafront and is presently a terminus, however once the CRL opens, station

modifications mean that it will enable traffic through in both directions.

Between Waitemata (Britomart) and Maungawhau stations, two new underground stations are being built – Te Waihorotiu and Karanga-a-Hape – enabling central Auckland, New Zealand's biggest employment hub, to be properly connected by rail.

CRL will double the number of people within 30 minutes of the city centre. When fully operational, 54,000 passengers an hour will use CRL stations at peak times, which is equivalent to 16 lanes of motorway. The project will help reduce vehicular

Figure 1. Overview of the City Rail Link.

congestion, decarbonize Auckland, and deliver significant economic benefits.

Link Alliance is completing all the design and system engineering works, the construction of three stations, the associated running tunnels, the connections to the existing railway lines, all electrical and mechanical equipment and rail systems, and finally the testing and commissioning.

Civil construction is essentially complete. It included Tunnel Boring Machine (TBM) excavation, mining at Maungawhau Station and the 32-metre deep Karanga-a-Hape Station, and top-down and bottom-up cut-and-cover methodology at Te Waihorotiu Station and Karanga-a-Hape Station entrances requiring inter alia significant diaphragm wall and piling works.

Ultimately, because we are a railway project, expertise in systems engineering and in railway development have been fundamental requirements.

Being New Zealand's first metro and building within an already densely populated inner city, CRL has specific challenges which are addressed by innovation and investing in people. Link Alliance has more than 2,000 team members involved in building the CRL. We have brought in experience from round the world as well as building up expertise within the country.

Delivery of the heavy civil works started mid-2019 and progressed well in a covid-19 environment, with the project now delivering architectural, and systems fit-out.

2 ULTIMATELY A RAILWAY PROJECT

Link Alliance is the first construction organisation in New Zealand to gain a Rail Operators and Rail Access provider licence under NZ's Railway Act 2025. Meeting the requirements for this as well as planning, controlling, and coordinating work within the Link Alliance Rail Network has required significant innovation and finding solutions for unique and New Zealand-first challenges.

Railway systems works are being carried out in two distinct environments: the first is defined by the newly built underground structures and the second is adjacent to the existing North Auckland Line

(NAL). The phasing of works is dependent on scheduled block of lines (planned periods without commuter rail traffic) and takes place within a very strict regulatory framework.

The transition from heavy civil towards fit-out works is an important phase in the life of the project. It required great attention upstream during design phases of the civil and systems packages, engineering, and in preparation of works, to ensure that integration would be successful and that the project progresses as planned.

Moving towards the testing and commissioning phase of the project – scheduled to start in 2024 – will be another critical transition. The systems teams, which have been integrated into the project from the start, are defining the tests to verify subsystems, systems integration, and validation.

Testing and commissioning plans are being developed in collaboration with the future owners and operators of the CRL: Auckland Transport for the stations and KiwiRail for the rail infrastructure. This integration will help to secure successful testing and commissioning processes and successful handover.

Although CRL links together Auckland's rail network and will fundamentally change the network's dynamics towards a metro-type operation, it is technically a network extension. In particular, the technology of the main systems, such as signalling, remains unchanged. The rolling stock supplied by Auckland Transport is also the same, which will limit risk during the testing and start-up phases.

3 RISKS ASSOCIATED WITH THE PROJECT

There are multiple, interconnected, significant risks that have required careful management including consenting, utilities works, ground conditions, design development, productivity, and interfaces with other infrastructure and construction activity. In addition, being a railway project has meant that we have also had to manage risks associated with systems integration, testing and commissioning. Integration of new infrastructure within Auckland's transport network is another risk which must be managed.

Because this is the first underground metro project in New Zealand, relevant stakeholders have also needed to ensure they have capacity to accept and manage a type of asset that's the first of its kind in the country. Risk associated with this has been mitigated by working closely with stakeholders including the future asset owners, Auckland Transport and KiwiRail.

Two key decisions – made from the outset – have facilitated significant mitigation of project risk: the adoption of an alliance model to deliver most of the works, and making this alliance responsible for civil and system works, including testing and commissioning. Both decisions have enabled the removal of interfaces and helped to optimize the project.

The performance of the alliance is essentially measured collectively, where all risks are shared between partners except for a limited number associated to well defined events. The Variation Benchmarking Register (VBR) defines events giving (or not) the right to adjust the TOC (Target Outturn Cost) and time to completion.

Regarding ground conditions, only a limited number of Extreme Geological Conditions give right to variation. Such conditions must be significant subsurface conditions that are included in the Geotechnical Baseline Report (GBR) and are outside the parameters specified for that subsurface condition.

The relevant subsurface conditions included in the GBR are associated with dangerous gas, excessive groundwater inflows (limited to specific tunnel areas) and only for the TBM tunnel, excessive concretionary interbeds and volcanic rock, ground and groundwater contamination, and unknown manmade obstructions. For example, ground anchors were known to exist under Aotea Centre and the risk of poor TBM progress in that area is named as a shared risk.

The mechanism of risk sharing requires that a comprehensive and efficient risk management process is in place to reduce the alliance partners exposure to additional costs and consequent pain, which in return impacts negatively the margin of the constructors and designers.

4 WHY SELECT AN ALLIANCE MODEL? WHAT ARE THE BENEFITS?

The first call to possible tenderers was made at the beginning of 2017 as part of a ‘design & construct’ contract for the civil, electrical, and mechanical part of delivering the main stations and tunnels (initial C3 contract scope). During the selection process, various events prompted the client to change its approach: the tender was relaunched in June 2018 in the form of a ‘competitive alliance’. Project requirements were also scaled up to provide for a predicted increase in patronage. In particular, allowances were requested for nine-car trains, instead of Auckland’s current six-car capacity.

Link Alliance signed the C3 contract in July 2019. While starting C3 works, it continued to develop and cost the rail systems and connection to the existing railway network (initially planned in two additional contracts: C5 and C7). These additional works were integrated into the original contract in September 2020.

It is rare to have a single entity oversee delivering the whole of civil and systems works, including testing and commissioning. However, the decision to have a single entity has definitively permitted removal of interfaces and to optimize design and delivery.

Link Alliance includes seven New Zealand and international companies: City Rail Link Ltd (the client); three construction partners Vinci Construction Grands Projets, Downer NZ and Soletanche

Bachy International and three design partners WSP, AECOM and Tonkin + Taylor. Future asset owners - Auckland Transport and KiwiRail - are project partners by way of a stakeholder agreement with City Rail Link Ltd.

Link Alliance is a truly international organisation with our people employed by many different companies from both New Zealand and overseas.

The project’s mission is clear. We are working to ‘transform Auckland with a rail network people love to use’.

The alliance relies on some key principles: performance requirements are collectively held between client, contractors and designers (one team), the project is governed by a Project Alliance Board (PAB) with representatives from all parties, decisions taken are best for project and at PAB level unanimously, alliance participants share all risks (except for a few identified in the agreement), liability between parties is limited to the fee and there is no possible recourse to arbitration nor litigation. A target cost with a pain and gain sharing mechanism has also been set up to drive financial performance.

Figures 2 & 3. Link Alliance – One Team.

Consequently, the alliance model strongly drives participants to find solutions and mitigate measures together while focusing primarily on performance and delivering the project with the best possible outcomes across a range of objectives. Eight Project Objectives were defined to drive high performance in terms of health, safety and wellbeing, collaborative relationships and stakeholder engagement, programme, performance of the team, best value (cost), sustainability and environment, social outcomes, and legacy. Key Result Areas (KRA) with financial incentives were also developed.

The alliance’s induction helps team members to understand the project scope, what the project’s core objectives are, how an alliance works and the importance of our objectives and charter – the document which sets out the project’s overarching mission, values, and accepted behaviours for working together as one team.

Stakeholders have been involved in the project’s planning and design process, fostering a sense of ownership, and ensuring best-practice integration of the rail network and improved accessibility. The intensity of construction within urban residential and business environments has also meant that stakeholders are kept front of mind and environmental impact is mitigated by going above and beyond consent compliance.

During the covid-19 pandemic, New Zealand closed its borders for more than two years and several lockdowns were required in Auckland in adherence with a zero covid policy. Despite this challenging environment, the alliance has maintained progress, including the final TBM breakthrough taking place in line with the original contracted programme date. Strong performance during covid-19 restrictions can largely be attributed to the alliance model and an unwavering commitment to keeping our team safe and well.

Beyond significant technical and engineering challenges and the innovations required to deliver the CRL, the project has developed a unique and inclusive culture which embraces Māori values.

The CRL project has established a partnership with mana whenua through the CRL Mana Whenua Forum, made up of eight Māori iwi (tribes), to ensure that Māori values, culture and vision are respected and deeply integrated into the project. In particular, the architecture and naming of the stations are the result of this strong collaboration.

Key values are set out in the alliance's charter. These include Hui ē tāiki ē (working together as one team where trust, respect, collaboration and inclusion are valued); Pono tauutuutu (holding each other accountable through being reliable, responsible, decisive and committed); Aroha tauutuutu (Caring for each other through wellbeing initiatives, being supportive, making work enjoyable and being mindful of our wider community) and Marohi te tū (being inspired through passion, empowerment, being courageous and proud of the project we're all delivering).

The size and scale of the CRL means that we have been able to significantly contribute to leaving a legacy. Over 9,000 people have been inducted onto Link Alliance works and the alliance focuses on delivering programmes that upskill employees, support qualifications and licence achievement, improve wellbeing and financial literacy, provide opportunities for school and university student engagement and a Māori and Pasifika youth internship programme. As well as this, we have focused on investing in social procurement to enable delivery of values above and beyond commercial value and positively impact on communities for generations to come. To date, over \$112 million of our total spend has been with Māori and Pasifika businesses.

5 CHALLENGES ASSOCIATED TO THE UNDERGROUND WORKS

5.1 Description of the geology

The CRL's tunnel alignment is underlain by East Coast Bays Formation (ECBF), which is the local representative of the Waitematā Group. Waitematā Group sediments were uplifted at the end of the Miocene and eroded. During the uplift process, some faulting and folding occurred, while the ancestral Waitematā River and associated streams also cut into

the sediments, typically following weakened zones that were created during the uplift period.

The Waitematā Group is partially covered by a variety of terrestrial deposits and shallow marine sediments assigned to the relatively thin Pliocene to Holocene age Tauranga Group. At the southern end of the project, located just below the extinct Maungawhau volcano, the cut and cover tunnels pass through fractured to compact layers of basalt, as well as layers of very plastic volcanic ash deposits.

Figure 4. Waitematā group sandstones cliff within Auckland.

The depositional characteristics of the ECBF are consistent over a large area resulting in the typical lithologies being widespread across Auckland, although some exceptions can be noted. The most significant variations are the coarser and typically stronger sandstone layers, the uncemented sand phases and the rarer concretionary nodules. Uniaxial compressive strength of the ECBF is generally between 2 and 5 MPa, but in very cemented areas it can exceed 50 MPa. On the other end of the scale, in uncemented areas the mechanical properties are quite low.

6 TBM TUNNELS

6.1 Description

The twin bored tunnels MC30 and MC20 connect all four CRL stations: Maungawhau, Karanga-a-Hape, Te Waihorotiu and Waitematā. Each bored tunnel is about 1.6km long and follows a 3.5% downward slope.

Figure 5. Longitudinal geological section of the bored tunnels.

Figure 6. Longitudinal section of the bored tunnels.

In the past, several tunnels had been excavated with a TBM in the ECBF: Ōrākei Main Sewer, Rose-dale Outfall and the Waterview Connection.

Based on these experiences, we selected an Earth Pressure Balance (EPB) with the following characteristics: drilling diameter of 7.15m; a maximum pressure of 4 bar; a cutting wheel equipped with “rippers” and cutters for hard layers and with an opening percentage of 44% to overcome possible clogging. A single machine was selected to construct both tunnels. The TBM was named in memory of Dame Whina Cooper, a nationally respected leader who fought for many years for the rights of Māori people.

Figure 7 & 8. Dame Whina Cooper TBM (left) & MC30 bored tunnel (right).

Spoil from the TBM was carried out by a conveyor belt with a capacity of 600 tonnes/hour and tunnel transport was mainly achieved by electric vehicles on tyres (contributing to a better tunnel environment and improved sustainability outcomes).

Tunnel lining consists of precast rings, 30cm thick and reinforced with steel fibres, except for special areas where reinforced cages are used.

6.2 Underground challenges and technical solutions

6.2.1 The passage of the Aotea Centre anchors

Several decades ago, anchors were installed during construction of Aotea Centre (a large performing arts and events centre located in the heart of Auckland) and left in the ground. Investigation work was necessary to ensure the number, position, length, technical characteristics of the anchors, and confirm

that they were no longer under tension. In total 26 anchors were identified as clashing with the tunnel. The major impact was on the first tunnel drive for MC30, however some anchors also intersected the second tunnel.

Figure 9. Aotea Centre anchors intersecting the TBM tunnels.

For the first tunnel drive this resulted in 64m of tunnel impacted. Each anchor was made up of seven 15mm diameter strands and had an overall diameter equal to 60mm.

Figure 10. Anchors details.

Due to access and utilities diversion issues, it was hardly feasible to remove these anchors from the surface. The solution was therefore to cut and remove these obstructions from the TBM.

To facilitate this task, the TBM cutterhead was designed with bespoke knives and the screw conveyor with several access hatches. The operating instructions of the TBM have been adapted to this area: three stops were programmed in advance for inspection and possible removal of anchors. These stops were specifically programmed to avoid hyperbaric intervention. Regardless, training and documentation were completed to allow hyperbaric work if deemed necessary and a process was established to decide if additional stops were required.

Figures 11, 12 & 13. Anchors in the cutterhead chamber (left and center) & Tungsten knives on the cutterhead (right).

The TBM parameters were carefully monitored for any sign of cutterhead or screw conveyor torque increase. No such increase was observed. The passage of the anchors on both TBM drives was carried out without long stops and the TBM was able to progress at a very satisfactory average rate of 10m/day, validating the technical choices.

6.2.2 An alignment with very tight radius (140m)

The TBM and tunnel equipment were designed for an unusual tight radius, with 110m radius capability for the articulation of the shield. Two lengths of tunnel rings were selected: 1.1m and 1.6m. The first one was used in the tight curves and second one enabled the team to plan for better productivity in the other areas of the alignment. The outcomes in terms of TBM steering in these very tight curves were satisfactory.

On the second drive, the TBM was launched in a 140m radius curve. Knowing the challenges to efficiently steer a TBM in the launching phase, a 24m long launching cavern/stub tunnel was excavated and the shield was held in place in a curved in situ concrete cradle at launch.

Figure 14. The Launching stub tunnel on a 140m curve.

6.2.3 A complex interface at the TBM launching site

The TBM was launched at the Maungawhau Station site, a complex site due to other critical works being carried out at the same time: mined tunnels and station civil works. A 40-tonne temporary steel bridge was used to span over the MC50 tunnel entrance and to enable the crossing of the TBM gantries and associated logistics. In addition, the TBM had to be launched along a curved and 3% downhill alignment. For the second TBM drive, the shield was assembled on a 60m² tiny platform next to an 8m deep trench. Because no methodological steps could be left to chance, all were performed in four dimensions (with the fourth dimension being time).

Figures 15 & 16. TBM Launching area at Maungawhau, a busy area with several interfaces.

6.2.4 A challenge to optimize TBM assembly and reassembly

Significant efforts were required to optimize TBM assembly and reassembly and to save time the shield was delivered to the site in a full section, assembled away from the launching area and then transported (450 tonnes) to a launching cavern, the steel ring was assembled inside the tailskin at the factory, all gantries equipped with boogies and rail wheels to enable a fast transition from the slab surface to the tunnel lining, a caterpillar system embedded in the gantries to enable the 130m long back up to travel back in the tunnel after each break out, no disconnection of the gantries between each drive, embedded jacks in the steel rings to optimize the station crossing.

Figures 17 & 18. Shield transport down to the portal.

7 ACHIEVEMENTS

The first TBM drive (MC30) was completed in December 2021. After the start-up phase, the TBM achieved an average travel rate that was 30% better than the 15m/day initially planned. During the covid-19 restriction period, New Zealand borders were closed. Link Alliance could not rely on experienced tunnellers coming from abroad and consequently focused on investing in training people in New Zealand to build professional and efficient tunnel teams. The progress achieved demonstrates the success of this strategy. Lessons learnt during the first phase realised improved productivity on the second drive (50% better than planned), which was completed in September 2022.

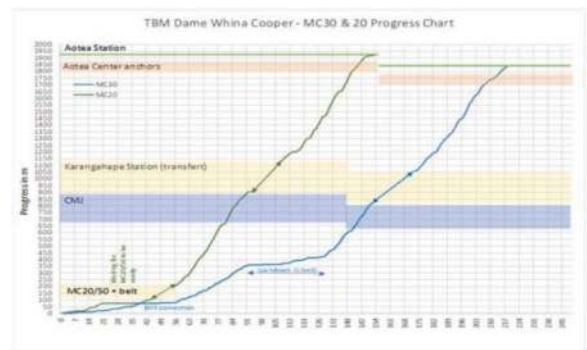

Figure 19. TBM progress curves tunnels MC30 & MC20.

Figures 20 & 21. TBM breakthrough in MC20/MC30 cavern (left) & TBM crossing Karanga-a-Hape (right).

8 MINED TUNNELS

8.1 Description

Several critical and significant underground structures had to be mined:

- The two 230m long train platforms at Karanga-a-Hape Station (excavated section 76m²), the five associated adits and connecting tunnels to the two station entrances: Beresford Square and Mercury Lane.
- At Maungawhau Station, four rail tracks merged underground into two rail tracks to enable trains to run both directions on the North Auckland Line. This requirement necessitated the design and construction of a conical tunnel to connect MC30/MC60 tracks and a conical cavern to connect MC20/MC50 tracks, as well as a tunnel dedicated to the MC50 track.
- Four cross passages between Maungawhau and Te Waihorotiu stations to connect the two bored tunnels MC20 and MC30.

8.2 Challenges and technical solutions

8.2.1 Underground structures at Karanga-a-Hape station

The reference design for this deep station was based on an access to the middle of the train platforms by inclined adits. The design was simplified by providing access to the farthest points of the platforms using the two entrance shafts. This change resulted in simplified construction methodology, savings and CO₂e reduction.

The tunnels are located in well cemented and strong ECBF layers, which enabled excavation in two phases with a road header, ground support limited to bolts and shotcrete, and efficient tunnelling operations.

Figure 22. Karanga-a-Hape Station reference design and as-constructed design.

During the design stage, special attention was paid to the intersections between adits and tunnels. They are complex structures, particularly considering that the sections of the adits and the tunnels are quite similar. They required careful modelling to optimize them structurally and enable safe and efficient construction sequencing. Additional ground supports and the use of spilling were required to address two specific challenges: the cover of strong ECBF above the tunnels could be reduced in some areas to about 2 metres, and the presence of a fault with fractured material.

Figure 23. MC20, Adits 4 & 5 connections to Beresford Square shaft.

Figures 24 & 25. Karanga-a-Hape tunnel lining construction (left) & tunnel excavation (right).

8.2.2 Underground structures at Maungawhau station

The design for this station was optimized by shifting the location of the tunnel portal and reducing the lengths of the tunnels. These changes resulted in 45% less tunnel works, faster excavation, savings and CO₂e reduction. These design changes also enabled earlier TBM launches.

Figure 26. Maungawhau reference design.

At Maungawhau, the ECBF is weaker and the tunnels intersect lenses of uncemented material. Excavation proceeded in two phases, but with shorter advances and stronger support including the use of lattice girders and canopy tubes. An excavator was sufficient for excavating this material.

Figure 27. Maungawhau as-constructed design.

Figure 28. MC20/50 cavern sequence of the excavation works.

The ground support and the sequence of works were carefully designed (the MC20/50 with a 18m span is so far the largest cavern ever built in ECBF in Auckland), and heavy monitoring was in place during construction in order to ensure that construction of the Maungawhau portal and tunnels would not affect a main critical water supply line to Auckland – named Huia 2 – with a 1.4m diameter.

8.2.3 Achievements

All mining works were completed safely with minimum movements and settlements, and within programme tolerance. Achieving mining work in time was critical so that the TBM could pass through Karanga-a-Hape Station on its way to Te Waihorotiu Station.

9 THE SUSTAINABILITY CHALLENGE

Early in the CRL project’s development, we understood the immense opportunity to benchmark sustainability outcomes to that will leave a lasting legacy for New Zealand for generations to come.

We drew strongly from Te Ao Māori (the Māori worldview) and used Infrastructure Sustainability Council (ISC) certification to externally validate our sustainability practices. In fact, we adjusted our ISC manual so it included mana whenua cultural interests – a world first.

To ensure decarbonisation was prioritised by alliance participants, sustainability was formally integrated across the management system so that all decisions, including design, construction, whole-of-life cost, procurement and change management considered carbon footprint implications.

Industry-leading decarbonisation measures that have contributed to this reduction include reducing the amount of cement in concrete, changing the mined tunnel designs at Maungawhau and at Karanga-a-Hape stations to reduce excavation, material reuse, using self-adjusting ‘smart’ lighting and ventilation systems to reduce station operational footprints.

The integration of decarbonisation into decision-making has yielded a projected 60,500 tCO₂e reduction in total carbon footprint over the CRL’s 100-year design lifespan, a 19% reduction which reduces the expected carbon payback time once the CRL is operational to under six years. Once operational, CRL is projected to reduce Auckland’s transport emissions by 28,000 tCO₂e, every year.

According to ISC criteria the project has reached ‘leading’ level. This is the highest possible level for the design phase and the project score is the best ever measured in New Zealand.

10 CONCLUSIONS

City Rail Link, New Zealand’s first underground metro project, is associated with challenges and has several valuable lessons. Its successful delivery adopting an alliance model thus far has been enabled by well-defined and shared values and objectives, strong organisational set-up, state of the art construction methods, innovations, careful design and works preparation, risks management, sustainability, and a steadfast focus on the ultimate goal: delivery of a safe and reliable rail system.

Nuclear decommissioning in the UK: Cross-sector collaboration and learning with the tunnelling and underground space sector investigating alternative approaches to reactor dismantling and graphite retrievals

Daniel Garbutt*

Magnox, Nuclear Decommissioning Authority, London, UK

Martin Knights

London Bridge Associates, London, UK

ABSTRACT: Magnox, part of the Nuclear Decommissioning Authority (NDA) overseen by H.M United Kingdom (UK) Government's Department of Energy Security and Net Zero, is tasked with decommissioning the UK's nuclear reactor fleet which includes the 22 first-generation graphite core Magnox reactors. The previous strategy for decommissioning the Magnox reactors, reviewed in the 1990s, was to defer reactor dismantling for approximately 85 years after reactor shutdown. This involved preparing each reactor for many decades of quiescence; the Care and Maintenance (C&M) phase. In 2019 the NDA Board approved a change to the Magnox reactor decommissioning strategy from blanket deferral to Site Specific Strategies. This enables a combination of continuous and deferred decommissioning to be applied on a site-specific basis, avoiding fleet wide quiescence, and instead creates a rolling programme of decommissioning. The revised strategy involves reactor dismantling being brought forward at some sites, which creates opportunities to develop new technologies and innovative approaches such as the retrieval and possible processing of nuclear materials such as contaminated asbestos, irradiated steels, and graphite to allow for potential beneficial re-use. Magnox has identified cross-sector learning and collaboration as one of the ways of being able to meet the aims of its mission effectively and efficiently. Currently Magnox is engaged with the Tunnelling, Mining, and Underground Space sector to establish an understanding of what technology or methodology transfers from these sectors may be feasible to aid in reactor dismantling (which includes graphite core retrieval). Taking learning from industries that have experience of working in hazardous confined spaces and utilising extractive processes.

Keywords: Planning: Nuclear Decommissioning, Sustainability, Technology Transfer, Robotics and Automation, Cross-Sector Collaboration, Innovation

1 INTRODUCTION

Magnox, part of the Nuclear Decommissioning Authority (NDA) overseen by H.M United Kingdom (UK) Government's Department of Energy Security and Net Zero, is tasked with decommissioning the UK's nuclear reactor fleet which includes the 22 first-generation graphite core Magnox reactors, see Figure 1.

In 2019 the NDA board approved a change to the Magnox reactor decommissioning strategy that moved away from the blanket deferral to site specific strategies. The approach now consists of a combination of continuous and deferred decommissioning. This has resulted in reactor dismantling being brought forward at some sites and is creating opportunities to develop innovative approaches and technologies such as the retrieval and possible processing of a variety of nuclear materials which may allow for beneficial re-use.

Figure 1. Magnox sites on great Britain in the UK.

*Corresponding author: Dan.Garbutt@magnoxsites.com

In 2021, Magnox initiated the implementation of a programmatic approach to align with its new strategic direction. As a part of this initiative, the organisation established the Strategic Enablers Programme, focused on examining site-specific strategies for continuous reactor dismantling and identifying critical factors essential for driving overall strategic change.

Within the Strategic Enablers Programme, Magnox developed a research and development, innovation, and engagement process (RDIE) to identify opportunities aligned with priority areas, supporting the achievement of new mission objectives, Figure 2, and adhering to the NDA benefits framework. These benefits encompass a safer, greener, faster, cheaper, skills-enhancing, and knowledge-creating approach.

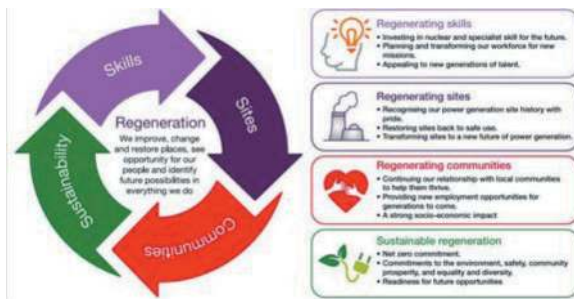

Figure 2. Magnox mission (Magnox 2022).

The programme facilitates pathfinder projects that undergo the RDIE process, showcasing potential benefits. These agile, sprint-type projects aim to deepen understanding within specific opportunity areas, potentially paving the way for larger-scale research, development, technology transfer, or implementation programmes.

In contrast to traditional approaches within the nuclear sector, the NDA and Magnox recognise the significance of cross-sector collaboration in effectively addressing decommissioning challenges through a system-of-systems perspective. This understanding has led Magnox and NDA to engage with diverse industries to enhance their capabilities in addressing the overall decommissioning mission.

Magnox is currently spearheading a “lead and learn” approach to reactor dismantling, with ongoing work at Trawsfynydd in North Wales. The team at Trawsfynydd adopts a pragmatic dismantling approach based on current knowledge and requirements, setting a benchmark for future improvements in dismantling other designated reactors.

To achieve these improvements, Magnox actively collaborates with other sectors to explore relevant approaches, processes, and technologies that may be transferable to the dismantling of designated reactors. Specifically, the organisation has engaged with experts in the tunnelling and underground space sector to investigate potential applicability of techniques used in mining and tunnelling to the Magnox mission. The rationale behind this collaboration lies

in the similarities between the challenges posed by confined space hazardous operations and extractive technologies in the underground space sector, and those encountered during reactor dismantling and handling of core materials.

As this project progresses a deeper understanding of the opportunities will emerge, however in this paper the efforts of building understanding between the nuclear decommissioning sector and the underground space sector will be outlined and how this intends to foster improved project scoping and delivery in time. The authors intend an update paper to follow.

2 THE GRAND CHALLENGES

Sitting behind the strategy and the programmes objectives of Magnox and this specific project are the NDA Grand Challenges. These challenges are:

Reducing our waste and reshaping the waste hierarchy

- finding new ways to drive the waste hierarchy, increasing recycling and re-use to reduce volumes sent for disposal.

Intelligent infrastructure

- using autonomous technology to manage assets and buildings proactively and efficiently.

Moving humans away from harm

- reducing the need for people to enter hazardous environments using autonomous systems, robotics, and wearable technology.

Digital delivery

- adopting modern approaches for putting data to work, to improve planning, training, and aid decision-making.

These challenge themes are deliberately broad and they’re applicable across the NDA group, across different market sectors and have wider societal benefits. There will be areas where the nuclear sector already excels and so it would naturally take a lead in driving innovation, for example, in radioactive waste and radiation-related safety. However, it is acknowledged that the NDA group actively need to seek opportunities to collaborate and partner more widely and work with other sectors. This project sits as an example where Magnox, part of NDA, has experience and understanding in one key area but requires expertise and experience of another sector to compliment and drive a collaborative project to possible innovation.

3 VALUE FRAMEWORK

When collaborating across different sectors, it’s crucial to understand the driving forces behind the approach to programmes. In cases like metro systems, new railways, and utility development, the benefits are clear. Simply put, creating, or upgrading underground assets improves services or utilities, leading to better lives for the local or

national population. Nuclear decommissioning focuses on removing assets that no longer serve the people or the nation. Still, it's essential to ensure benefits for both in carrying out these programmes. The primary task has been based around defining the benefits that guide this programme of work. To do this, the collaborative team including Magnox, London Bridge Associates, OTB, and GCG has outlined and understood the landscape of benefits for a nuclear decommissioning project. This process aligns the underground space sector with Magnox's established principles.

Decisions made by the NDA group must offer value for money. This means using resources in a way that maximizes overall value, not just minimizing costs. The value framework doesn't make decisions, but it helps develop criteria to evaluate options (NDA, 2021) (see Figure 3).

Figure 3. NDA value and benefits framework (NDA 2021a).

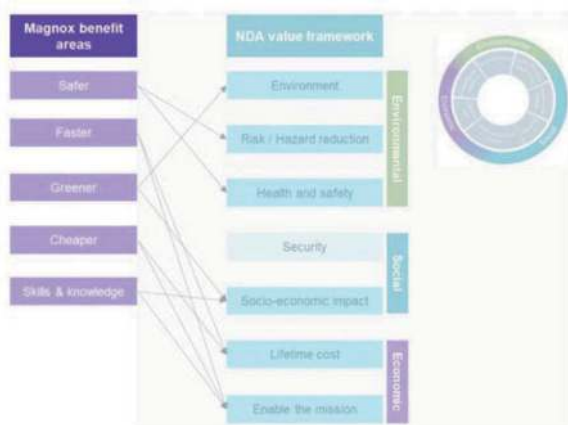

Figure 4. Magnox benefits aligned to nda value framework.

Magnox has aligned a benefits framework with the NDA value framework. This forms the foundation of Magnox's RDIE process, enabling Magnox to assess developmental areas that align with its mission (depicted in Figure 4).

4 SCOPE

Undergoing a strategic shift, Magnox is actively devising an optimal roadmap for dismantling reactors. This strategic transition presents a range of potential options for selecting the subsequent decommissioning site. This approach is deliberately designed for flexibility and a comprehensive grasp of the full spectrum of activities. The scope of this project spans three distinct stations within that strategy, each marked by its own set of characteristics, while maintaining a certain level of consistency across the entire fleet. This standardised approach enables the systematic accumulation of knowledge that can be readily applied to any advantageous scenario that may arise.

4.1 Reactor sites

Among the sites under consideration are Dungeness A (DNA), Hunterston A (HNA), and Oldbury (OLD). The rationale behind choosing Oldbury (Figure 5) stems from its structural resemblance to the Advanced Gas Reactors (AGRs), particularly concerning reactor vessel assembly. This alignment positions Oldbury as a potential hub for generating synergies as the purview over AGRs decommissioning transitions to the stewardship of the NDA and Magnox.

Figure 5. Oldbury reactor buildings.

Dungeness A emerges as a prime contender within the ongoing decommissioning trajectory, making it a judicious candidate for in-depth investigation. Adding to its appeal is the presence of geologically intriguing conditions that warrant exploration.

In stark contrast, the Hunterston A reactors deviate from the conventional configuration of the Magnox Fleet. These reactors, positioned sitting above ground, feature a distinctive characteristic: the placement of the

fuel rod assembly at the bottom, bucking the trend. This unique orientation, that can be described as an “upside-down” setup compared to the rest of the fleet, sets Hunterston A apart as a departure from the established norm and a key candidate for investigation.

4.2 *Establishing intelligence*

Magnox’s objectives for this project are to explore feasible mining and tunnelling techniques applicable to accessing the reactor, dismantling it, and retrieving the graphite and other materials within the assembly. Central to this endeavour is the development of a pragmatic strategy to address risks and uncertainties inherent in utilising mining or tunnelling methods for reactor dismantling and graphite and other material retrievals.

To achieve these goals, it is necessary to understand the capabilities required in terms of personnel, processes, and technology to effectively execute potential options. Equally crucial is a comprehensive understanding of the planning prerequisites, data requirements, and the progression of concept development, design, and construction needed to actualise these potential options.

While Magnox has a substantial history of decommissioning facilities, the objective of this project is to explore these facets in the context of potential novel solutions, which are previously uncharted by the organisation. This exploration is accompanied by a rigorous assessment of the sustainability implications. Magnox’s overarching mission is environmental remediation and sustainability via resource management. Thus, any strides toward circular economy benefits are integral, and this is encompassed as part of the benefits framework.

Additionally, Magnox seeks to gauge the technological readiness of the wider infrastructure sector to meet potential demands associated with executing a programme of this nature. In essence, the collective aim is to cultivate insights and a broad understanding of the risks and opportunities intrinsic to alternative methods for reactor dismantling using mining and tunnelling methods and technologies.

5 OPTIONS DEVELOPMENT

The options development process is currently in hand. The processes began with bringing the integrated team together to understand the Magnox mission along with a site visit to Oldbury to assess the reactor buildings and the site layout, this was followed by a session of key questions and targeted information requests by the London Bridge Associates lead supply chain partner team. This information gathering exercise has enabled the integrated teams to understand the limitations of the scope and grow appreciation of the direction from which Magnox is growing its intelligence.

The LBA team is adopting a “sensing” or intuitive approach to this high-level review of potential options

i.e., bringing together a bespoke team of experienced engineers whose expertise includes mining, tunnelling, construction, mechanical & electrical plant equipment, and robotics in a nuclear environment. The teams innate experience enables a collaborative development by blending intuition and technical skills working with subject matter experts within Magnox to jointly review ideas & concepts; deciding on options; subsequently testing their feasibility and outline methodologies. The team is encouraged to step outside their conventional thinking, collaboratively challenge one another and are encouraged to visit the world of the possible rather than the conventional solutions. This high-level approach to developing ideas and options is a basis for progressive workshops to jointly:

- a) Agree which ideas to take forward for further review.
- b) Establish ideas assess their feasibility and develop. Options.
- c) Review current & future technologies.

In addition, an assessment of risks, procurement strategies, programme delivery and costs will be undertaken.

5.1 *Technology development and transfer*

The scale of the nuclear decommissioning mission in the UK is vast and complex, the timescales run in the century scale. This can provide challenges in development of approaches that may become obsolete or embed risk in future activities for decommissioning. This means that the strategic approach that the NDA and Magnox must take is one based on understanding the current technology landscape but with a view to how this can be developed towards addressing some first of a kind complex challenges decades in the future. This means there is a degree of horizon scanning required as well as uptake of the role of influencing the development of the technology and innovation ecosystem to meet the needs of the nuclear decommissioning sector. This culminates in a flexible strategy that requires room to investigate multiple technology and process strands, this crucially makes room for rapid learning and agile change of direction, with banked learning from experience, when areas of investigation reach the limitations of their strategic value and are no longer viable to progress. The aim is to build understanding of where to encourage development and investment across the supply chain and within other government bodies or where to adopt technologies and processes from other sectors.

As outlined by the Grand Challenges, removing humans from harm is a key focus. The NDA invests significantly in various collaborations and technology developments with regards to robotics and automation, including Artificial Intelligence (AI) and Machine Learning (ML) to address this focus, see Figure 5. The Robotics and Artificial Intelligence Collaboration Hub (RAICo1) facility was established by NDA through Sellafield along with the United

Kingdom Atomic Energy Agency (UKAEA), the National Nuclear Laboratory (NNL) and the University of Manchester. This facility and the approach which is supported is focused around bringing where possible end to end process and technology that is supported through robotics and AI and focused on various nuclear applications.

Figure 6. Tele-existence robotics development for nuclear decommissioning (NDA 2022).

As part of this project Magnox is utilising the learning at RAICo1 and the Automated Sort and Segregation (Auto-SAS) collaboration within the NDA estate to understand how this may be part of a broader technology picture that includes processes and technologies from the mining and tunnelling sector. The aim is to build a picture of to what extent there is a plug and play ability, or where further investment within the technology and innovation supply chain is needed to meet feasible options outlined in this project's work. This ultimately will provide Magnox with an intelligence upon which to base any decisions on where to develop its capability in this area.

5.2 Systems thinking for innovation

Evolving systems thinking wider than the nuclear silo is acknowledged in the Grand Challenges. Therefore, building an approach that acknowledges the interconnected and interoperable aspects of the sociotechnical landscape within which nuclear interacts is a pragmatic way of progressing the mission.

It's important to underscore that the overarching objective of this project is to overcome constraints in thinking about reactor dismantling and material retrieval. Constraining nuclear-related challenges within existing safety and regulatory confines, whilst intended to enhance safety, can inadvertently hinder innovation.

This becomes evident when building the picture of the decommissioning approach, where certainty, safety and security are perceived as coming from established regulated existing approaches, however there are no established consistent existing approaches to graphite cored commercial reactor

dismantling so far. This therefore dictates we must not constrain thinking in developing an approach as security, safety and certainty can come from other sectors and be just as relevant and robust for the nuclear decommissioning mission.

5.3 Balancing opportunity and risk

Opportunities and risks evolve as understanding develops, they can grow from singular ideas at the very beginning of a programme to fully detailed, researched, evidenced, and justified statements as time goes on. The pursuit of reducing assumptions through targeted development of opportunities and risks as early on as possible is aimed at providing certainty and clarity for decision making and project execution at later stages.

This project is broadening the opportunity landscape and the perception of risk of those opportunities in relation to using mining and tunnelling methods and technologies for reactor dismantling and material retrievals. Outside the box thinking and feasibility development work are vital stages in planning of major national programmes of work.

The pursuit of value is an important driver; however, it is necessary to build a comprehensive understanding of what value means to the work being carried out and the ecosystem within which it resides. This approach provides the client organisation with the ability to build overall intelligence. They can then cost effectively target deeper dives into areas which provide enough justification to form a possible solution or be considered as part of a wider system of solutions. This approach is an effective tool for transferring understanding and capability from one sector to another; enabling the development of a collaborative understanding of the opportunities and risks as well as reducing assumptions and challenge constraints. The earlier these activities begin the greater the data to inform options and support programme development towards well balanced and understood decisions based on defined benefits with clear value.

6 CONCLUSIONS

The decommissioning of nuclear reactors and the nuclear estate is the most significant infrastructure project in the United Kingdom, lasting centuries. This endeavour's social, economic, and technical impacts have the capacity to mirror the transformative influence of the industry's inception on society, science, and engineering.

This project is an example of the approach to thinking cross-sector in relation to the challenges presented by the nuclear sector. The NDA and therefore Magnox have recognised that this way of working can offer a wide range of benefits to its programmes as well as providing a catalyst for further innovation and sustainable approaches across sectors.

On long term projects such as nuclear decommissioning a flexible but programmable approach is required that balances both risk and opportunity, it is vital to explore ideas and develop learning through an agile strategy. Progression to effective outcomes is rarely linear in nature, however through taking the approach outlined in this paper Magnox recognises that value can be achieved and retained at all points in its strategic journey.

Building relationships across sectors are an essential step in approaching system engineering challenges, these relationships may vary in format, but they are very rarely a waste of resource as they all tend to move the intelligence and understanding of the programme forward and unlock potential and enable ideas.

ACKNOWLEDGMENTS

The authors would like to acknowledge the wider integrated teams that have been crucial in building intelligence and understanding in this new area of technical collaboration between sectors. The support and endorsement from teams across the Magnox

sites that fully embrace taking a different look at challenges has facilitated our supply chain partners in open-minded investigation. The professionalism and enthusiasm of our supply chain partners is of great value to the team at Magnox and we would like to thank London Bridge Associates, OTB Engineering and Geotechnical Consulting Group for their insights.

Planning of alignment & proposed actions for tunnel collapse in diverse ground conditions on the steepest railway curves in the Eastern Ghats, India

Rishabh Gupta*

Assistant Manager, RITES Limited, Gurugram, India

Lalit Kumar

General Manager, RITES Limited, Gurugram, India

Amit Kumar

Joint General Manager, RITES Limited, Gurugram, India

ABSTRACT: In 1960, the Indian Railway successfully completed the Kothavalasa–Kirandaul (KK) BG line, East Coast Railway (ECoR) primarily built to transport iron ore. Currently, ECoR is planning for doubling line (a new railway line parallel to existing one) in Kothavalasa–Kirandul line section. This 445 km long railway line has more than 58 existing tunnels and 45 tunnels are proposed for second line. The existing railway line passes through one of the steepest vertical gradients of 1 in 60 (uncompensated) upto (8 Degree Curve). This region is thinly populated and has dense forests. Proposed line is planned to increase freight capacity of the section. RITES Limited was assigned the task of conducting the feasibility study, preparing Detailed Project Reports (DPR) and further was awarded with Project management consultancy (PMC) for tunnel construction for the Kothavalasa–Kirandul line section. This paper focuses on a specific 51 km segment between Boddavara–Karakavalasa section of KK line (Andhra Pradesh), which includes methodology, challenges, and recommendations for planning project with similar conditions.

Furthermore, a detailed case study of Cavity formation during tunnel construction in adjacent section ie. Jarati-Malliguda of KK Line in which RITES is PMC for Railways is discussed highlighting unexpected geological conditions that were not initially anticipated during the feasibility stage and how they were treated. The study becomes crucial as the region lies in intense rainfall frequency zone ie. 175 days a year that could further potentially impact the nearby construction activities being held at site.

Keywords: Doubling Line, Steepest Gradient, Feasibility, Adjacent operational tunnel, Intense rainfall

1 INTRODUCTION

RITES Limited was awarded the work to study the proposed alignment of 51-kilometer stretch within the Boddavara-Karakavalasa section of the KK railway line, fixing location of portals, conducting Geological & Geo-technical investigations and preparation of Detailed Project Report. This focuses on its planning procedures and methodology of a railway doubling project. Further the PMC works for one of the sections in connection with adoption of parallel doubling in Manabar - Jarati - Malliguda section of KK line (Odisha) is discussed to shed light on unexpected geological conditions that were not initially foreseen during the project's feasibility stage and its treatment with solutions without hampering project quantities.

2 LOCATION OF PROJECT

KK Line pierces through three states of India i.e. Odisha, Andhra Pradesh & Chhattisgarh. The line has a length of 445 km, out of which 138 km lies in Andhra Pradesh up to Gorapur which will be joining South Coast Railway, rest of the line will remain in the Rayagada division of East Coast Railway 131 km. lies in Odisha up to Khadapa, 176 km lies in Chhattisgarh up to Kirandul. The KK section is classified. as a Group E-special class line in which speed should be below 100 km/h. The doubling of this line will be for capacity augmentation and contribute to growth in the regions, steel plants and ore mines in states. This line is mainly used for freight purposes which is a huge profit benefiting Waltair Division. Nearly 3,000 crore (US\$

*Corresponding author: rishabhgupta141@gmail.com

380 million) of profit comes through this line. The location of the project is shown in Figure 1.

The project discussed in this paper lies in Koraput district of Odisha (Southeastern Region of India) which lies in the eastern ghats of India with hills up to 900-950 m height with Koraput at 870 m elevation above Mean Sea Level (MSL).

Figure 1. Location of the Project.

3 GEOLOGY OF THE PROJECT LOCATION

This region is a part of Eastern Ghats Mobile Belt (EGMB), covering parts of Odisha, Andhra Pradesh, Tamil Nadu, and a small part of Karnataka. It comprises of a typical assemblage of charnockite and khondalite groups, migmatitic gneisses, granitoid, and pegmatite, all metamorphosed to high-grade granulite facies. The principal rock units of the eastern ghats are the granite gneisses, the charnockite series, the khondalite series, and the Granites. The charnockite series and the khondalite series are more in proportion in the hill ranges, whereas the granite gneisses are more in proportion in the plains between the hill ranges and the east coast. Three main stratigraphic units have been recognized in this area. They are the granite gneisses, the charnockite series and the khondalite series. Detailed mapping and geotechnical investigations further supported the observations. Refer Figure 2 for geological classification of the project location.

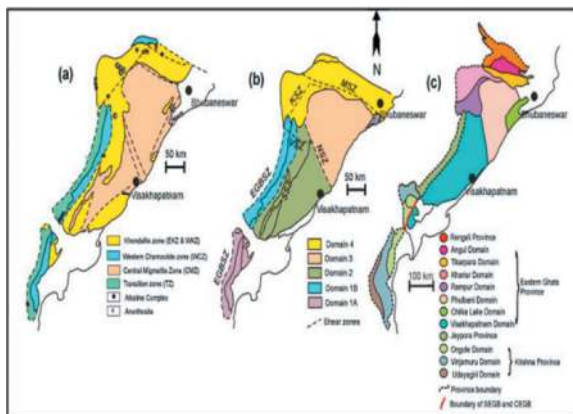

Figure 2. Geology of the project area.

4 METHODOLOGY FOR PLANNING ALIGNMENT

4.1 General Methodology

Initially the data and information available from employer and generated from desk study is analysed and a base alignment is plotted on google earth. Based on these studies, the alignment is proposed by establishment of a digital terrain model for the tunnel route of the project on SRTM or ASTER. Further locations are decided for geotechnical investigations, and the data collected from site is analysed and then preliminary designs are prepared. The design of tunnels along with other submission such as, method statement for construction activities, safety tunnel, design of surveillance systems, quality assurance plan, EIA and environmental mitigation plan, maintenance and safety manual is submitted in Pre final design submission stage. Final design submission is made by incorporating the comments from client. Figure 3 depicts the flowchart for steps of alignment study. Further, cost estimate is submitted for construction of tunnel for the project.

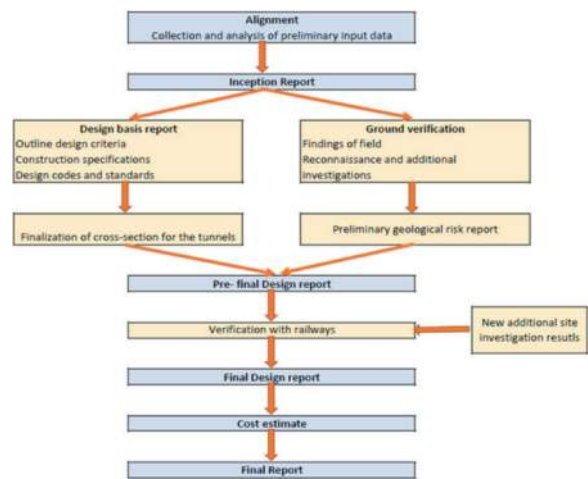

Figure 3. Flow chart summarizing methodology of study.

4.2 Site Reconnaissance Studies and Observations

Input Data by Railways: At the outset, the railways handed over an alternative route to RITES Limited for an initial assessment of its viability and to evaluate its techno-economic implications in contrast to following the existing route in parallel. Existing alignment drawings with bridge and tunnel GADs were also provided for review and references.

4.2.1 Site Studies & Verification for Existing Alignment

The existing alignment is 51km from Boddavara-Karakavalasa. The section is having five stations i.e. Boddavara(Ch:33), Shivlingapuram (Ch:45), Tyada (Ch:51), Chimdipalli (Ch:63), Borra (Ch:72) and Karakavalasa (Ch:83).Gosthani River, Gurubedda Nadi, Pedda Gedda are the major streams flowing

through the project area (Detour portion). Chinna Gedda Nala, Kodi Gedda Nala, Burudha Gedda Nala, Kakadi Gedda Nala and Anjoda Nala Gosthani River, Gurubedda Nadi, Pedda Gedda are the major rivers crossing the alignment. The topography of the area is varied with waterfalls, meandering rivers, green forests, mountains, hills and undulating plains. The tunnels were unlined in portions from Shivlingapuram to Chimdipalli with deep valleys in right and high cuttings in the left in majority of section. There were some patches of slope stability arrangements at station yards & intermediate locations.

4.2.2 Site Studies & Verification for Detour Alignment

- The detour alignment is matching with starting and ending station of the section i.e. Boddavara and Karakavalasa whereas intermediate 5 stations are proposed at new locations.
- For all new stations, the yard has been kept at 1 in 1200 grade than existing 1 in 260 and the station Building side 100m and on the other side 50m wide strips of Land has been proposed for acquisition to accommodate necessary Rail Infrastructure. Also, Two new High Level Passenger Platforms of 400m x 7m along with minimum Passenger amenities have been proposed on UP Loop & DN Loop which are connected by FOB.
- After Boddavara Station (Ch:33), the ghat section starts and route stipulating to deep valleys ranging from 30-120 m requirement of huge retaining walls, long viaducts, and huge filling.
- New Shivlingapuram Station (Ch:48) is planned at lower level at north side of existing station, double maintenance of stations at same location.
- After Shivlingapuram Station, ghat section further continues right hand of existing line with deep valleys ranging from 150-220 m requirement of huge retaining walls, long viaducts, and huge filling.
- New Chimdipalli Station (Ch:61) is planned at right side of existing yard, which involved huge filling as existing yard has falling valley at right side making it construction unfeasible and O&M issues during operation.
- The detoured new Gummakota Station (Ch:74) & New Mulapadu Station (Ch:93), building has been planned on right hand side of the Yard. After station boundaries, ghat section continues and alignment negotiates both right- and left-hand curves. The proposed alignment passes through Over Head Power Line of different types at eight locations, Where adequate clearance is not available at the crossing point suitable shifting/diversion has been proposed.
- New Adaru Station (Ch:111), has been planned on right hand side of the Yard and after station boundaries, the ghat section continues with proposal of long viaduct of nearly 100 spans.

- The proposed detour doubling route will meet the existing Main Line of Existing Karakavalasa station. The existing station Yard is at 1 in 400 grade and the same grade has been followed for proposed remodeling.

4.2.2.1 Comments on Detour Alignment

- Majority of portions of detour alignment is through deep valleys with long viaducts, high retaining walls, huge fillings leading to huge width of additional land acquisition as filling slope is (2H:1V) as per railway standards.
- As the location is water charged area, hydrological studies for the new locations of bridge to be studied in detail and new routes to be made for construction leading to further deforestation in green field areas.
- Although the proposed new upline alignment would have higher speed i.e. 110kmph as compared to existing alignment i.e. 45kmph, but it must be noted that for efficient working of system, the whole system needs to be in sync, if either part is updated the system shall not function with expected outputs.
- As the project is detour alignment, proposal for railway safety in tunnels shall require additional adits, cross passages, and escape tunnels wherever applicable.
- Out of 7 stations in detour alignment there are 5 new stations, leading to double maintenance of stations at nearby locations, also stations are located on majorly fillings whereas current stations are made on verge of cutting, huge fillings must be planned for new locations and land acquisition could be a nuisance during execution.
- Railways had done additional land acquisition in past during execution of existing alignment by acquiring wider width at each structure for future doubling, but as the proposed alignment is detour, the benefit of available land acquisition cannot be redeemed.
- Further issues for land acquisition in forest areas, environmental impact on flora and fauna and most importantly new access roads in approaches for construction may tend to deteriorate more the sustainability quotient of project in case of a complete detour alignment.

Recommendation for Parallel Alignment Study

Further on discussion with pros and cons of the detour alignment, it was decided to study an alternate parallel alignment from Boddavara-Karakavalasa, and comparative studies shall be conducted for choosing the best alignment for the project location. The proposed alignment shall be designed parallel to the existing line to share the existing infrastructures, electricity, water supply, signalling systems and approach roads which would overall bring a huge impact on project cost when compared to detour alignment.

4.2.3 Methodology for Parallel Tunnel Alignment Study

To study the parallel alignment with different types of structures all throughout the alignment. it was not possible to propose a railway line with a fixed distance from existing line. Hence, the criteria to make decisions on proposed alignments was to decide its distance from existing railway line as mentioned in below Table 1.

Table 1 . Centre to Centre Track Distances Structure wise.

S No.	Structure	Distance from Ex. Alignment
1	Tunnels & Its Approaches	25-35 m at Tunnels and 15-25 m at approaches
2	Major Bridge	20 m
3	Station Yard	Min. 5.3 m
4	Open Earthwork Sections	Min 6.5 m

(I) Tunnel & Its Approaches Centre to Centre distance b/w proposed and existing tunnels.

During the excavation of a cavity the ratio between the major and the minor principal stress increases in the adjacent rock. The new state of stress depends on the shape and the dimensions of the cavity, the initial state of stress in the rock, and various other factors. The rock is anticipated to be fairly intact all throughout alignment as majority of sections has unlined tunnels. Therefore, the state of stress in the rock surrounding the tunnel should be approximately the same at different stations, and the normal stress parallel to the centreline of the tunnel should have approximately the same value in every profile.

Figure 4. Stress Distribution in Circular (Tunnel) (a/c=1) Reference KARL TERZAGHI and F. E. RICHART, JR.

With below mentioned parameters, the ratio of x/a becomes ineffective for horizontal tangential stress ratio and vertical stress ratio at wall portion of tunnel. Furthermore, the ratio of c/a becomes less ineffective for horizontal tangential stress ratio for said parameters, however it shows positive trend along vertical stress ratio but overall

with such given horizontal distance between two tunnels, it is evident that the stress ratio are in permissible ranges as shown in Figure 4.

Let us assume poisson's ratio of surrounding rock = 0.2

The overburden at tunnel portal from crown (z) = 10 m

Clear Center to Center Distance b/w tunnels (x) = 25 m

The Width to Height Ratio (a:c) = 9:9 = 1:1

Excavated diameter of the proposed tunnel, D = 9 m

The safe distance b/w proposed, and existing centerlines is calculated as below-

Distance from center of proposed tunnel to minimized stress zone = $2.5 \times D = 22.5\text{m}$

Radius of existing tunnel = $0.5 \times D = 4.5\text{m}$

Length of existing trolley refuge (trolley refuges are also towards proposed tunnel) = 3.5m

Margin for overbreak's due to over excavations = 2m

Safe distance b/w proposed and existing tunnel = 32.5m

Further, there are some aspects which are not quantifiable directly at planning stage to decide the alignment.

The are –

- Progressive loosening of surrounding rock mass around existing tunnel over a period post construction.
- Loosening leads to reduction in C, phi and E values of the geology.
- Impact of vibration on surrounding rockmass due to running of train.
- Hydrogeological wakening of rock mass over period (especially in unlined tunnel portions).
- Quality and health of existing lining in tunnels.

Hence, the adopted safe distance b/w center lines of proposed and existing tunnels are 35m.

Additionally, Tunnel orientation relative to dip and strike is an important consideration in tunnel design and construction. In general, it is recommended to orient the tunnel perpendicular to the strike of the rock layers which would create more stable tunnel. Furthermore, if the tunnel is being constructed through a region with a lot of faults, it may be necessary to orient the tunnel at an angle to the strike of the rock layers to avoid crossing the faults. Tunnels that are oriented parallel to the strike of the rock layers are more likely to be flooded whereas Tunnels that are oriented perpendicular to the strike of the rock layers are more likely to experience rockfalls.

(II) Minor Bridges: The criteria for fixing Standard RDSO spans for minor bridges depends on two criteria:

- If the proposed bridge is upstream of the existing bridge, then in that case the inner

clearance of the box shall be matched with the existing structure (here it is Hume pipes) to avoid any surge on walls of minor bridge.

- If the proposed bridge is downstream of the existing bridge, then in that case the inner clearance of the box can be enlarged or kept same as mentioned above with the existing structure.

- (III) Major Bridges: Existing major bridges were constructed with wide open footings and hence safe centre to centre distance of 20m was decided for proposed parallel major bridges. It was proposed to minimize the impact on existing bridges during construction of proposed bridges. Also to avoid the overlapping of foundations as large open foundations are proposed in existing bridges, so adequate distance of 20 m is proposed to have a safe distance during construction and long term loading patterns in foundations of existing and proposed bridges. Also, it was decided to consider the same span configuration of the proposed major bridges to existing bridges to provide same waterway of upstream portions. However, precautions need to be taken when in curve, it must be ensured that the pier doesn't fall in nallah contours which can lead to scouring. Therefore, detailed hydrological studies is required for finalization of proposed bridge piers w.r.t existing bridges.
- (IV) Station Yards: The gradients under station limit are proposed to be the same of the existing levels to provide switchovers, points and crossing across the yard limits. Also, the centre to center distance between loop and main lines for new lines have been kept minimum 5.3 m as per latest SOD (BG) of Indian Railways.
- (V) Open Earthwork Sections: The track center distance between proposed embankments to existing embankments is kept minimum to 6.5 m for coach clearances in curves, drains and retaining structures wherever required.

4.2.3.1 Remote Sensing Technology for Geological Mapping

The project gets started with the planning phase by sketching the first plan in an Arc GIS software. ArcGIS surface analysis was used to generate contours, slope, aspect, and hill shade from DEM and then photogrammetric maps were prepared to facilitate portal locations and other studies. Two main groups of rock types are recorded along the proposed alignment i.e., Khondalite group and Charnockite group. The geological map of study area had been prepared based on Remote Sensing Technique along with ground truth verification using Geographical Information System software.

A geological map (Figure 5) is showcasing the final output.

Figure 5. Geological Map of Project Location.

4.2.3.2 Site Studies & Verification for Parallel Alignment

- (I) Boddavara (Ch:33), to Shivalingapuram (Ch:45), is lying in flatter terrain to start with for early 3-4 kms and remaining section in ghat section after Tunnel-1. While travelling through alignment along increasing chainage, the general trend is to have deep valley (50-100m) on the right-hand side and uphill slopes on the left. Therefore, the alignment was proposed to the left in this section and no scope of cut & connection was found in this section.
- After Tunnel-1A (Ch:36): there is a non-perennial waterfall at the left of existing alignment so to plan a structure and track center at waterfall location the proposed alignment was set to offset 100 m towards the hill side with following points. (Figure 6)
- The alignment towards the right side is not suitable as the valley is about 50m deep and would involve construction of large number of bridges. (**Option Green**)
 - Also, the existing radius of curve is 218.8 m (i.e., minimum) with an 8-degree curve so providing an offset track with lesser radius is not practical and feasible.
 - The other option is to propose bridge between existing line and Boddavara waterfall. This brings the proposed alignment closer to the rock fall zone of the fall and increases the risk for long term to the train operations. (**Option Blue**)
 - Another option was to propose alignment with offset of 100 m from existing line by providing underneath tunnel considering adequate vertical and lateral cover at Boddavara fall, so that rock fall zone and water ingress is avoided. Although the tunnel length would increase but the option was best suited for future durability of structure and cost maintenance at this location. (**Option Red**)

But on subsequent discussions with ECoR, it was finalized for providing offset of 35-40 m from the existing line to the left to avoid land acquisition issues and restrict levels difference between existing and proposed alignments and ways for waterfall diversion were also explored to provide construction feasibility during rainfall season.

Figure 6. Option comparison at Boddavara Waterfall.

- (II) Shivalingapuram to Tyda section is lying comparatively at a higher elevation with no accessibility from nearby roads except for in Tyda station.
- (III) Tyda to Chimdipalli station is majorly covered with tunnels adjacent to vertical steep rocks and deep valley. Also, there has been an incident of failure of pier at existing bridge locations (Br. No 249) leading to huge economic loss. The Chidmipalli station lies just adjacent to T-29 and is non-accessible from any nearby road.
- (IV) The joint site observations and terrain information available presents the fact to follow left side alignment from Shivlingapuram to Chimdipalli and no cut & connection location was feasible.
- (V) The Borra station lies just adjacent to T-38B and is easily accessible from the main road. It is one of the biggest tourist spots in Andhra Pradesh and there are certain reasons for keeping the alignment to the left side. The cover to Borra caves is thin towards the right of the existing alignment. Further, there are karst cavities present to right of the alignment. Also, the alignment from Borra to Karakavalasa region is inhabited by descent amount of population with villages situated to the right of the alignment.

4.2.3.3 Comments over Parallel Alignment

- Major section is in cutting through competent rock mass; therefore, it can be assumed that that 2H:1V or steeper can be provided with minimum support along the alignment in cutting heights more than 6-8 m.

- The area is water charged, hydrological studies for the existing bridges can be referred in detail and this may be useful in estimating proposed bridges configurations.
- The proposed new upline alignment is designed with higher speed i.e., 60kmph as compared to existing line speed i.e., 45kmph. Therefore, upline speed is enhanced by a slight percentage, the overall system is benefitted as currently the upline speed was 40-45 kmph and downline speed was restricted to 30-35 kmph to avoid derailment.
- The most important benefit from this parallel alignment was that the existing tunnels could be useful for escape tunnel and portions where the existing tunnel is opening, there adits are provided for efficient safety rescue exits.
- Out of 5 stations in existing alignment all stations are planned in vicinity of the existing alignment using same station buildings and providing 3-4 lines (main + Loop) as per requirement. No requirement of land acquisition was required within station top point limits. Railways had already done additional land acquisition in past during execution of existing alignment by acquiring wider width at each structure for future doubling, the benefit of available land acquisition can be therefore redeemed.

Figure 7. Existing, Parallel & Detour Alignment on Google Earth.

Figure 7 depicts the alignments of existing (white) proposed detour (magenta) and proposed parallel (red) at a glance. The merits and demerits of detour and parallel alignment are discussed in detail, prima facie through details mentioned in Table 2 and the cost comparison for both the alignments was done on costing based on recent awarded works in East Coast Railway zone and the results stated that the detour alignment was 43 % more costlier than the parallel alignment as per rates worked out in year 2021-22. The information regarding rates and costing is sensitive and cannot be made public. Therefore, Parallel alignment is far more feasible and economic as compared to Detour alignment and it was approved by railways in due discussions and currently construction for doubling is in progress.

Table 2 . Comparison of Existing vs Detour & Parallel Alignment.

S. No	Point of consideration	Existing Alignment at Site	Detour Alignment	Parallel Alignment by RITES
1.	Route Length	51 km with 5 stations	92 km with 7 stations (2 old and 5 new)	51 km with 5 Stations
2.	Gradient	1 in 60 (uncompensated)	1 in 80 (compensated on curves)	1 in 60 (Uncompensated)
3.	Max. degree of Curvature	8 degrees	6.48 degrees	8 degrees
4.	Tunnel length	17.5 km	16.15 km	27 km
5.	Minor Bridges	204	34	78
6.	Major Bridges	16 (length -1.05 km)	20 (length -8.174 km)	8 (length -0.6 km)
7.	Road Crossings	One crossing near Borra, No ROB and RUB	Four Crossing, 3 ROB and 7 RUB	One crossing near Borra, No ROB and RUB
8.	Speed	45 km/hr	110 km/hr	55-60 km/hr
9.	Station Gradient	1 in 260 in all stations and 1 in 400 at Karakavalasa.	1 in 1200 in all stations and 1 in 400 at Karakavalasa.	1 in 260 in all stations and 1 in 400 at Karakavalasa.

5 CASE STUDY OF CAVITY FORMATION ON ACCOUNT OF GEOLOGICAL SURPRISE AND ITS TREATMENT

Efficient planning and geotechnical investigations during the feasibility studies does not rule out guarantee non-occurrence of geological overbreak's in tunnelling. Therefore, a case study in similar project area of a cavity overbreak is discussed in this segment of technical paper and the solutions devised to address these challenges were formulated considering the adjacent operational tunnel, utilizing the allocated quantities specified in the contract to prevent non-scheduled variations, and, most importantly, project schedules.

5.1 Geological /Geotechnical Studies During Pre-Excavation of Tunnel-1

Tunnel-1 was planned with 320 m total length with extended. cut & cover boxes both sides with offset distance of 28-30 m c/c with the existing alignment. The tunnel portal was planned at an overburden cover of 8m and maximum cover at mid portion was 53 m. The alignment in this section is running almost perpendicular to the strike direction of the rock with steep dipping, such orientation of the rock mass is generally a fair condition for tunnelling.

Two boreholes were performed at the portals and Geophysical surveys (Seismic Refraction Tomography) were also conducted at the portal location and detailed geological mapping at existing tunnel and proposed portal locations. Water table met in both the boreholes ranging in depth from 10 to 13.5m depth and seepage to minor inflow of water also recorded along the existing cutting & inside tunnel which indicates possible occurrence of water during construction. The Seismic depth probe reveals four-layered model having different seismic velocities

Figure 8. Tunnel 1 (a) Details Geological Plan (b) Geological L-section (c) SRT results (d) core photographs.

with varying thickness. Refraction results indicates that the area is generally covered by 1.0m to 10.0m thick layer of overburden comprises of topsoil (compact nature) with boulders/cobbles/fragment of weathered Granite/Granodiorite in silty/sandy matrix having seismic velocity of the order of 700 to 1178 m/sec.

5.2 Construction Methodology, Face Mapping and Cavity Formation at Tunnel-1

Tunnel portal locations both sides showed gentle slope terrain covered with varying thickness of overburden material underlying the basement rocks, therefore SC-V was proposed for initial patch of tunnel portal for a length of 50 m at start of P1 location (Ch:1+680). Refer Figure 9 for detailed support arrangements.

SR. NO	CONSTRUCTION SEQUENCE - HEADING & BENCHING - CLASS 5	REMARKS
1.	Advance of face by top heading for complete length of tunnel or as per the proposed excavation methodology by contractor.	"x" = (1.5 m)
2.	Muck removing from face and dumping it to the designated yard.	
3.	Scale down all loose blocks/fragments using Boomer before spraying shotcrete.	
4.	1 st layer shotcrete - Spraying of minimum thickness 50mm of Grade M25 on the exposed rock surface.	Sealing shotcrete of 50 mm at rock surface.
5.	Installation of 1 st layer Wire mesh (150x150mm) on the initial shotcrete layer and fixing it firmly on the undulated surface ensuring there is no gap between rock surface and wire-mesh.	
6.	Install the lattice girder and the wiremesh on the outer surface of lattice girder. At no time shall the face be advanced beyond "x" metres of the last erected lattice girder.	"x" = 1.5 m
7.	Install fore piling through lattice girder at every "x" metre, wherever required.	"x" = 4.0 m, 25Ø, L= 6.0m
8.	2 nd layer shotcrete - Spraying Final layer shotcrete to cover lattice girder, w/mesh and forepoles ensuring complete lattice girder is embedded in shotcrete.	Application of final 150mm layer shotcrete of Grade M25.
9.	Install rock bolts (SN/SOR) as per the rock support given in respective drawings.	25Ø, L=6 m @1.5 m c/c, Fy=210 KN
10.	Benching excavation to be done as per site specific condition but limited to maximum 50 m beyond top heading.	
11.	After steps 1 to 10, the same cycle shall be repeated.	

Figure 9. Support Class V construction methodology and Typical Tunnel Cross section with class V support arrangements.

Instrumentation & monitoring during tunnel operation: During the tunnelling operation, below safety instruments were installed for monitoring the behaviour of tunnel and its impact on the surrounding structures. The instrument monitoring systems were following types –Surface monitoring system such as inclinometer to monitor stability of portal slopes. These instruments were installed on the portal ground surface in the array. Bi-reflex target, MPBX, pressure cell, strain gauge, etc. Bi-reflex target (BRT) –Measures deflection, and settlement and was used in traversing. Multipoint borehole extensometer (MPBX) – used for measuring differential settlement. Pressure cells were installed in the tangential direction in the primary

lining measures the strain in the rock mass and stress in the shotcrete, Pressure cell installed in the radial direction measures the hoop stress in the primary lining of shotcrete. Strain gauges (SG) – Measures the compression and tension in the primary lining.

Figure 10. Pre-Cavity Photograph of Proposed & Existing Tunnel -1.

Cavity Formation: On 30th May 2022, at (Ch:1700) the vertical cover was 6-8 m and the rockmass of the face was in damp condition with little seepage observed on the face. Seepage in the basic enclaves was favourable for slipping the rock along the joints due to smooth slickenside nature of the joints. Refer Figure 10, the figure was taken before cavity formation.

Figure 11. Face Mapping at RD 20 m i.e., Ch:1700.

Excavation for Round length-1m at this chainage completed at morning shift and all the support system installed by evening. Detailed face mapping is attached in Figure 11 which shows intermediate shear band with highly sheared rock mass. Since night it continued heavy rainfall for more than 3 days and the work was suspended. At this stage, the excavated face was pierced 20 m inside from the portal starting point. Suddenly on 4th Day when the rainfall stopped in morning 8 am, a cavity occurred at face and all the support provided at the face were dismantled. Huge quantity of loose rockmass cum debris came down which damaged lastly installed LG, forepoles and other supports as provided. Immediately at 9pm once again loose rockmass came down and damaged another set of LG with fore-poles and rockmass covered up till crown portion. No further activities done at that night shift because it was risky to approach the face.

The cavity is visible in the upper part of the top heading. Fortunately, no casualties occurred during face

Figure 12. Damaged LG, Forepoles, Wire Meshes at RD 20m.

instability (Figure 12). The relieving outcome was that the instruments installed in initial 20 m, showed very little deformation results and were in permissible limits. However, the overbreak extended further beyond 22 m (Ch:1722) ie. RD 20m to RD 42m in increasing chainage and complete daylighting of tunnel at the mid-section occurred which can be seen in Figure 13 below.

Figure 13. Complete Daylighting of Tunnel b/w Ch:1700 - Ch:1722.

5.3 Recommendations for treatment

- For different reasons no work was carried out to stabilize till it was confirmed no further movement is observed for two days, luckily no further rain occurred at site location. As the track centre between two tunnels was nearly in the range of 25-28 m in this section it was decided to excavate the muck at 60-degrees with temporary slope stability arrangement of 50 mm shotcrete and one layer wire mesh (150x150x6) at required patches so that lateral cover to existing tunnel is not breached. Continuous monitoring of existing tunnel was being done and results were within permissible deformations and showed settling trends. The upper slope and the adjacent slopes were temporary contoured in such a way for efficient discharge of water. Also, relief holes were proposed in slope walls for dissipation of water pressures.
- The portion looked like a discontinuous tunnel section, for which a proposal for Cut & cover box

was planned in the mid portion to reinstate the ground and to ensure continuity between initial length of tunnel with the remaining leftover length. The temporary slopes stabilized during muck removal were although provided temporary support arrangements, but due to the region experiencing high intensity rainfalls, the location was vulnerable for future failures, so to provide a box structure and to reinstate the ground conditions above it was the prime goal to cater the situation. However, there were major problem in providing cut & cover box firstly limited site conditions due to muck disposal hill on both sides of existing tunnel. Also, Gantry machine fixing for outer and inner lining for cut & cover box was not possible in the mid tunnel location due to non-availability of horizontal clearance for mobilization of gantry machine. Additionally, the contract under execution is item rate contract, so additional quantities of cut & cover box would have led to deviation in contract, so the proposal need to be made so that the provided quantity for the 20 m section could be utilized for minimum variation and optimization of project quantities.

Figure 14. Synoptic view of NATM, Open Damaged portion of T-1.

Solution Proposed

Therefore, a proposal was made keeping in view the above points by providing a support arrangement of lattice girder at 1m spacing centre to centre with base plates and wire mesh encircling the lattice upper portion tied with tie rods. The wire mesh was fixed to bent down fore poling and existing wire mesh. Galvanized iron sheet was placed as outer shuttering and shotcrete M25 was shot from inside so to provide a tunnel profile up to 150 mm thickness (50mm +100mm) in two layers. This thickness was provided to counter any possibility of shortcomings during operation and to ensure the inner profile of gantry to meet at the time of secondary lining throughout the chainages. Refer Figure 15 at next page.

Furthermore, Support Class V was assumed at this length, however with this scheme saved an additional layer of wire.

mesh, lattice girder nos., shotcrete thickness, rock bolts 6m lengths (1000no.s).

Figure 15. LG, Wire mesh & GI sheets for outer shuttering of Gantry.

- The outer face of the cut & cover was wrapped in water proofing membrane 2mm thick and tunnel excavation material from support class 5 was backfilled on the cut & cover location contoured in such a way that the natural ground conditions, water channel routes are reinstated to original.
- Furthermore, after due removal of muck from the mid portion which took nearly 40 days, false portal was made at Ch:1720 and further working for Tunnel -1 was commenced as competent rock mass was encountered as can be seen in Figure 16 and probe holes confirmed the same. An average round length of 3-4 m was with minimum support requirement as predicted in pre-construction phase.

Figure 16. Highly competent rockmass at & beyond Ch:1720 (T-1).

6 CONCLUSION

The parallel doubling project in Indian Railways is a major initiative to increase the capacity and efficiency of the country's rail network.

Here are some of the benefits of the parallel doubling project:

- Increased capacity: The project will double the capacity of the affected rail lines, allowing for more trains to run simultaneously.
- Utilization of available land boundaries in extent of existing railways alignment leading to reduction in menace in comparison to new land proposal plans.
- Reduced congestion: The project will help to reduce congestion on both freight and passenger lines, improving the efficiency of the rail network.
- Improved travel experience: The project will improve the travel experience for passengers by reducing overcrowding and delays.
- Boosted economy: The project will help to boost the Indian economy by making freight transportation more efficient and reducing transit times.

However, the only disadvantage and the most challenging work is that the working operation of existing tunnel gets impacted and existing structures needs to be monitored closely for any deformation due to parallel construction activities. Due planning for alignment is mandatory for any project and criteria mentioned in this paper are recommended to be followed. Furthermore, it must be practiced that a comprehensive detailed study of borehole investigation along with geological mapping and geophysical surveys and results must be correlated as whole which is mandatory. For instance, a patch of T-1 with complete loose rock mass and soon after 15-20 m, excellent quality granitic gneiss occurred for them or extend of remaining tunnel. The challenges encountered during the planning and construction of this project are poor geology, less overburden, rainfalls & water ingress, steepest alignment cavity overbreak, and parallel tunnel. Accordingly, the railway team, PMC as well as the construction team, had managed well. The planning, design, and construction process adopted for this section will be helpful for future tunnelling in the parallel tunnelling projects (Doubling) for railways.

Comparison of carbon footprint emissions in tunneling projects using innovative methods

Pegah Jarast & Verya Nasri*

AECOM, New York, USA

ABSTRACT: Climate change has long been one of the global issues related to energy consumption, and greenhouse gas emissions caused concern. Construction industry is a big contributor to carbon footprint emissions. In U.S., the construction processes generate the third highest greenhouse gas (GHG) emissions among industrial sectors. Hence, construction organizations need to manage and mitigate their carbon-related risks in the carbon-constrained future. The carbon footprint emissions in the construction stage are mainly from the raw materials supply, transport, and the construction activities. Among various construction processes, tunnel construction results in a significant amount of carbon emissions since almost all tunnels are lined with concrete materials and they utilize various types of high energy-consuming equipment for excavation. In order to identify and mitigate carbon emissions in tunneling projects, it is required to reliably estimate carbon footprints of all materials and construction activities in these projects. Improvements in reducing the carbon emissions in a tunnel project comes in three forms- improvement in equipment, replacement of materials or changes in the design. Improvement in equipment means developing non-fossil fuel powered vehicles for mined tunnels. The substitution of components such as cement replacements, fibers or GFRP rock bolts and new design concepts such as permanent sprayed concrete linings or Composite Shell Linings (CSL). The purpose of this paper is to evaluate carbon footprint emissions of different tunneling construction method and reviewing the state-of-the-art in terms of carbon costing for tunnel projects before going on to illustrate the potential benefits of these innovations as well as highlighting successful projects using them. Total saving in CO₂ emission of a tunnel project is calculated in order to have a better comparison of the impact of each of these improvements.

Keywords: Tunnelling, Carbon footprint, GHG, Greenhouse gases, Life cycle assessment, LCA, Lining, concrete mixture, TBM

1 INTRODUCTION

Carbon footprint analysis is becoming more and more popular in every industry due to increasing concerns about global warming and greenhouse gas (GHG) emissions. The construction industry is a major producer of CO₂ emission. Huang et al (2018) reported that in 2009, the total CO₂ emission of the global construction sector (which includes building and infrastructures) was 5.7 billion tons, contributing 23% of the total CO₂ emissions produced by global economic activities. In the U.S., the construction processes generate the third highest greenhouse gas (GHG) emissions among industrial sectors. It is therefore important that this sector significantly reduces its consumption of energy and materials. One of the most relevant activities within this sector is tunneling construction. The significant impact of the construction industry largely arises from the embodied carbon in the primary

construction materials – cement and steel and utilizing various types of high energy-consuming equipment. Improvements in reducing the carbon emissions in a tunnel project come in three forms: improvement in equipment, replacement of materials, or changes in the design. Improvement in equipment is materialized by developing non-fossil fuel-powered vehicles for mined tunnels. Replacement of material comprises cement replacements and using supplementary cementitious materials, use of fibers instead of rebar, or GFRP rock bolts instead of steel rock bolts, while new design concepts can include changing the design from cast-in-place lining to permanent shotcrete lining, reducing lining thickness or any design strategy to lower material consumption. In addition, to achieve a comprehensive understanding of whole-life carbon of a tunnel project, the induced carbon during Use & Maintenance stage of the tunnel and improvements in reducing the carbon emissions in this stage should be analysed.

*Corresponding author: Verya.Nasri@aecom.com

This paper starts by reviewing the state-of-the-art methods for estimating carbon emission in tunnel projects before going on to illustrate the potential benefits of these innovations highlighting successful projects. Total savings in CO₂ emission of a tunnel project is calculated to compare the impact of different improvement strategies.

2 METHODS OF CARBON EMISSION REDUCTION

2.1 Design optimization

Innovative design and techniques can significantly reduce the carbon footprint of tunnels. However, introducing new and not universally accepted concepts always face client resistance due to the absence of established design codes and production standards, and limited data on their performance.

As previously explained the main source of carbon emission is material (cement and steel). Thus, minimizing the use of materials for temporary support (which accounts for 35 % of the total carbon footprint) in favor of using them for permanent support is the key step of a sustainable design.

In traditional design, the tunnel lining consists of a temporary lining and a cast in-place secondary lining installed later as the permanent lining. Steel mesh is used as reinforcement. This is known as the Double Shell Lining approach (DSL) (Thomas 2019b). Figure 1 shows the detail of traditional lining.

Permanent Sprayed Concrete Linings (PSCL) have increasingly been used in recent years in which

all the concrete sprayed is considered part of the permanent works. The lining consists of several passes of sprayed fiber-reinforced shotcrete, sometimes with a spray applied waterproofing membrane (SAWM) sandwiched in between. ITAtech has produced a report on Sprayed Applied Waterproofing Membranes, explaining the technology, its merits, and its weaknesses, and presenting case studies (ITAtech 2013). Figure 2 shows the detail of the PSCL lining.

2.2 Carbon reduction through materials

Research shows that more than 80 % of the CO₂ emissions in the construction phase of a tunnel are attributable to construction materials (cement and steel). Thus, reducing the need for cement and steel can make a significant contribution to reducing CO₂ emissions. In some cases, this comes along with a reduction in construction costs.

2.2.1 Reduction of portland cement using supplementary

supplementary Cementitious Materials

90 % of CO₂ emission of conventional concrete mixtures comes from the Ordinary Portland Cement (OPC). Therefore, we can control a very large portion of our CO₂ emission issues in concrete by paying attention to the amount of cement, the type of cement, and the amount and the type of Supplementary Cementitious Materials (SCM) which can replace OPC. The CO₂ emission of a material can be calculated using the following formula:

Figure 1. Traditional lining design.

Figure 2. Optimized lining design.

Mass of CO₂eq = CO₂eq Factor × Material quantities (1)

where CO₂eq factor is the amount of equivalent CO₂ per pound or kg of material which is obtained from Environmental Product Declarations (EPDs).

Table 1 shows the CO₂ eq factor for different types of cement and SCMs. As shown in Table 2 using Portland Lime Cement (PLC) instead of Ordinary Portland Cement reduces the CO₂ emission by 7 % while using high SCM mixtures can reduce the CO₂ emission by 45 %. A mixture is considered high SCM when: slag is greater than 50 % of total cementitious materials; or when fly ash is greater than 30 % of total cementitious materials; or when slag is greater than 40 % and fly ash is greater than 20 % of total cementitious materials. High levels of cement replacement by SCMs can result in lowering the early strength of concrete. High early-strength concrete is required for stripping segments from the formwork. For example in precast segmental tunnel linings, 13-15 MPa compressive strength is often required within 5-6 hours of casting for a safe stripping procedure. This is the focal point of today's industry research, and so far, the only solution has been using of Alkali-Activated Binders (AABs) produced with sodium carbonate. The concern with the use of AAB is the risk of the alkali-silica reaction (ASR) and long-term durability issues.

Table 1. CO₂eq factor for different types of cement and SCMs.

Cementitious Materials	CO ₂ eq Factor
Ordinary Portland Cement (OPC)	0.92
Portland Limestone Cement	0.85
Ground Granulated Blast-Furnace Slag	0.15
Fly Ash	0.0093
Silica Fume	0.014

2.2.2 Using steel fiber reinforcement instead of steel rebar

Steel fiber reinforcement can significantly reduce the embodied carbon in tunnel linings, compared to rebar. Rebar mass in unit concrete volume of tunnel segments, for example, ranges between 90 to 160 kg/m³. Using Equation (1) and considering the CO₂eq factor of 1.85 for steel, the carbon emission of rebar is about 166.5 to 296 kg/m³. In comparison, the steel fiber mass in unit concrete volume (fiber content) of tunnel segments is often 40 kg/ m³ or less. Considering the CO₂eq factor of steel fiber is 0.88, carbon emission of fiber reinforcement in concrete segments is calculated as 35.2 kg/m³. This results in a 5 to 8 times reduction in CO₂ emission when rebar is replaced by steel fiber.

2.2.3 Optimizing aggregate gradation

Traditionally, aggregates are designed according to ASTM standards based on coarseness factor charts which can be unreliable at times. Tarantula Curve (Taylor 2015) is a new and effective tool that was developed based on all workability tests including slump, the box test, ICAR Rheometer, visual observation, and float test. This helps optimize the aggregate amount in the concrete mixture and thus reduce the cement paste volume (total cementitious content and water). The carbon emission due to aggregate optimization can be reduced by up to 14 % because of the optimized use of cementitious paste.

2.3 Improvements in equipment

The impact of the operation of construction machinery (carbon emission from fuel and electricity) is relatively small compared to the main sources of carbon emissions of tunnels which are construction materials (concrete and steel). However, for highly mechanized tunnel projects the carbon emission of construction equipment is still significant because of the size of tunneling projects.

Construction sites are ideal for alternative fuels since the vehicles do not have to travel far from the refuelling sources. CO₂ emission reduction by alternative fuel vehicles also causes a reduction in the demand for ventilation. However, it presents different fire hazards compared to fossil fuel vehicles.

Great improvements have been made in this area by equipment manufacturers. For example, Normet unveiled in 2019 a battery-powered spraying robot as part of its SMARTDRIVE electric vehicle range. Nasta in Norway has teamed up with Hitachi, Siemens, and Sintef to look at hydrogen fuel cell-powered excavators. Epiroc and Volvo have launched ranges of electrically powered drill rigs, loaders, and trucks while mining. In Norway, Stattnett is building the first "fossil (fuel) free" tunnel, a 4 km cable tunnel northeast of Oslo (Thomas, 2019a).

Moreover, the optimization of consumption time, controlling the direction and flow of the energy stream and timely shutting down the extra internal combustion engine drives in the system is also important methods to control CO₂ emissions (Song and Xia, 2022).

There are two common sources of emission for equipment; the diesel fuel consumed to move in and out of the tunnel in every cycle and the electricity consumed by the equipment during operation. Explosives which may be used during the drilling and blasting advancing method is another source of CO₂ emission.

To have an idea, the accumulated quantity of CO₂ emission due to the articulated trucks used to remove the rock from a tunnel is presented in Figure 3 (Rodriguez, R. 2020). The tunnel taken as a reference is a double tube tunnel in Northwest of Spain with a slope of about 1% upwards. The depth was 125 m in average.

Figure 3. CO2 produced by muck pile transportation [Rodríguez et al., 2020].

To have an idea, the accumulated quantity of CO2 emission by the mobile electric generators used in the reference tunnel is presented in Figure 4 (Rodríguez, R. 2021).

Figure 4. CO2 produced by electric generators [Rodríguez et al., 2020].

Various types of TBMs have specific power requirements. Table 4 shows the total cutter head power for different TBM diameters. The CO2 per kWh for electric power packs using hydraulic motor depends on the area and it changes between 106 and 750 grams of CO2 per kWh (EIA, 2017).

Table 2. Total Power of TBM for Different Tunnel Diameter [Adapted from Robbins, 2017].

No.	Tunnel Diameter	Cutter Head Power	Total Power
1	11.5 ft	1,340 kW (1,836 hp)	2,010 kW
2	13 ft	2,100 kW (2,816 hp)	3,200 kW
3	14.1 ft	2,345 kW (3,143 hp)	3,517 kW
4	14.1 ft	960 kW (214.5 hp)	1,440 kW
5	15.1 ft	1,260 kW (1,690 hp)	1,890 kW
6	15.8 ft	2,275 kW (3,050 hp)	3,413 kW

As an example, assuming TBM has an average production rate of 100 ft per 20-hour shift to allow 4 hours for maintenance and total CO2 emission for 100 ft advancement of a 13 ft tunnel can be calculated as following:

$$3200 \text{ kW} \times (106 - 750) \text{ grCO}_2/\text{kWh} \times 20 \text{ hr}/100\text{ft} = 6,780 - 48,000 \text{ kg.CO}_2/100\text{ft} = 222 - 1575 \text{ kg CO}_2/\text{m}$$

2.4 Reduction of operational carbon

Tunnels are energy intensive pieces of infrastructure once they are in operation. They require continual maintenance, periodic major refurbishments and upgrades, while lighting, ventilation and a multitude of additional systems use energy 24 hours a day. Operational Carbon is simply the carbon that is used during operation of the tunnel (i.e. when it is built).

It is clear that the energy used in the life of a tunnel is dependent of how well it is designed and built and then how well it is operated. But they are not mutually exclusive activities and to a great extent the ability of an operator to manage his assets energy consumption efficiently is governed by the quality of the product with which he is supplied.

Figure 5 shows the GHG emissions of different stages (processes) in 100 years. The 4-km long Chinese double-track four-lane highway tunnel emits around 375.5 thousand tons of CO2 eq. The tunnel ventilation and lighting at operation stage plays a leading role in the life cycle which shares a proportion of 56.12% of the total emissions. The maintenance stage contributes about 12.99% of the emissions while the construction stage is responsible for 30.89% of the GHG emissions. The three processes with the highest GHG emissions at construction stage are casting & lining (27.25%), rock support (25.33%) and road work (22.03%). Moreover, tunneling and waterproof & drainage process are responsible for 8.54% and 8.47% of the GHG emission at construction stage. A similar case of GHG emission ratio over its whole life cycle is the Swedish Norra Lanken Tunnel, whose GHG emission contributions are 36% (construction stage), 56% (operation stage) and 8% (maintenance stage) (Miliutenko et al., 2012).

Figure 5. GHG emissions in different stages (processes) of the tunnel [Guo et al. 2019].

3 CASE STUDY

Montreal Blue Line Extension (PLB) project consists of five stations and a 9.3 m diameter TBM tunnel.

The tunnel is approximately 6 km long. The tunnel is 15 m deep on average and will be excavated through the rock. The baseline design included temporary shotcrete as initial support and a section with Cast in Place (CIP) concrete using Ordinary Portland Cement (OPC) concrete mixture as the final lining.

Figure 6 shows the geometry of the final lining of the baseline design. Table 3 presents the mixture design for temporary shotcrete, CIP arc, and CIP invert slab.

To reduce carbon emissions, an alternative case was suggested (Jarast et al, 2023). In this case, while a similar internal geometry was assumed, CIP lining was replaced with a thin low-carbon permanent shotcrete lining which acts as both initial support and final lining.

Figure 7 shows the geometry of the section for this case. In this design, 27 % of the cementitious material was replaced by slag and silica fume (22 % slag and 5 % silica fume which is considered a moderate SCM mix). Table 4 presents this shotcrete mixture design. Using Formula 1

presented in section 2.2.1, the embodied carbon footprint for the unit volume of baseline concrete mixture and low-carbon shotcrete mixture can be calculated. Table 5 and Table 6 summarizes the detail of CO₂ emission calculation for the baseline design and low carbon shotcrete design, respectively. The quantities of materials are picked from Table 3 and Table 4.

Based on the geometry of the tunnel presented in Figure 6 and Figure 7, the volume of shotcrete, and the invert slab per 1m of the tunnel can be calculated. Having these quantities together with the information presented in Table 5 and Table 6, the total CO₂ emission per 1 m length of the tunnel can be estimated. Table 7 and Table 8 summarizes this calculation.

4 CONCLUSION

This paper presents the state-of-the-art methods in terms of carbon costing for tunnel projects and

Figure 6. Tunnel geometry-low carbon design.

illustrates the potential benefits of these innovations as well as highlighting successful projects using them.

Considering the scale of tunnel projects, this reduction in CO₂ emission is significant and should

not be ignored or underestimated. The steps toward improving sustainability include using electrically powered vehicles in the tunnel, using cement replacements in concrete to the maximum extent possible, using fiber reinforcement instead of steel

CRCC Rus, Moscow, Russia

ABSTRACT: Over the last 12 years the length of the Moscow Metro has grown 1.5 times. More than 200 km of new lines, 109 stations and 11 electric depots have been built. In March 2023, the Big Circle Line – the most ambitious project of the Russian Metro and the largest metro ring line in the world – was put into operation. Mosinzhproekt Joint Stock Company is the general designer and general contractor of the construction. Within the framework of the Agreement between the Government of the Russian Federation and the Government of the People's Republic of China on Encouragement and Mutual Protection of Capital Investments, the limited liability company 'CRCC Rus', a subsidiary of the Chinese railway construction corporation CRCC in the Russian Federation, is taking part in the construction of the Moscow Metro. For the construction of Moscow Metro facilities, the said Chinese company manufactured six tunnel boring mechanised complexes, five of them with a diameter of 6.25 m and one with a diameter of 10.8 m. These shields ensured sediment-free tunnelling in the difficult mining, geological and hydrogeological conditions of Moscow's dense urban development, including the use of unique measures to ensure safe completion of tunnelling operations: 11 tunnels of the South-Western and Eastern sections of the Big Circle Line under the operating stations Michurinsky Prospekt and Prospekt Vernadskogo, under the motorways Michurinsky Prospekt, Leninsky Prospekt, Prospekt Vernadskogo, under the railway tracks of the Kyiv direction, the Nagatinsky flood of the Moscow River, the Museum-Reserve 'Kolomenskoye'; 6 tunnels of the Kommunarskaya line, including one under main underground communications and city motorways - Moscow Ring Road and Kaluga Highway. The Chinese company built 5 metro stations in excavations up to 30 m deep in dense urban development. The report presents in detail the experience of joint work of Mosinzhproekt JSC and 'CRCC Rus' LLC on construction of underground transport infrastructure facilities in the city of Moscow.

Keywords: Tunnelling, TBM, Big Circle Line, Chinese metro builders, Metro construction, Moscow Metro, Russian metro builders

1 INTRODUCTION

The programme for the development of urban transport adopted by the Moscow government envisages intensive expansion of its underground component – the metro, the first line of which was put into operation on 15 May 1935 (Zertsalov, Konyukhov, Merkin, 2015; Neutatz, 2013; Naumov, Kusyy, 2006). Currently, the Moscow Metro consists of 14 lines with a total length of more than 460 km (in double-track) with 263 stations. It is among the world's leading metros in terms of construction rates and a number of operational indicators, for example, in terms of train frequency – during peak hours it is no more than 90 seconds, and on the Big Circle Line

(the largest metro ring line in the world), which was commissioned in 2023, it is 80 seconds. Over the last 12 years, the Moscow Metro has been expanding at an unprecedented pace, with maximum involvement of scientific, technical, material and labour resources, with intensive application of the achievements of world metro construction. As a result, the length of the Moscow Metro has grown 1.5 times. More than 200 kilometres of new lines, 109 stations and 11 electric depots were built. The works are carried out in the shortest possible time and with high quality. A large-scale system of research and design, construction and installation and auxiliary organisations is involved. By 2027, according to the Moscow Government's plans

*Corresponding author: konyukhovds@mosinzhproekt.ru

(Postanovlenie ..., 2012), 25 more stations and 58 km of lines are to be built (Figure 1).

Figure 1. Moscow metro with development perspective up to 2027 (<https://2023god.com/karta-metro-moskvy-v-2023-godu-novye-stancii/>).

It is planned to extend the Sokolnicheskaya line southwards by 2.4 km and build another station – Potapovo. The extension of the Lublinsko-Dmitrovskaya line to Fiztech station and the Solntsevskaya line westwards to Vnukovo airport, near which the metro station of the same name will be located, has been completed. In 2024 it is expected to open a new line – Troitskaya. After 2023, the Arbatsko-Pokrovskaya line will be extended northwards to Golianovo station, and the Rublyovo-Arkhangelskaya and Birylevskaya lines will be opened in stages.

2 METRO CONSTRUCTION IN THE PRC AND CRCC COMPANY

For a long time, the cooperation between Moscow metro builders and foreign ones was limited to exchange of experience, scientific and technical achievements, purchase of imported tunnel boring equipment, etc. In recent years, the scale and pace of metro construction in the capital have led to the involvement of foreign contracting organisations directly in construction works. Chinese metro builders were the first in this case, which is quite natural, given the achievements in this field, as well as the long-standing professional ties between Russian and Chinese metro builders, who have been cooperating since the very beginning of metro construction in China.

The pace at which subways are being built in the People's Republic of China shocks the world. The first underground in Beijing began construction three decades later than in Moscow, in 1965. Xue Liqiang, a representative of the CRCC, admits that it was the

Moscow Metro that became a benchmark for them, and that their teachers were specialists from Russia. But here is the case when the student surpassed the teacher. If in 2006 the Chinese capital had 114 km of metro, in 2012 it had 442 km, and in 2015 – 708 km. By 2020, the goal was set to bring the length of the underground in Beijing to 1050 km. And this is only in one city! The length of the metro network in China exceeds 8.7 thousand kilometres. The Underground operates in 43 cities. The annual growth is substantial. An important role in its implementation is played by the Chinese railway construction corporation China Railway Construction Corporation Limited – CRCC (<https://english.crcc.cn/>). This mega-scale construction company, established in November 2007 in Beijing, is one of the most powerful and largest general construction groups in the world, operating not only within the PRC, but also in more than 130 countries and regions around the world, engaging in contracting, planning and design consultancy, etc., as well as in the construction industry. CRCC has a complete production chain including research, planning, survey, investigation, design, construction, supervision, operation, maintenance, investment and financing; playing a leading role in the design and construction of tunnels and urban railway transport in particular. It employs 267,000 professionals, operates four in-house design institutes, and has accumulated vast experience at home and abroad, recognised by many international professional awards and distinctions. CRCC has extensive experience with information modelling technologies. The company has developed high-quality and up-to-date software for these purposes.

3 MOSCOW METRO FACILITIES BUILT BY 'CRCC RUS'

Within the framework of the Agreement between the Government of the Russian Federation and the Government of the People's Republic of China on the Encouragement and Mutual Protection of Capital Investments, CRCC's subsidiary in the Russian Federation, CRCC Rus LLC (<https://moscow.cataloxy.ru/firms/www.crcc.cn.htm>), participates in the construction of the Moscow Metro. To date, 11 tunnels of the South-Western and Eastern sections of the Great Ring Line have been built in Moscow under the existing stations Michurinsky Prospekt and Prospekt Vernadskogo, under the motorways Michurinsky Prospekt, Leninsky Prospekt, Prospekt Vernadskogo, under the railway tracks of the Kyiv direction, Nagatinsky flood of the Moscow River, the Museum-Reserve 'Kolomenskoye'; 6 tunnels of the Kommunar'skaya line, including one under main underground communications and city motorways – Moscow Ring Road and Kaluga Highway. The Chinese company built 5 metro stations in excavations up to 30 m deep in dense urban areas.

The participation of ‘RCC Rus’ in the construction of the largest project of Moscow metro builders – the Big Circle Line – occupies a special place. The tender was open, everyone could take part in it. The Chinese firm won. In January 2017, a contract was signed between Mosinzhproekt JSC and the Chinese company ‘CRCC Rus’, under which foreign specialists (mainly employees of the 16th CRCC department) built three stations of the Third Metro Interchange Loop – the Big Circle Line (BCL, 69 km, 31 stations and two electric depots) in Moscow. Chinese specialists were involved in the construction of the stations: Aminievskaya (including the crossing tunnels with tunnelling structures and dead ends behind the station), Michurinsky Prospekt and Prospekt Vernadskogo: a double-track tunnel from Nagatinsky Zaton station to Klenovy Boulevard and further – to the transition chamber, single-track tunnels towards Kashirskaya station. At the same time, ‘CRCC Rus’ is engaged only for the main construction (tunnelling works), while finishing and installation of equipment, engineering fills (installation and testing of traffic control systems and other precision transport systems) are the responsibility of Russian specialists.

The section from Prospekt Vernadskogo station to Aminievskaya station (including Michurinsky Prospekt station) of the Great Ring Line (Figure 2) is 4.63 km long.

Engineering and geological conditions of the construction site belong to the III (complex) category of complexity – geological processes are widespread and have a decisive impact on the choice of design solutions, construction and operation of facilities.

In geomorphological respect the site belongs mainly to Teplostanskaya upland, dissected by deep erosion valleys, gullies, ravines. The above-mentioned remnant-erosional upland has a pronounced stepped character, the lower stages are covered with fluvio-glacial and lake-glacial sediments and, connecting with alluvial terraces, represent a plain, within which the north-western part of the route section is located; the south-eastern part of the route section is located on moraine hills within the middle stage of the upland. The natural gentle undulating accumulative relief of the fluvio-glacial plain, in some places moraine, is technogenically modified, relatively planned by the existing

Figure 2. Route of the section between Prospekt Vernadskogo and Aminievskaya stations.

development. The technogenic impact on the geological environment is manifested in the corresponding technogenic lithogenesis. As a result of landfilling of the territory, a layer of technogenic bulk soils was formed.

Quaternary soils are underlain by a sandy-clay layer of Mesozoic sediments. These sediments in the lower part of the section are represented by clayey rocks of the Middle and Upper Jurassic overlying Upper Carboniferous carbonate rocks. The upper part of the Jurassic sediments section is composed of clayey sands, in some places changing into strongly sandy clays. The Upper Jurassic sands are overlain everywhere by Cretaceous sediments, represented by sands easily liquefied under very low destructive stresses, often floating. Below are Upper Carboniferous sediments represented by clays and limestones.

Hydrogeological conditions are characterised by the spread of the Meso-Cenozoic sediments water-bearing complex represented by several horizons. Practically everywhere two, and in some areas – three aquifers are traced, confined to relatively well permeable sands in alluvial sediments and sandy interlayers in the Don-Moscow water-glacial sediments, forming a single first above-marine aquifer complex from the surface. Clayey moraine sediments serve as a relative aquifer.

The depth of groundwater occurrence of the first surface water-bearing complex in this area is 5-10 m, increasing up to 15 m in some places on the watershed slopes. At lower watersheds groundwater is revealed at a depth of 3-10 m from the surface, in local areas – even at a depth of up to 3 m. The amplitude of changes in groundwater levels is 2-4 m, and in some areas – more than 5 m, and is clearly man-made. Spreading of weakly permeable moraine and cover tuffs from the surface is very favourable for formation of water table, usually at the depth of 2-3 m.

The second supra-Jurassic aquifer complex is formed by aquifers confined to marine sands of Cretaceous and Jurassic age.

The aquifer complexes are hydraulically connected along the river valleys. Their static levels coincide near the valleys and differ at the watersheds, with the levels of the supra-Jurassic aquifer complex being 3-7 m lower. The depth of the level of the supra-Jurassic aquifer complex varies from 12 to 33.5 m. The sustained regional water table, represented by a thick mass of Jurassic clays, lies at a depth of 100 to 115 m, depending on the relief. Below it lies the Balkovsko-Podolskoye water-bearing complex. The water-bearing rocks are organogenic limestones with subordinate interlayers of clays, marls and dolomites. Absolute elevations of the roof of the Balkovsko-Podolsky aquifer are 90-80 m. The lower water table of the Balkovsko-Podolsky horizon is represented by Rostislavl clays and marls.

Thus, the geotechnical conditions are in general quite complicated, especially in connection with the adopted design and technological solutions.

All three mentioned stations are shallow-buried and were built in the excavation for two-track tunnels.

The Aminievskaya shallow-buried station is located as part of the south-western section of the BCL in the Ochakovo-Matveevskoye district of Moscow, at the intersection with the Kyiv direction of the Moscow railway. Depth of embedment is 15 m. The structural scheme is three-span, with two rows of columns and an island platform 163 m long and 12 m wide. The axis of the station is orientated parallel to the nearby Aminievskoe Highway. The station should provide pedestrian connections with the railway platform and through the underground passage – with the opposite side of Aminievskoe Highway (Figure 3).

Two underground concourses access both sides of Aminievskoye Shosse to bus stops, residential neighbourhoods and public buildings.

The length of the crossing between Aminievskaya and Michurinsky Prospekt stations is about 1,473 m. The tunnel route passes under the Kyiv direction of the Moscow railway, the Ochakovka River and Michurinsky Prospekt station of the Kalininsko-Solntsevskaya line of the Moscow Metro. Depth of embedment – 19.5-34.3 m.

The Prospekt Vernadskogo station (Figure 4) has a depth of 17.3 m. Engineering and geological conditions of the projected construction site belong to the III category of complexity. The structural scheme is three-span, with two rows of columns on a 12 m wide island platform. The station has four underground levels. In the central part of the platform there are stairs for transfer.

Michurinsky Prospekt station has a unique layout due to the complex topography of the site and the elevated transfer to the newly built Michurinsky Prospekt station of the Kalininsko-Solntsevskaya line. It is one of the deepest for shallow stations (depth of 19.4 m, 7 underground levels). The structural scheme is three-bay with two rows of columns on a 14 m wide island platform. The architectural solution realised in it is dedicated to the Russian-Chinese friendship.

Lifts were installed at all three stations – without them nowadays station complexes in Moscow are simply not built.

In addition to the described sections of the Moscow Metro, ‘CRCC Rus’ successfully completed the excavation of 9 tunnels with a diameter of 6.25 m of the South-West section of the Great Ring Line, including the application of unique measures to ensure safe completion of tunnelling works in the area of existing structures.

Work was carried out along the Kaluga Highway in Greater Moscow (Kommunarka district) Ulitsa Novatorov metro station – Stolbovo metro station on the section from Ulitsa Novatorov station to Kommunarka station (Figure 5), including in the area of existing city infrastructure facilities.

a

b

Figure 3. Aminievskaya station of the BCL: a – location; b – interior of the station platform.

Figure 4. Prospekt Vernadskogo station of the BCL.

Complex works – bottomless tunnelling in difficult hydrogeological conditions under dense urban development (Mazein et al., 2019), under the Nagatinsky Zaton of the Moscow River, under the territory of the Kolomenskoye Reserve Museum – were carried out on the Eastern section of the BCL: metro sections between the stations Kashirskaya and Nizhegorodskaya, on the section from the Nagatinsky Zaton station to the Klenovy Boulevard station and further to site No. 2 (Figure 6). For the period of

tunnelling, geotechnical monitoring (Merkin et al., 2021) and scientific and technical support of construction (Konyukhov, 2022; Kulikova, Potapova, 2022) were organised.

Figure 6. Eastern section of the BCL.

4 CHINESE BUILDING INDUSTRY BASE AND TUNNELLING EQUIPMENT AT MOSCOW METRO FACILITIES

In the Russian Federation, ‘CRCC Rus’ has set up in-house production of high-precision tunnel lining. For this purpose, 12 sets of tooling moulds for 6.0/5.4 m diameter lining and 4 sets of tooling moulds for 10.5/9.6 m diameter lining are used. More than 14,000 tunnel lining rings with a diameter of 6.0/5.4 m and 1,500 tunnel lining rings with a diameter of 10.5/9.6 m have been manufactured and installed (Figure 7).

For the construction of metro facilities in Moscow, the company ‘CRCC Rus’ manufactured in the PRC in accordance with the customer’s specifications and delivered to Russia six TBMs: 6.25 m diameter – 5 units, 10.8 m diameter – 1 unit (Figure 8). The technical characteristics of the specified TBMs are as follows (data for 10.8 m diameter TBMs given in brackets): rotor diameter, m – 6.28 (10.8); diameter of TBM shell, m – 6.25 (10.84); length of TBM head part, m – 9.5 (11.4); total length of TBM, m – 87 (68); total weight, tonnes – 460 (1700); power, kW – 1750 (6000).

For transportation from China to Russia, the panel complexes were disaggregated into 14 and 40 elements for 6.25 m and 10.8 m diameter and 2 to 130 t and 5 to 180 t respectively.

Figure 7. Chinese-made high-precision tunnel lining blocks.

Figure 8. General view of the head part of the pobeda TBM.

In addition, CRCC delivered five ZOOMLION T8030-25U (<https://cranemarket.com/specs/tower-cranes/zoomlion/t8030-25u>) full-swing tower cranes with increased lifting capacity: maximum lifting capacity up to 25 t, maximum boom length 50 m, maximum crane height 45 m, as well as two grapple units for the construction of wall-in-ground enclosures.

Two TMPCs (ZTE6250 DZ399, name Eugenia; ZTE6250 DZ401, name Polina) are used for tunnelling the CRCC tunnels. A 10-metre long 10-metre long TBM (the name Pobeda as a symbol of the long-standing friendship between the two countries, based on mutual support and trust, as a reflection of our countries’ contribution to the victory in World War II) was used to bore a 3-km tunnel on the BCL section between Nagatinsky Zaton and Klenovy Boulevard stations. Its design was carried out by Chinese colleagues according to the technical specifications developed by Mosinzhproekt specialists in accordance with the hydrogeological conditions at the construction site and taking into account the accumulated experience of

using 10-metre shields in Moscow. This is the third 10-metre TBM used in Moscow for the construction of double-track transport tunnels. This method of tunnelling makes it possible to avoid construction of tunnelling structures and ventilation shafts, respectively, without freeing up additional construction sites, which is very important, given that the line section passes near the Kolomenskoye Museum-Reserve.

The tunnels between Aminievskaya and Michurinsky Prospekt stations were tunnelled with the help of 6-metre TBMs Evgeniya and “Daria”, from Aminievskaya station to site No. 6 located in front of Davydково station was tunnelled with the similar TBM Maria. The same Galina (ZTE6250DZ400) and Polina (Figure 9) traversed the tunnels between Prospekt Vernadskogo and Ulitsa Novatorov stations.

Figure 9. TBM Polina.

All of the above shields ensured non-sudden tunnelling in difficult mining, geological and hydrogeological conditions of dense urban development of Moscow, including the use of unique measures to ensure safe completion of tunnelling works.

In general, since 2017 ‘CRCC Rus’ has carried out the following scope of works: tunnelling of tunnels with the use of 6.25 m diameter TBMs – 15 tunnels with a total length of 19800 m, the same with 10.8 m diameter – 2 tunnels (200 m), construction of the main structures of station complexes at 5 stations (225000 m³). In addition, ‘CRCC Rus’ carried out design works for the South-West section of Prospekt Vernadskogo station – Kuntsevskaya station of BCL.

5 SCIENTIFIC AND TECHNICAL COOPERATION BETWEEN RUSSIAN AND CHINESE METRO BUILDERS

Interaction between Chinese and Russian metro construction specialists was not limited only to solving production tasks. The exchange of scientific and technical experience is of great value. From 15 to 18 November 2019, the 1st International Conference on Underground Space Research and Utilisation (EUUS2019, <https://www.earthsciencematters.com/first-international-conference-on-the-exploitation-and-utilization-of-underground-space-euus2019-in-wuhan>

china/) was held in Wuhan (PRC). This conference was organised by the Institute of Rock and Soil Mechanics, Chinese Academy of Sciences (IRSM-CAS) and the State Laboratory of Geomechanics and Geotechnical Engineering (SKLGME), with the participation of 30 research institutes and enterprises. The delegation of Mosinzhproekt JSC took part in the conference (Figure 10) with a report devoted to the analysis of the parameters determining the value of the soil overshoot coefficient during mechanised tunnelling (Konyukhov, Polyankin, 2019). Based on the analysis of engineering-geological and technological factors, the specialists of Mosinzhproekt JSC developed recommendations for determining the over-excavation factor depending on the type of soil and diameter of the TBM (Konyukhov, 2022; Kulikova et al., 2022).

Figure 10. The delegation of Mosinzhproekt JSC.

6 CONCLUSION

The experience of joint Russian and Chinese metro builders in laying new lines and constructing underground metro stations of the Moscow Metro has demonstrated the productivity and efficiency of such cooperation. A rational distribution of design and construction works has been worked out, taking into account the capabilities and experience of the parties. This opens up great prospects for further industrial cooperation. In particular, there are prospects for joint metro construction works in Africa, Asia and the Middle East.

A high social and economic effect has also been achieved directly in Moscow. For example, thanks to the launch of the new BCL Aminievskaya, Michurinskiy Prospekt and Prospekt Vernadskogo stations, local residents will be able to save up to 40 % of their daily travelling time in the city, the existing metro stations will be significantly relieved: Prospekt Vernadskogo station of the Sokolnicheskaya line – by 25 %, and Michurinskiy Prospekt station of the Kalininsko-Solntsevskaya line – by 35%.

The joint labour of Russian and Chinese metro builders has a great future.

ABSTRACT: The undisturbed soil of the metro shield tunnel is cut and mixed by the shield machine, and foam agent and water are added to produce a large amount of shield muck with high moisture content and poor properties. The direct transportation and disposal of shield tunneling slag not only occupies land resources, but also has potential environmental pollution and landslide risks. The rock layer where the shield tunneling slag is located itself is a natural resource containing crushed stone, fine sand, and clay, and it is a waste of resources to transport and dispose of. In order to solve this problem, a technology that uses a complete set of processing equipment to screen, precipitate, and filter shield tunneling soil has been proposed. This technology can reduce the amount, resource, and harmless use of shield tunneling soil on site, protect the ecological environment, reduce transportation noise and dust disturbance, and save engineering construction costs. The technology was applied in the fourth phase project of Shenzhen Metro, which reduced the transport volume of shield spoil by 50%, produced 4.6 million cubic meters of aggregate, saved 170 million euros, reduced carbon emissions by 54,520 tons, and reduced land occupation by 1.93 km². This technology can provide a reference for the green, low-carbon, and low-cost treatment of various tunnel projects' waste soil.

Keywords: shield tunneling slag, resource reuse, emission reduction

1 INTRODUCTION

Along with the continuous progress of urbanization, it has become a general trend to solve the problem of urban traffic congestion through the development of rail transit. According to the China Urban Rail Transit Association, the mileage of rail transit in operation in China has exceeded 10,000 km, and the kilometers of lines under construction have exceeded 6,000 km, of which the proportion of underground lines is over 70%. While the development of urban rail transit brings great convenience to the public, its construction and excavation process also affects the environment in a non-negligible way. Most of the city subway tunnels are constructed by shield method, and the slag production is also growing with the increasing mileage of subway construction, for example, the Shenzhen Metro produces about 4 million cubic meters of slag on average

per year. In the past, the slag disposal method is mainly landfill elimination, taking up a lot of land resources, and transportation costs are high, also brings dust, groundwater pollution and other environmental problems. To carry out the slag resourcefulness, minimization, harmless treatment, take the slag as a kind of "urban mineral resources", can greatly reduce the exploitation of natural resources, protect the urban ecological environment, provide significant social, environmental and economic benefits.

In the aspect of slag resource utilization research, Hangzhou Wall Material Innovation Office used construction slag as raw materials to explore the industrialization of new recycled slag wall materials approach. A feasibility study on the use of slag for the preparation of cement mixes was carried out by Hao et al. at Zhengzhou University, China. At the same time, Zhang et al. investigated the feasibility of low-temperature

*Corresponding author: panhaijun@shenzhenmc.com

burnt clay as a cement mix, and found that the clay used has high activity under the condition of 550-600℃ burnt. Clay wrought at this temperature range has higher cementitious strength values when used as a mixing material in cement. Yu and others from Guangxi Brick Industry Co., Ltd. have produced a series of lightweight unburned hollow bricks that satisfy national standards using soil curing technology. Prof. Wu of Wuhan University of Technology studied the preparation and pollutant filtration performance of multi-functional ceramic grains with shield tunneling slag base. The prepared slag ceramic grains were light brown in color, with smooth surface and intact enamel layer, and the interior was loose and porous, honeycomb-like, with a small number of connecting holes. Li et al. used shield tunneling slag as the main raw material, supplemented with magnesium oxide, to produce a moderate strength and excellent performance ceramic granule for phosphorus removal from water at a relatively low temperature. However, little research has been done on large-scale resourcefulness, minimization, and harmless treatment of shield tunneling slag in situ at worksites.

This paper provides a reference for the efficient disposal of slag in other underground tunnel projects by introducing the application of in-situ large-scale resourcefulness, minimization and harmless treatment technology of shield tunneling slag in Shenzhen Metro.

2 SHIELD TUNNELING SLAG TREATMENT PROCESS METHOD SELECTION

Shenzhen Metro mainly compares the following shield tunneling slag treatment methods.

2.1 Plain sedimentation method

The method is the most primitive one, mainly through bedding, or building slag pool sediment filter, etc., to make the slag water content reduced to meet the requirements before transportation, as shown in Figure 1. The method occupies a large area, is greatly affected by weather and other influences, and all the

Figure 1. Plain sedimentation method site photos.

slag still needs to be transported and then landfilled, so it is inefficient and cannot meet the needs of subway shield construction.

2.2 On-site mechanical and drying

This method is mainly composed of multi-stage screening (slurry separation), flocculent settling, filter pressing and other processes, the input equipment mainly includes screening machines, belt (plate) filter presses and other equipment, as shown in Figure 2. This method occupies a relatively small site, the water content of the mud cake after filter-pressing is low, clear water discharge can be realized, and materials such as sand and stone screened out can be reused without being affected by the weather, etc., and the actual slag that needs to be transported out is greatly reduced. The dual filter press configuration allows for a throughput of 400-500 cubic meters per day.

Figure 2. Mechanical dewatering and drying equipment constructed on site by Shenzhen Metro.

2.3 Consolidation method

The method is to add environmentally friendly stabilizing curing agent in the slag, through mechanical mixing to make the curing agent and slag fully mixed, so that it is transformed into immobile state, or to form a tight joint. This technology enables the slag to be disposed of in a shorter period of time. This method takes up a small area and has a high treatment efficiency, but causes an increase in the size of the outgoing slag and an additional road occupation due to the landfill. More than 1,000 cubic meters per day of handling capacity can be achieved. Figure 3 shows solidification equipment on site.

3 SHIELD TUNNELING SLAG RESOURCEFULNESS, MINIMIZATION, HARMLESS TREATMENT IN SHENZHEN METRO APPLICATION

The main components of shield tunneling slag are crushed stones, fine sands, clay, etc., which have great potential for resource utilization in engineering

Figure 3. Solidification equipment used on site by Shenzhen Metro.

construction. Taking Shenzhen Metro Line 14 as an example, there are about 4.95 million cubic meters of shield tunneling slag, and the sandstone content in the garbage reaches more than 40%, indicating huge potential for resource utilization and reduction. In Shenzhen, the main method used for resource utilization, reduction, and harmlessness treatment of shield tunneling slag is on-site mechanical dewatering and drying.

3.1 The main techniques and processes

The efficient resource utilization and reduction treatment technology for shield tunneling slag involves equipment consisting of a feeding system, a screening system, a sand washing and whirling system, and a filtering system. The shield tunneling slag undergoes processes such as screening, whirling, flocculation, filtering, and tail water treatment to reduce the moisture content and improve the content of sand and mud cake (as shown in Figure 4). The equipment uses a raw shield tunneling slag as input, which is conveyed by the feeding conveying module to the feeding screening module for the first step of processing. The feeding screening module contains functions such as uniform feeding, vibrating particle size classification, and multi-stage high-pressure spray cleaning, producing clean coarse sand aggregate that can be used for on-site construction or sold; the screened off sand-water mixture is processed by the sand washing and whirling module to produce clean medium and fine sand that can be used for Shielding Grouting or sold for other on-site uses; the muddy water obtained after whirling enters the flocculation module for treatment, and the clarified water is used in the clear water pool; the precipitated muddy water enters the filtering module and is dehydrated to obtain a dry mud with low moisture content (less than 30%) that can be directly transported for use or as a raw material for resource utilization products

such as self-burning bricks. The clarified water from the flocculation module and the accelerated flocculation module is recycled within the system. If the shield tunneling slag contains too much moisture, the system needs to discharge water. The advanced catalytic oxidation water treatment module is used to treat the water to achieve discharge after reaching the standard.

Figure 4. Schematic diagram of slag treatment process.

3.2 Key techniques

3.2.1 Efficient dilution defoaming technology

According to the different fluidity (density) of shield tunneling slag, vertical slag lifting equipment is used to send the shield mud to the mixing and stirring device, and at the same time, defoamer (dosing between 0.05-0.1%) is added and stirred through the defoamer dosing device, so as to defoam and deodorize the residual foaming agent of the shield tunneling slag, and also to effectively promote the separation of mud and sand. Figure 5 and Figure 6 present the slag water before and after treatment, respectively.

Figure 5. The slag water before treatment.

Figure 6. The slag water after treatment.

3.2.2 High-efficiency sand and mud separation technology

The screening system receives wet slag from the shield tunneling slag pit, and through gravity separation, screens and recovers medium-fine sand ranging from 0.2 mm to 6mm for reuse. The fine sand and mud smaller than 0.2 mm will enter the mud pit and be pumped by a plunger pump to an automatic high-pressure circular box filter press for dewatering treatment, resulting in mud cakes with a moisture content of 20% to 35% and clear water. The separated clear water will enter the clear water pool and be pumped back to the screening system by a pressure pump for recycling. The sand produced from the separation of mud and sand meets the requirements for resource utilization. Figure 7 illustrates the separation equipment of sand and mud.

Figure 7. The separation equipment of sand and mud.

3.2.3 High-efficiency mud concentration technology

The overflowed slag after gravity sorting by cyclone is pumped to the concentration tank, and through the center feed pipe and splitter inside the concentration tank, the slag is concentrated and drained with high

efficiency, so that when the slag is concentrated to more than 25% concentration, it is discharged to the transfer pool, and the clean water obtained from concentration is sent to the clean water tank to wait for reuse (as shown in Figure 8).

Figure 8. Concentrated slag.

3.2.4 High-efficiency filter press dewatering technology

First, the slag is quickly concentrated by a high-flow slag pump, and then filled into the chamber of the filter press, which can shorten the filtration time. Then, the high-pressure plunger pump is started to mechanically dewater the slag under high pressure, resulting in a moisture content of about 30-35% in the dry mud after filtration. The entire filtration and dewatering process takes about 20-30 minutes. After completion, the system will automatically unload the filter plates, and the dry mud will automatically fall onto the conveyor belt for transportation to other processes. Figure 9 presents the effect of filter press dewatering.

Figure 9. Filter press dewatering.

3.2.5 The slag water harmless treatment technology

The clear water obtained through the flocculation module and accelerated flocculation module can be recycled within the system. If there is too much moisture in the shield tunneling slag, the system

needs to discharge water. When the indicators such as surfactants in the shield tunneling slag water exceed the standard, the slag water treatment module needs to be activated to use advanced catalytic oxidation water treatment technology to treat the shield tunneling slag water to meet the standard before clear water discharge.

3.2.6 Equipment intelligent, integrated, modular design technology

To solve the problems of equipment ground adaptability and system intelligence, integration, and modularization, and further improve the efficiency and ability of shield tunneling slag processing, firstly, the type and quantity of equipment configuration are determined based on detailed geological investigation of each area and the prediction results of shield tunneling slag properties and proportion of rock and mud. When configuring, equipment with adjustable parameters are selected as much as possible, and parallel settings are used to improve the system's self-adjusting ability. Then, through intelligent equipment development, modular design of subsystems (as shown in Figure 10), and integrated assembly simulation based on BIM (as shown in Figure 11), the configuration and installation plan of the shield tunneling slag processing system are determined in combination with the site and geological conditions. After on-site assembly and commissioning are completed, the intelligent central management platform developed during the equipment operation process can achieve intelligent central control of the system. Not only can it monitor the running status of each module, but it can also issue commands to each module to adapt to different operating conditions in a timely manner. It can achieve one-person operation of all equipment in the control room, and the system can operate automatically with chain start-stop, status monitoring, and automatic alarm functions. Each module and the central control platform can interactively exchange information, adjust operating parameters based on module feedback information, and greatly improve equipment adaptability. The efficient resource utilization technology for shield tunneling slag truly achieves intelligence, integration, and modularization of shield tunneling slag resource utilization.

Figure 10. Main module construction.

Figure 11. BIM modeling of shield tunneling slag treatment equipment.

3.3 Main technical parameters

3.3.1 System parameters

- (1) System floor area: about 800 m² (pure equipment takes up about 470 m²).
- (2) System processing capacity: 1400 m³/d.
- (3) Installed power: about 800 kw.

The system processing capacity can be matched according to the construction capacity of the shield machine.

3.3.2 Product particle size range

- (1) Coarse sand particle size range: $\geq 3\text{mm}$.
- (2) Fine sand particle size range: 74 μm ~3mm.
- (3) Filter cake particle size range: $\leq 74\mu\text{m}$.

The particle size range can be adjusted as needed.

3.3.3 Product separation effect

- (1) The moisture content of coarse sand and fine sand is less than 30%, and they do not drip during transportation.
- (2) The separated filter cake has a moisture content of less than 30%, and it does not drip during transportation.
- (3) The coarse sand aggregate and medium-fine sand are clean; the fine sand contains less than 5% clay.

The moisture content and clay content can be adjusted as needed.

3.4 Application in shenzhen metro

Based on the resource utilization, reduction, and harmless treatment technology of mechanical dewatering and drying method, Shenzhen Metro has promoted and constructed 84 sets of shield tunneling slag treatment facilities in the Line 12, Line 13, Line 14, and Line 16, as well as the branch line of Line 6,

treating over 10 million cubic meters of shield tunneling slag. It has achieved significant economic, social, and environmental benefits.

- (1) In terms of economic benefits, it realizes resource reuse and reduces construction costs. Taking the Phase IV project of Shenzhen Metro as an example, the resource utilization disposal produces approximately 2.3 million cubic meters of resource products, with a potential resource value of about 140 million yuan, and reduces over 3 million cubic meters of slag that needs to be transported and disposed of externally. By reducing the volume of slag transportation through reduction disposal, the cost of external transportation during construction is reduced. Taking Line 14 of Shenzhen Metro as an example, the reduction rate after treatment is approximately 40%. Compared to traditional direct disposal, the use of shield tunnel wet soil along the entire line can reduce transportation costs by 127.68 million yuan.
- (2) In terms of social benefits, by recycling and reducing the actual amount of slag transportation through resource utilization and reduction disposal, it reduces the occupation and impact on road resources and land resources during construction, realizes resource recycling, and enhances public happiness.
- (3) In terms of environmental benefits, this technology can reduce emissions from slag transportation, landfill occupation, land and water pollution, promote ecological civilization construction, and explore the path to carbon peaking in the industry. Taking the Phase IV project of Shenzhen Metro as an example, the actual reduction in landfill area for slag is approximately

1,150 acres (calculated based on a 3-meter landfill). Calculated based on an average round trip of 25 km and 2 trips per day, it is equivalent to reducing carbon emissions by over 180,000 tons, which is equivalent to the carbon sequestration of 90,000 poplar trees in Xinjiang in one year.

- (4) In terms of resource recycling, the obtained crushed stone and fine sand aggregate are directly used in concrete, grouting, and other projects, and the obtained filter cake is used to produce non-burning building materials, such as non-fired bricks, wall panels, and ceramisite. The obtained clean water is recycled in the screening, sand washing, and construction processes.

4 CONCLUSIONS

The technology based on mechanical dewatering and drying method for the resource utilization, reduction, and harmless treatment of shield tunneling slag has changed the traditional method of directly transporting and dumping slag, which that once could only be discarded can now be utilised as a resource. If further research and development is conducted on large-scale resource utilization technologies for the filtered mud cakes, such as manufacturing bricks, ceramic particles, and board materials, zero discharge of shield tunneling slag can be achieved. This technology has strong innovative demonstration effect and reproducibility, and has been widely applied in water tunnel and other shield tunneling projects. It can also be applied in other shield tunneling projects to improve resource utilization, environmental friendliness, and low-carbon levels in related fields.

Development and prospects of railway tunnels in China

ABSTRACT: Briefly introducing the achievements in the development of railway tunnel construction in China. By 2022, the operating mileage of railways in China has reached 155,000km, including 17,873 railway tunnels that have been put into operation, with a total length of 21,978km; There are 3,025 railway tunnels under construction, with a total length of 7,704km. Through large-scale railway tunnel engineering practice, China has achieved a series of achievements in tunnel design theory and methods, tunnel standard system, unfavorable geological tunnel construction technology, risk management system, and disaster prevention and rescue technology. Especially in recent years, China's railway large-section tunnel mechanization construction technology has made great progress. A large number of tunnel projects have been built in complex environment areas such as soft rock deformation with high ground stress, rock explosion with hard rock, high ground temperature, and high-pressure water-rich karst, making outstanding contributions to railway construction and economic and social development in China. Based on the problems faced in the construction of railway tunnels in China, this paper proposes prospects for the support system, design methods, intelligent construction, and other aspects of railway tunnel construction in China.

Keywords: Railway Tunnel, Design Theory, Standard System, Risk Management

1 INTRODUCTION

In recent years, China's railway system has experienced significant advancements in terms of the expansion of its operating road network, the establishment of standardized systems, the improvement of transport services, and the promotion of scientific and technological innovation. These developments have resulted in notable accomplishments. As of the conclusion of 2022, the total operational distance of China's railway system amounted to 155,000 kilometers (Excluding Taiwan Province data, as well as subsequent references). Notably, the high-speed railway network accounted for 42,000 kilometers^[1]. This extensive high-speed rail infrastructure stands as the most expansive globally, significantly enhancing the accessibility of travel for a wide range of individuals.

The rapid development of China's railway system has correspondingly led to significant advancements in railway tunnel construction, yielding numerous notable

achievements. Initially, it is noteworthy to mention that the magnitude of the tunnels that have been utilized is substantial. As of the conclusion of 2022, China boasted a network of 17,873 operational railway tunnels, spanning a collective distance of 21,978 kilometers. This figure encompasses 4,178 tunnels specifically designed for high-speed railways, which account for a total length of 7,032 kilometers. Furthermore, the theory of tunnel design is undergoing continuous development, with the standard system experiencing ongoing improvement and construction technology advancing rapidly. In recent years, there has been a continuous emergence of tunnel design theories and methods in China that exhibit distinct characteristics. These include the surrounding rock deformation control method, mechanized large-section design method, and total safety factor method. As a result, a complete set of tunnel design standards for each speed target value has been formed, and various tunnel construction technologies, especially

*Corresponding author: lixucq@sina.com

unfavorable geological treatment technologies, have developed rapidly. Furthermore, a considerable quantity of significant tunnel projects have been constructed. China has successfully undertaken various tunnel projects in challenging terrains such as plateaus, cold regions, loess areas, and urban complex environments. These achievements have been recognized through prestigious accolades including the Fidyk Prize and the World Tunnel Association Award, highlighting China's significant global impact in the field of railway tunnel construction.

2 OVERVIEW OF RAILWAY TUNNELS

Based on statistical data, it is observed that as of the conclusion of 2022, China had a substantial network of operational railway tunnels, numbering 17,873 in total. These tunnels collectively spanned a distance of 21,978 kilometers. Notably, among these tunnels, 4,178 were specifically designated for high-speed railways, covering a total length of 7,032 kilometers. The magnitude of this infrastructure undertaking is noteworthy. Simultaneously, there is a considerable proliferation of ongoing and prospective tunnel initiatives. In China, there is currently an ongoing construction of 3,025 railway tunnels, collectively spanning a distance of 7,704 kilometers. Currently, there are 5,376 railway tunnels in the phase of planning and design, encompassing a cumulative length of 13,221 kilometers^[2]. In China, a significant railway tunnel project has been undertaken, encompassing the construction of numerous railway tunnels that are currently underway or planned for future development. These railway tunnels exhibit several notable features, including their considerable length, diverse construction techniques, and significant challenges encountered during their construction.

2.1 *Extra-long railway tunnel*

The Dayaoshan Tunnel on the Heng-Guang double track in China commenced operations in 1987. Spanning a length of 14.295km, this tunnel holds the distinction of being the inaugural extra-long railway tunnel constructed in China. Over the subsequent three decades, a significant quantity of exceptionally lengthy railway tunnels have been constructed in China^[3]. As of the conclusion of 2022, China has successfully constructed and put into operation a total of 259 railway tunnels of extended length. These tunnels collectively span a distance of 3498 kilometers. Among these tunnels, there are 12 that have a combined length of 283 kilometers. The Guanjiao Tunnel holds the distinction of being the longest among them, measuring 32.690 kilometers in length. Furthermore, it is worth noting that there are currently 26 tunnels being constructed, each spanning a distance of over 20 kilometers. Collectively, these tunnels will amount to a total length of 692 kilometers. The presence of numerous extensive tunnels

indicates a substantial enhancement in China's proficiency in tunnel construction and utilization.

2.2 *Diversification in construction methods*

The primary method employed in China's railway tunnel construction predominantly involves the utilization of borehole-blasting techniques, intending to acquire a comprehensive understanding of the New Austrian Tunnelling Method (NATM) concept. In recent years, the construction industry in China has witnessed significant advancements in the field of large-scale construction equipment. As a result, there has been a notable increase in the construction of tunnels using large-diameter Tunnel Boring Machines (TBM) and shield technology. This shift in construction practices signifies a gradual transition from manual labor-intensive methods to mechanized approaches. Regarding the topic of Tunnel Boring Machines (TBM), it is noteworthy that the construction of the Xikang Railway Qinling Tunnel spanned from 1995 to 1999. This tunnel, measuring a length of 18 kilometers, required the utilization of two TBMs for its successful completion. The length of construction for a single Tunnel Boring Machine (TBM) was 5.2 kilometers, achieving a monthly progress peak of 531 meters. Between 2008 and 2015, the West Qinling Tunnel of the Lanzhou-Chongqing railway spanned a total length of 28 kilometers. This tunnel was constructed using two TBMs, each with a construction length of 12.7 kilometers and a highest monthly progress of 833 meters^[4]. The Shiziyang Tunnel of the Guangzhou-Shenzhen-Hong Kong high-speed railway, which commenced construction in 2009, holds the distinction of being the inaugural shield tunnel for a high-speed railway project situated underwater. It is noteworthy for its ability to withstand a maximum water pressure of 0.67 megapascals. The construction of the Shiziyang Tunnel, a railway tunnel, commenced in 2016. At that time, it held the distinction of being the largest shield tunnel in China. The tunnel boasted a shield outer diameter measuring 13.1 meters and was designed to withstand maximum water pressure of 0.78 Mpa.

2.3 *Difficulty in tunnel construction*

China's expansive landmass and the intricate geological and environmental circumstances surrounding tunnel construction have necessitated the implementation of numerous tunnel projects in hazardous mountainous regions, karst water-abundant areas, loess regions, cold climates, urban environments with complex surroundings, and sea-crossing zones. During the tunnel construction in the aforementioned areas, numerous challenges are encountered, including but not limited to high stress rockburst, significant deformation, elevated ground temperature, high-pressure water influx, intense seismic activity, frost susceptibility in cold regions, and close proximity to existing structures.

Consequently, the construction process is characterized by considerable difficulty.

3 ACHIEVEMENTS IN THE DEVELOPMENT OF RAILWAY TUNNELS

Through the large-scale construction of railway tunnels in the last 40 years, China's railway tunnel has made a series of achievements in survey means, design theory, standard system, disaster prevention and rescue, mechanization, and complex environment construction technology.

3.1 *Continuous innovation in survey methods*

In order to find out the geological conditions of the tunnel accurately, the railway tunnel survey methods in China have been continuously innovated, and an integrated survey technology of "air-sky-ground" has been formed. The so-called "air-sky-ground" integrated survey technology refers to a comprehensive survey method composed of satellite platforms such as high-resolution images, thermal infrared remote sensing, multi-spectral lithology remote sensing, aviation platforms such as aerial photography, aerial geophysical exploration, unmanned aerial vehicles, three-dimensional tilt photography, and ground platforms such as three-dimensional laser scanning, ultra-deep horizontal drilling, kilometer-level vertical drilling and high-precision ground geophysical exploration. Compared with the traditional survey, the "air-sky-ground" integrated survey technology can greatly reduce the workload of operators in the process of deep-buried long tunnel survey, greatly improve the efficiency of survey work, improve the accuracy of survey work, reduce the exploration cost, and provide a basis for formulating a reasonable tunnel project plan^[5].

3.2 *Continuously developing design theory*

The concept of New Austrian Tunnelling Method (NATM) was first introduced in China during the 1970s. Subsequently, NATM gained significant popularity and was extensively employed in the construction of tunnels throughout the country. This adoption of NATM played a pivotal role in facilitating the successful completion of numerous large-scale railway tunnel projects in China, thereby making notable contributions to the field of tunnel construction in the country. In recent years, significant progress has been made in the evaluation and classification of surrounding rock stability and the design of surrounding rock deformation control in China's railway tunnel construction. This progress has been achieved through the assimilation and application of concepts from the "New Austrian Tunnelling Method," "Norwegian Tunnelling Method," and "New Idea

Method," as well as through the consideration of China's unique topography, geological conditions, and diverse characteristics of railway tunnels. These efforts have led to the development of tunnel construction methods that are specific to China, thereby advancing the theoretical framework and methodologies for railway tunnel design in the country.

3.2.1 *Standard design method of surrounding rock stability classification*

The primary design methods employed in China's railway tunnel construction include the utilization of standard design and analogy design approaches. Based on extensive engineering experience, it is suggested that the self-stability of the surrounding rock be adopted as a criterion for developing a comprehensive classification system. Furthermore, standard design parameters are proposed based on the classification of the surrounding rock. For a considerable duration, the design and construction of railway tunnels in China have been heavily influenced by the conventional design approach that relies on the classification of surrounding rock stability. This method has played a crucial role in facilitating the extensive development of railway infrastructure in the country. However, during the process of construction, the rock formations exposed during excavation do not necessarily align with the expected characteristics of the surrounding rock. This discrepancy makes it challenging to accurately assess and interpret the conditions on-site. Additionally, the supporting parameters can vary in strength, leading to potential weaknesses or strengths in the overall structure. In recent years, extensive scientific research and testing have been conducted by railway builders in China to enhance and reinforce the quantitative classification of surrounding rock. The refinement of the elastic wave velocity range of surrounding rock with different lithology is achieved through the introduction of the basic quality index (BQ). Additionally, the concept of surrounding rock sub-level is proposed. Based on the findings regarding the self-stability characteristics of the surrounding rocks under various combined conditions, the rocks of Grade III, IV, and V are classified into two sub-grades. The sub-grade division standard is determined based on the index combination corresponding to each sub-grade. Consequently, the BQ value range for each sub-grade of the surrounding rocks is established. The findings have been incorporated into the 2016 edition of the Design Code for railway tunnels, providing valuable guidance for the design and construction processes of railway tunnels.

3.2.2 *Mechanized large section design method*

The tunnel construction team of Zhengzhou-Wangao High-speed Railway Hubei Section, through carrying out scientific research and field practice related to large-scale tunnel mechanized large-section supporting construction, summarized and put forward the

related methods of railway tunnel mechanized large-section design and construction. Using qualitative and quantitative methods, palm surface stability is divided into three types: stable, temporary stable, and unstable, and the advanced support measures (including palm surface shotcrete, advanced small pipe, pipe shed, tunnel face anchor, advanced grouting, etc.) are determined according to the evaluation results of palm surface stability. In the design method of tunnel support, the load-structure model is used to calculate, the surrounding rock pressure of shallow buried and eccentric compression section is adopted according to the formula value of tunnel design code, and the deep buried section is determined according to the measured values of deformation and stress^[6].

Figure 1. Design model of advance support in palm surface.

3.2.3 Total safety factor method for tunnel supporting structure design

Xiao Mingqing and his team have developed the “total safety factor method for tunnel supporting structure design” based on their extensive experience in tunnel engineering design, construction, and research. The conceptual framework of this methodology is as follows: The relationship between the supporting structure and the surrounding rock is commonly understood as the interaction between the acting force and the reaction force. However, the coordination of deformation between these elements is often not taken into strict consideration, resulting in a significant simplification of the problems that need to be addressed. The determination of whether the tunnel requires support and the calculation of the necessary supporting force necessitate the utilization of numerical analysis incorporating various constitutive models that accurately reflect real-world conditions. Simultaneously, the safety and deformation of the supporting structure itself are assessed using the load-structure model. This integration of modern and traditional analysis methods enables the achievement of safety evaluation and quantitative design of supporting parameters. The figure below illustrates the calculation model for determining the total safety factor of a composite lining structure.

Figure 2. Calculation model of total safety factor method.

3.3 The standard system is improving day by day

From the 1980s to the beginning of this century, the construction standard of China’s railway tunnel was relatively low, with a common speed of 120km/h for railway tunnels in mountainous areas. The tunnel excavation area is generally 50 ~ 60m² for single track and 80 ~ 100m² for double track. After entering the 21st century, with the rapid development of high-speed railways and intercity railways, the tunnel section has gradually increased, and the excavation section of the high-speed railway tunnel can reach 160 m². The maximum excavation span of Beijing-Zhangjiakou high-speed railway Badaling Great Wall underground station tunnel is 32.7m, and the excavation area is 494.4m². It is the largest traffic tunnel in the world at present. Through the engineering practice of various tunnel sections and various geological and environmental conditions, a complete set of technologies for building railway tunnels under different regional environments, different climatic characteristics, and different geological conditions has been formed.

After recent years’ development, China’s railway tunnel has established the standard system of high-speed railway with the speed of 250km, 300km and 350km/h, and a series of standard systems of railway tunnel with the speed of 120km, 160km and 200km/h, and has successively issued relevant specifications 20 Yu Ben and compiled 46 sets of general standard drawings. China railway tunnel has formed a systematic standard system from survey, design, construction, acceptance to operation and maintenance, which has provided strong technical support for the development of China railway tunnel.

3.4 The disaster prevention and rescue system has further matured.

Railway tunnel is a semi-closed structure, which will seriously threaten the safety of passengers in case of fire and other accidents. With the continuous development of railway tunnels, China’s railway tunnel implements the development concept of “people-oriented” and attaches great importance to the disaster prevention and rescue of railway tunnels. Based on absorbing and digesting foreign advanced tunnel disaster prevention and rescue concepts and related

technologies, and fully combining China's national conditions and economic and social development level, this paper puts forward the general principle of "people-oriented, safe evacuation, self-help first and convenient rescue", compiles the Code for Design of railway tunnel Disaster Prevention and Evacuation Rescue Project, determines the main standards of China's railway tunnel disaster prevention and rescue project, and fills the gap of China's railway tunnel disaster prevention and rescue. Through the engineering practice of a batch of extra-long tunnels, emergency rescue stations and other facilities inside and outside various types of tunnels have been built, and a disaster prevention and evacuation rescue system covering civil structural facilities, electro-mechanical facilities, monitoring system, management system and evacuation mode has been gradually established.

In recent years, through the practice of tunnel engineering in plateau areas, research on disaster prevention and rescue of tunnels in high-altitude areas has been carried out. Combined with the characteristics of difficult evacuation and rapid spread of smoke in high altitude areas, the disaster prevention and rescue principles and engineering schemes of tunnels in plateau areas have been further put forward.

3.5 *The mechanization of tunnel construction has been continuously improved*

The mechanized construction of railway tunnels in China has experienced significant advancements. Before the 1950s, the construction of railway tunnels in China primarily relied on manual excavation and manual operation. During the latter part of the 1950s, there was a gradual introduction of small-scale rock drilling machines, as well as digging and loading equipment. Consequently, small-scale mechanized construction began to emerge as a prominent practice. During the 1980s, there was a gradual introduction of foreign advanced multi-arm drilling equipment to implement large-scale mechanised supporting practice. Since the year 2000, China has made significant progress in the independent development and production of various equipment, such as multi-arm drilling rigs, wet spraying manipulators, and integrated machines for anchor drilling and injection. These advancements have resulted in a notable reduction in labor intensity during construction, enhanced operational safety, and improved construction efficiency. Consequently, China has established a comprehensive equipment system that encompasses advanced geological prediction, excavation, loading, support, inverted arch construction, waterproofing, secondary lining, and maintenance.

Furthermore, alongside the progressive mechanization of the borehole-blasting technique, there has been notable advancement in China's shield and tunnel boring machine (TBM) tunnels. China has employed tunnel boring machine (TBM) technology for the construction of various railway tunnels,

including the Xikang Railway Qinling Tunnel, Southwest Railway Mogouling Tunnel, Lanzhou Railway Zhongtianshan Tunnel, and Lanzhou-Chongqing Railway West Qinling Tunnel. The TBM construction method has emerged as a significant option for the construction of exceptionally long tunnels in mountainous regions. The shield method is extensively employed in tunnel projects that traverse intricate urban environments and underwater regions.

In a broad sense, significant advancements have been made in the mechanization of tunnel construction, leading to a continuous enhancement in the level of construction mechanization. Consequently, this has resulted in a substantial reduction in the physical exertion required by construction workers and a notable improvement in the overall quality of construction.

3.6 *Rapid development of tunnel technology in complex environment*

China has a vast territory, and it is inevitable to build a large number of railway projects in special areas such as dangerous mountainous areas, karst areas, loess areas and severely cold areas. The construction of railway tunnel faces a series of problems such as high-ground stress, high ground temperature, high-intensity earthquake, karst water inrush, collapsible loess, and freezing injury. In recent years, through the technical research of tunnel builders in China, a large number of tunnel projects have been built in the above-mentioned complex environment areas, marking a new step in the construction technology of railway tunnels in China.

— Through the engineering practices conducted in Chenglan Railway Yue Longmen Tunnel, Lanyu Railway Muzhailing Tunnel, and Cheng Gui Railway Gaopo Tunnel, our country has successfully identified the deformation mechanisms associated with different types of large deformations, including high-stress extrusion, high-stress rock mass expansion bending, and fractured rock mass extrusion. Consequently, a grading evaluation standard and prediction method have been proposed for implementation during the survey and design stage as well as the construction stage. Moreover, the concept of "optimising tunnel shape, active reinforcement, grading control, and strengthening support" has been established as a comprehensive approach to address these deformation challenges.

— China has developed a rockburst grading identification standard for the initial stage of survey and design and detailed judgment during construction, based on the engineering practice of Bayu Tunnel in Lalin railway. The principle of active disposal, known as "early warning first, active control, more machines and fewer people, ensuring safety," has been proposed. Additionally, the principle of "predicting before construction" has been put forth specifically for rock burst tunnels. The utilization of extensive mechanization in the rock burst tunnel construction is evident, aiming to maximize the

safety of the workers involved. A comprehensive technical system for the treatment of rock burst engineering is established, incorporating an active support system consisting of a prestressed anchor and a high-strength protective net.

— China has developed a classification system for high ground temperature and standards for assessing thermal damage. This has been achieved through the implementation of railway projects in high-ground temperature environments, including Lari railway, Da Rui railway, and Lalin Railway. Notably, the Sangzhuling Tunnel in the Lalin railway represents the world's highest rock temperature in a traffic tunnel. The proposed principle for waste management involves enhancing geological forecasting, implementing measures to prevent and control thermal damage, providing comprehensive cooling support, appropriately adapting materials, and reinforcing labor safety. This principle aims to establish a comprehensive system for preventing and controlling damp heat in the construction environment of high geothermal tunnels. By employing ventilation cooling, ice cooling, and mechanical refrigeration, the physical and mental well-being of operators is effectively safeguarded. An operational safety guarantee system has been established for high-ground temperature tunnels during their operational period.

— China has made significant advancements in the construction technology of collapsible loess through the implementation of high-speed railway projects in Zhengxi, Baolan, and Yinxi regions. The presence of water causes a transformation of loess from a solid state to a more fluid state, thereby increasing the construction risk and posing challenges for settlement control. The pressure distribution law and deformation characteristics of the surrounding rock in high-moisture loess cross-section tunnels have been identified through scientific research. Consequently, a large-section construction technology for high-moisture loess tunnels has been proposed, thereby addressing the technical deficiency in the construction of loess tunnels with high moisture content both domestically and internationally. This development has resulted in the establishment of a comprehensive technical system for constructing loess tunnels under varying moisture content conditions.

— China's railway underwater tunnels have made significant advancements in terms of engineering practices, as exemplified by the Liuyang River Tunnel in the Wuhan-Guangzhou railway, the Shiziyang Tunnel in the Guangzhou-Shenzhen-Hong Kong High-speed railway, and the Shantou Bay Tunnel in the Shantou-Shantou High-speed Railway. These tunnels have evolved from initial breakthroughs to encompass larger diameters, higher water pressures, and more intricate geological conditions. The ongoing construction of the Jintang subsea tunnel within the Yongzhou railway encompasses a comprehensive length of 16.2 kilometers. This tunnel is designed to be buried at a maximum depth of 85 meters, with a diameter measuring 14 meters. Additionally, it is engineered to

withstand a maximum water pressure of approximately 0.85 megapascals. This particular subsea high-speed rail tunnel holds the distinction of being the longest in terms of length, while also experiencing the highest water pressure among all such tunnels globally.

4 ICONIC ENGINEERING

Here are some projects that have been completed or are under construction in China.

4.1 *Xinguanjiao tunnel of Xige Second Line*

Xinguanjiao Tunnel is the key project of the second line of Qinghai-Tibet railway from Xining to Golmud, with a total length of 32.69km, a maximum buried depth of 910m, and an average elevation of 3600m. It is designed as two parallel single-line tunnels with a line spacing of 40m and a design speed of 160km/h, and is constructed by the borehole-blasting method, with a total length of 10 inclined shafts of 15350m. It is the first railway tunnel with a length exceeding 30km in China. Construction started in November 2007 and it was put into operation in December 2014. It is the first long tunnel at high altitude in China and the first long tunnel at high altitude in the world. With the completion of Guanjiao Tunnel, the cross-ridge line in this section was shortened by about 37km, and the train running time was shortened from 2 hours to 20 minutes. Figure 3 shows the entrance of the Xinguanjiao Tunnel.

Figure 3. Guanjiao tunnel.

The construction of tunnels has presented numerous technical challenges, including the need for long-distance ventilation in plateau regions, the deformation of wide fault zones within specific areas, the occurrence of high-pressure water gushing from water-rich zones in lengthy sections, as well as the implementation of disaster prevention, evacuation, and rescue measures to ensure safety during the operation of exceptionally long tunnels in plateau environments^[7]. Despite these challenges, a comprehensive set of construction techniques specifically designed for high-altitude, extra-long tunnels has been successfully developed and implemented. The project received numerous

accolades both domestically and internationally, including the ITA Major Engineering Award, FIDIC Excellent Engineering Award, Qinghai Science and Technology Progress Award, China Railway Society Science and Technology Award, China Construction Industry Association and Construction Enterprises Association Science and Technology Award, and China Civil Engineering Zhan Tianyou Award. The construction of the Guanjiao Tunnel has significantly advanced tunnel technology in China and has offered valuable technical assistance for the development of extra-long tunnels exceeding 30 kilometers, particularly those situated at high altitudes within the country.

4.2 Beijing-Zhangjia high-speed railway new badaling underground station tunnel

The Badaling tunnel, situated within the Beijing-Zhangjiakou high-speed railway, holds the distinction of being the longest tunnel. Spanning a total distance of 12.01 km this tunnel boasts a design speed of 250 km/h. It consists of a single tunnel accommodating two railway lines. The tunnel has a minimum depth of 4m and a maximum depth of 432m. The route consistently traverses significant landmarks such as Juyongguan, Shuiguan, and the Badaling Great Wall. The Badaling Great Wall Station is an underground station that forms part of the Beijing-Zhangjiakou high-speed railway. It is situated within the new Badaling tunnel, approximately 3km from the tunnel exit. The station is located below the Guntiangou parking lot in the Badaling Scenic Area and is close to the Badaling Great Wall. The transportation system consists of two stations that are served by four lines. The side platform has an effective length of 470m, and the overall construction area spans 68,300 m². The rail surface is buried at a maximum depth of 102m, while the tunnel excavation at both ends has a maximum span of 32.7m and a maximum cross-sectional area of 494.4 m². This tunnel currently holds the distinction of being the largest traffic tunnel. The subterranean section of the station comprises a compact subterranean excavation complex, consisting of three tiers arranged in a vertical sequence: the platform tier, the entrance tier, and the exit tier. This complex encompasses a total of 78 cavernous spaces of varying sizes, 88 cross-sectional areas, and 63 intersections. The rock wall thickness between caves is limited to a minimum of 1.2 meters. In 2016, the world witnessed the commencement of a remarkable project - an underground excavation high-speed railway station. This project stands out due to its unprecedented construction scale, buried depth, excavation span, cross-section area, and the intricate cavern structure it entails. Figure 4 presents a cross-sectional perspective view of the Badaling underground station, while Figure 5 illustrates a schematic cross-sectional view of the super-long tunnel associated with the Badaling underground station.

Figure 4. Perspective view of Badaling underground station.

Figure 5. Schematic cross-section of the super-long tunnel in Badaling underground station.

The Badaling Great Wall Station holds the distinction of being the inaugural subterranean high-speed railway station in China. The five characteristics of this phenomenon encompass strict adherence to environmental protection measures, deep burial of waste materials, a lengthy operational lifespan, the presence of densely constructed caverns, and a geological setting that is considered to be of low quality. Throughout the construction process, there are four technical challenges that need to be addressed. These challenges include disaster prevention, rescue and evacuation measures, environmental and cultural relics preservation, as well as the construction of super-large span tunnels and dense cavern groups. The environmental protection technology of constructing tunnels through the Great Wall and scenic spots has been established through scientific research. Additionally, the development of environmental construction for deep underground stations has also been undertaken. This study proposes the component design method for the surrounding rock bearing arch of a super-long-span tunnel, the new construction method of V-shaped excavation for a super-long-span tunnel, the new technology of high-performance fast tensioning prestressed anchor cable, and the theory and control standard for step-by-step deformation control of a super-long-span tunnel. These advancements contribute to the development of a construction

technology for super-long-span tunnels and dense tunnel groups with weak broken surrounding rock. The findings of this study serve as a valuable technical reference for future projects of a similar nature [8].

4.3 Cheng Gui railway Yujingshan tunnel

The Yujingshan Tunnel, located on the Cheng Gui Motorway railway, is a dual-track tunnel designed to accommodate speeds of up to 250km/h. It spans a total length of 6,306 meters. The tunnel structure unveils a substantial karst cave and an intricate subterranean network of rivers. The line runs along the top of the karst cave hall, with a length of 95m, a width of 230m perpendicular to the line, and a height of 50 ~ 120 m, showing a “broad bean” shape, a dome-shaped top and a karst cave volume of 1.08 million square meters. The bottom of the cave hall is a slope-filling body of 30m~90m, and a large underground river develops at the bottom of the slope body, with a river surface width of 10 ~ 15m, a flow rate of 70m³/s in rainy season and a height difference of 120m from the surface of the underground river to the rail surface. The underground river is the only water source for downstream hydropower stations, and its ecological environment is sensitive. This giant cave and underground river system are extremely rare in the world of engineering construction, and it is praised as “the first cave of China’s high-speed railway” by the industry. Faced with a series of problems such as structure, foundation form, construction organization, operation and maintenance, etc., during the construction process, innovative measures were gradually improved through repeated research and demonstration tests, which solved the above problems, and several disposal technologies filled the gaps at home and abroad.

Figure 6. Schematic diagram of karst treatment of Yujingshan tunnel in Cheng Gui railway.

4.4 Yongzhou railway Jintang cross-harbour tunnel

The Ningbo railway starts from Ningbo East Station in the west, passes through Beilun District of Ningbo City, Jintang Island, Cizi Island and Fuchi Island of Zhoushan City, and reaches Baiquan Station of Zhoushan Island. The main line is 76.4km long, of which the newly-built line is 70.1km long. Jintang subsea tunnel starts near Taishan West Road, Beilun District, Ningbo City, passes through Sigu Mountain to the north, then enters the sea on the west side of Qingzhi River, passes through Jintang Waterway, lands on Jintang Island in Zhoushan on the north side of Dapukou, and ends near Jin Shun Cement Preproducts Co., Ltd., Jintang Town, Dinghai District, Zhoushan City. The total length of the tunnel is 16.18km, with a single-hole and double-line layout. The shield tunnel passes through Jintang Waterway by shield method, with a length of 11.21km. The land on both sides of the tunnel is constructed by open excavation and mining method, with a length of 3.617km at the Beilun side, 1.313km at the Jintang side, and a total length of 0.04km at both sides of the tunnel. The stratum through which the tunnel passes mainly includes silty soil, silty clay, silty sand, and weakly weathered tuff. The maximum buried depth of the land section is about 250m, and the maximum water pressure of the sea section is about 0.85MPa^[9].

5 OUTLOOK

5.1 Steadily promote intelligence

In recent years, there has been a gradual decline in the presence of skilled construction technicians at tunnel sites due to the persistent rise in labor costs. Consequently, there has emerged a practical necessity to explore the possibility of substituting human labour with automated machinery in tunnel engineering construction. The reduction or absence of human presence is an inevitable trajectory in the future of tunnel engineering construction and development.

Based on the prevailing construction demand, technical proficiency, and developmental stage of railway tunnel construction in China, significant progress has been made in the accumulation and enhancement of tunnel design and construction methods under diverse geological conditions. This advancement is primarily attributed to the testing and implementation of an intelligent construction system. Notably, the breakthrough in tunnel intelligent construction technology theory, which is based on deep learning, has enabled the realization of a self-learning and self-adaptive intelligent tunnel construction system. Consequently, an intelligent tunnel construction system has been established, incorporating dynamic perception, implementation

analysis, accurate decision-making, and independent execution. This development holds great potential for the comprehensive promotion and achievement of intelligent tunnel construction.

5.2 *Further improve the construction technology of complex tunnels.*

With the in-depth development of China's railway construction, the main battlefield of railway construction in the future will be concentrated in the dangerous mountainous areas in the west, which will face more prominent geological and environmental problems. Although we have made some breakthroughs in high-stress environment, high-intensity earthquake resistance and high ground temperature, the intensity and scale of bad geology will exceed our understanding in future railway tunnel construction. Therefore, we should strengthen the summary of railway construction technology in the complex environment in China and form a complete set of technologies to prepare for railway construction in China.

5.3 *Further improve the level of tunnel operation and maintenance.*

The number of railway tunnel projects in China has been steadily increasing over the years. Consequently, there has been a corresponding rise in lining defects and diseases. This has brought attention to the heightened risk and pressure associated with the safe operation of high-speed railway tunnels. There is a pressing need to develop intelligent monitoring, maintenance, and disease treatment technology for tunnels based on Internet of Things (IoT) technology, as the current maintenance capacity falls significantly short of the demand for tunnel operation and maintenance. This study encompasses the investigation and advancement of a structural health

monitoring system specifically designed for tunnel and underground engineering. Additionally, it focuses on the development of an intelligent decision-making system for evaluating tunnel conditions based on big data analysis. Furthermore, it aims to enhance tunnel and underground engineering maintenance practices through the utilization of efficient technology and intelligent equipment.

ABSTRACT: The Ministry of Transport of China issued the *Green Transportation Facilities Assessment Technical Requirements* in 2017, aiming to promote green transportation facilities in China. This study uses the fuzzy Delphi method to evaluate the differentiated driving effect of this policy on the green initiative of mountain tunnel builders. One hundred thirty first-line builders from twenty-one mountain tunnels in southwest China participated in the survey. The screening thresholds of the first layer indicators are 7.27, 7.01, 6.99, and 7.07, respectively. First-line builders are most motivated to promote green concepts, but their motivation to save resources is insufficient. Among the various ways to promote the green concept, the government's strategic planning and supervision mechanism are more effective than private financing, education, training, and publicity activities. Mountain tunnel builders prefer to protect the eco-environment by safeguarding wildlife habitats, reducing polluting gas emissions, and controlling dust and light pollution. Rational planning of land resources and water resources is the core of saving resources in tunnel construction sites, and the use of recycled materials has also been recognized. Compared with intelligent equipment, energy-saving equipment, and technologies can better stimulate the green initiative of mountain tunnel builders. The widespread application of renewable energy is less motivating. The study results can provide evidence from first-line tunnel builders to adjust and improve *China's Green Transportation Facilities Assessment Policy*.

Keywords: Green assessment policy, Mountain tunnel builders, Green initiative, Fuzzy Delphi method, Differentiated driving effects

1 INTRODUCTION

China has achieved the world's fastest growth in transportation facilities over the past few decades. In 2019 alone, China built 330,000 kilometers of roads (new, rebuilt, and expanded), 8,000 kilometers of railways, and 1,710 kilometers of tunnels (Ministry of Transport of China., 2019). Such large-scale construction of transportation facilities has caused severe environmental problems and has attracted the attention of senior government officials.

To guide the construction of green transportation facilities, China promulgated the *Green Transportation Standard System* in 2016, and the *Green Transportation Facilities Assessment Technical Requirements* in 2017 (Ministry of Transport of China., 2016; Ministry

of Transport of China., 2017). There are also many well-established green building assessment tools and methods globally. The Leadership in Energy and Environmental Design Building Rating System (LEED), established and implemented by the United States, is the most complete and influential assessment standard in building environmental assessment, green building assessment, and building sustainability assessment around the world (USGBC., 2000). The Building Research Establishment Environmental Assessment Method (BREEAM) issued by the UK is the first and most widely used green building assessment method globally (British Institute of Architecture., 1990). Because of its core concept of "adopting measures to local conditions and balancing benefits", this method has been widely used in more than 76

*Corresponding author: liuyangtunnel@my.swjtu.edu.cn

countries. The German sustainable building evaluation standard overcomes the limitation of the first generation of green building evaluation standards. It comprehensively evaluates the sustainability of buildings from three dimensions ecology, economy, and society (DGNB., 2007).

The effectiveness of the newly promulgated policies in promoting green buildings and green transportation facilities should be tested. There have been many related studies, and the results provide a scientific basis for policy improvement. For example, Gao et al. (2016) evaluated the effect of the *Air Pollution Prevention and Control Action Plan* by cost-benefit analysis. The results proved the policy's cost-effectiveness as its benefit-cost ratio reached 6.32. To understand the impact of the *Emission Control Policy* on public health, soil acidification, and climate, Zhao et al. (2011) quantified the results of policy implementation in two situations. It proposed that the *Emission Control Policy* should include not only common pollutants but also VOCs and CO₂. Xu et al. (2019) used scenario analysis to evaluate urban development to determine whether Chinese urban planning policies meet the goals of sustainable urbanization. Yang et al. (2020) quantified the effect of open biomass burning on surface PM 2.5 during periods of heavy smog monitored by satellite and ground observation data. The results showed that the burning ban policy effectively reduced the occurrence of fires and reduced the PM 2.5 concentration in the whole area by 48.1% during the harvest season. Hu et al. (2020) discussed whether the Chinese ecological red line policy could achieve a balance between urban construction land and green space. After implementing this policy, the amount of urban soil grew, indicating that the policy has achieved a balance between land saving and land sharing.

The above-mentioned analysis methods used the results to infer the policy's impact and effect. It has limitations in evaluating the application effects of policies in different scenarios. Nor can it reflect the

green initiative preferences of the direct implementers of the policy. Therefore, this study explores the differentiated driving effects of *China's Green Transportation Facilities Assessment Policy* on mountain tunnel builders. The study results will provide reliable suggestions for policy improvement.

2 GREEN TRANSPORTATION FACILITIES ASSESSMENT POLICY

The Ministry of Transport of China issued the *Green Transportation Facilities Assessment Policy* in 2017. The assessment system given by this policy is a framework structure containing three layers of indicators. The first layer indicators are conceptual, showing the four main directions of green transportation facilities assessment—Green concept, Eco-environment protection, Saving resources, energy-saving, and low-carbon. The second layer indicators are refined based on the first layer and give thirty subdivided green transportation facilities assessment fields. The third layer of indicators gives sixty-one specific requirements of green transportation facilities assessment.

The green concept is further subdivided into four second-layer indicators and eight third-layer indicators (Table 1). Adhering to green and sustainable development is the prerequisite for building green transportation facilities. Firstly, the central and local governments should establish strategic planning to develop green transportation facilities (1.1.1, 1.1.2, and 1.1.3). Secondly, governments should also establish special funds to build green transportation facilities and broaden private financing channels (1.2.1 and 1.2.2). Thirdly, governments at all levels should organize and launch education, training, and publicity activities on green transportation facilities in various forms to expand the influence of the green development concept at the grass-roots level (1.3.1, 1.3.2, and 1.4.1).

Table 1. Green concept.

First layer	Second layer	Third layer
1 Green concept	1.1 Strategic planning	1.1.1 Implement a green transportation facilities development plan and develop the green design, construction, and maintenance plan based on system theory and cycle cost.
		1.1.2 Implement energy conservation assessment and environmental impact assessment.
		1.1.3 Establish an energy conservation and emission reduction management system and assessment mechanism.
	1.2 Special funds	1.2.1 Establish a special fund for green transportation facilities development.
		1.2.2 Implement the PPP development model and expand green transportation facilities financing channels.
	1.3 Education and training	1.3.1 Organize and launch green transportation facilities with special technical consultation.
		1.3.2 Launch education and training activities, such as green design, green construction, green maintenance, etc.
	1.4 Publicity	1.4.1 Launch green transportation facilities publicity activities through the Internet, newspapers, special seminars, etc.

Eco-environment protection includes ten second-layer indicators and twenty-five third-layer indicators (Table 2). The assessment of eco-environment protection first pays attention to the protection of wildlife habitat and the effect of ecological restoration (2.1.1~2.3.2). In addition, soil and water protection, pollution gas emission control, and dust control are also the key points of the eco-environment protection assessment (2.4.1~2.7.2). Finally, the station location should be reasonably arranged to avoid excessive sound and light pollution (2.8.1~2.10.2).

The saving resource is subdivided into eleven second-layer indicators and sixteen third-layer indicators (Table 3). The core of saving resources is to conserve land and water resources (3.1.1~3.6.1). Reduce the amount of earthwork excavation and excessive planning of temporary ground. Build drainage and storage systems following local conditions. Recycle the construction and domestic sewage. In addition, attention should also be paid to the reuse of recycled materials and waste materials (3.7.1~3.8.1). In particular, the recycling rate of tunnel slag is an essential indicator of

Table 2. Eco-environment protection.

First layer	Second layer	Third layer
2. Eco-environment protection	2.1 Habitat protection	2.1.1 Avoid nature reserves, wildlife habitats, wetlands, and other ecologically sensitive areas. If it's impossible to avoid, ecological protection schemes are given.
		2.1.2 Set up signs like no honking in wild animals' living areas. Build passageways suitable for wild animals' life.
	2.2 Ecological restoration	2.2.1 Formulate ecological restoration plans in the affected areas.
		2.2.2 Plant local green plants that are easy to grow and resistant to adversity. Introducing exotic species should be demonstrated.
		2.2.3 Plant vines above the protection work.
		2.2.4 Construction and domestic waste should be strictly harmless treatments.
		2.2.5 Including greening projects and animal passageways in the daily maintenance plan. Formulate a perfect conservation plan.
	2.3 Vegetation restoration	2.3.1 Slopes and tunnel openings are covered with green plants.
		2.3.2 The survival rate of green plants in mountainous areas is more than 90%.
	2.4 Water protection	2.4.1 Select construction and management techniques that are conducive to water protection.
		2.4.2 No asphalt or concrete mixing station is set up in the water source protection area. No materials or wastes containing harmful substances are piled up or dumped.
		2.4.3 Set up sedimentation tanks to treat the wastewater of concrete mixing stations and tunnel construction.
	2.5 Soil protection	2.5.1 Build permanent and temporary protection works to protect the exposed surface.
		2.5.2 Greening tunnel waste dump site. Set up blocking facilities if the waste dump site is near the water area.
		2.5.3 Use an environment-friendly snowmelt agent to remove snow. Use environment-friendly snow removal technology like microwave technology instead of traditional chloride-type snowmelt agents.
	2.6 Pollution gas emission	2.6.1 Use technologies like warm mix asphalt mix to reduce emissions of toxic gases such as asphalt fumes and sulfur oxides.
		2.6.2 The exhaust emission of construction machinery reaches the national standard.
	2.7 Dust control	2.7.1 Use dust removal measures like encapsulation, covering, and water spraying to transport powder materials such as lime and fly ash.
		2.7.2 Use ready-mixed concrete process. Sprinkle water to remove dust on the construction site, material yard, and footpath.
	2.8 Station layout	2.8.1 Mixing stations, power stations, and material yards are located downwind of the prevailing wind in sensitive areas.
2.8.2 The distance between the concrete mixing stations and residential areas is 300 meters. The distance between the asphalt mixture mixing stations and residential areas is 200 meters.		
2.9 Sound pollution	2.9.1 Reasonable arrangement of construction time and methods of strong noise radiation machinery.	
	2.9.2 The noise level of sensitive points such as residential areas, schools, and hospitals near the construction area needs to meet the national standard.	
2.10 Light pollution	2.10.1 Avoid shooting the lighting beam into the sky or outside the construction area at night.	
	2.10.2 Control the illumination of lighting facilities; do not disturb the nearby ecological environment and residents' normal life.	

Table 3. Saving resources.

First layer	Second layer	Third layer
3 Saving resources	3.1 Land use	3.1.1 Coordinate the use of various channels.
		3.1.2 Make full use of wasteland, abandoned land, and inferior land; try to avoid farmland and residential areas.
		3.1.3 Centralized layout of communication, power supply, and monitoring cables.
	3.2 Earthwork	3.2.1 Select suitable tunnel section style and parameters to reduce the amount of excavation and waste dump.
		3.2.2 Restore the original function of the temporary construction land after use.
	3.3 Temporary ground	3.3.1 Use wasteland, abandoned land, and service areas as temporary construction land. Strictly control its boundary.
	3.4 Drainage and storage	3.4.1 Integrated design of drainage and storage projects.
		3.4.2 The drainage works are in harmony with the natural water system.
	3.5 Sewage treatment	3.5.1 Set up sewage treatment facilities. Recycling construction wastewater and domestic sewage.
		3.5.2 Use reclaimed water for cleaning operations. Water consumption depends on the amount of dust and weather conditions.
	3.6 Saving water	3.6.1 Use equipment or measures containing water-saving technology in construction and daily life.
3.7 Recyclable material reuse	3.7.1 Use construction waste such as fly ash, coal gangue, and slag to replace part of the pavement materials.	
3.8 Old pavement material reuse	3.8.1 Old pavement materials such as asphalt, and cement reuse.	
3.9 Tunnel slag use	3.9.1 The utilization rate of tunnel slags is over 80%.	
3.10 Material storage	3.10.1 Build a special material shed for storing cement, asphalt, sandstone, and other materials.	
3.11 New materials	3.11.1 Use new materials, such as polymer concrete, high-strength lightweight concrete, natural asphalt, etc.	

Table 4. Energy-saving and low-carbon.

First layer	Second layer	Third layer	
4 Energy-saving and low-carbon	4.1 Energy-saving technology of mixtures	4.1.1 Warm mix asphalt pavement accounted for more than 10%.	
		4.2 Construction energy-saving measures	4.2.1 Use energy-saving construction equipment with frequency conversion function.
			4.2.2 Use centralized power supply in the construction areas. Build substations to replace diesel power generation.
	4.3 Energy-saving system	4.3	4.2.3 Improve the utilization rate and load rate of construction machinery, and reduce unit energy consumption.
			4.3.1 Use power supply and distribution system with energy-saving technology.
			4.3.2 Use an intelligent lighting control system.
			4.3.3 Use LED and other new energy-saving lamps.
			4.3.4 Use an energy-saving information board.
	4.4 Renewable energy	4.4	4.3.5 Use an intelligent ventilation control system to monitor the exhaust concentration, wind speed, and traffic flow in the tunnel in real time.
			4.4.1 Use renewable and green energy such as solar, wind, geothermal, etc.
4.5 Natural gas mixing station	4.5	4.4.2 Lighting equipment powered by renewable and green energy accounts for more than 15%.	
		4.5.1 Use clean energy instead of coal and diesel in mixing stations.	

green transportation facilities (3.9.1). Finally, the introduction and use of new materials in the future construction of green transportation facilities cannot be ignored (3.11.1).

The energy-saving and low-carbon indicators include five second-layer indicators and twelve third-

layer indicators (Table 4). Applying various energy-saving technologies is critical in assessing green transportation facilities, such as warm-mix asphalt technology, energy-saving frequency conversion equipment, and a centralized power supply system (4.1.1~4.2.3). In addition, the construction of intelligent and energy-

saving power supply systems, lighting systems, information systems, and ventilation systems should be comprehensively promoted (4.3.1~4.3.5). Finally, the assessment of green transportation facilities should also focus on using renewable and clean energy such as solar, wind, and geothermal energy (4.4.1~4.5.1).

3 METHODOLOGY

3.1 Fuzzy Delphi method

The fuzzy Delphi method is essentially a feedback-based anonymous consulting method. This method can avoid some of the possible disadvantages of a group decision. With the fuzzy Delphi method, the loudest or most senior person does not have the opportunity to control the group's will because everyone's opinions are collected. The final decision owner can ensure that essential views are not ignored by collecting thoughts from all group members. Therefore, the fuzzy Delphi method has been widely applied to business, NGOs, military, education, health care, and other fields and has achieved good decision-making results (Zangenehmadar et al., 2016; McLennan et al., 2017; Brunt et al., 2018; Salmon et al., 2018; Fritschy et al., 2019; Mirata et al., 2020; Grace et al., 2021). Figure 1 shows the survey process of the fuzzy Delphi method.

This study established a survey team of the *Green Transportation Facilities Assessment Policy*. This team is responsible for the organization, coordination, collection, summary, feedback, and necessary explanation during the whole survey process. The survey team transformed sixty-one third layer indicators into questionnaire questions. The survey team invited 130 first-line builders with years of experience in mountain tunnel construction in southwest China. The team distributed the prefabricated questionnaire to each respondent and explained the grading rules. The respondents were asked to assess their initiative to implement each policy indicator based on their work experience. The scores ranged from zero to ten. Zero is extremely reluctant, and ten is

extremely willing. The questionnaire survey was conducted anonymously, and the respondents were not allowed to discuss with others either.

Through three rounds of Distribution-Collection-Analysis-Feedback, the consensus of all respondents was obtained. The centroid method processed the collected questionnaire results (Figure 2).

The steps are as follows:

- 1) Calculate the triangle fuzzy numbers (TFNs) of each third layer indicator (Qiu et al., 2020).

After three rounds of surveys, the green initiative of mountain tunnel builders in implementing the third layer indicators has been collected by questionnaires. Calculate the green initiative assessment results' arithmetic mean for each third layer indicator (Equation (1)).

$$I_{fa} = \frac{I_{f1} + I_{f2} + \dots + I_{fn}}{n} \quad (1)$$

Where I_{fa} is the arithmetic mean value, I_{fn} is an independent assessment result, and n is the number of respondents. The minimum value (I_{fmin}), arithmetic mean value (I_{fa}) and maximum value (I_{fmax}) of the green initiative assessment results constitute the TFNs ($T_i = (I_{fmin}, I_{fa}, I_{fmax})$). The TFNs represent the respondents' consensus for the green initiative level of a specific indicator.

- 2) Convert the TFNs into a single value S_i . Equation (2) is used to convert the TFNs into a single value S_i .

$$S_i = \frac{I_{fmin} + I_{fa} + I_{fmax}}{3} \quad (2)$$

- 3) Calculate the green initiative threshold of each third layer indicator. The S_i represents the green initiative of each third layer indicator. A threshold (S_i) is needed to determine which indicators are the green initiative preferences of the mountain tunnel builders. The arithmetic

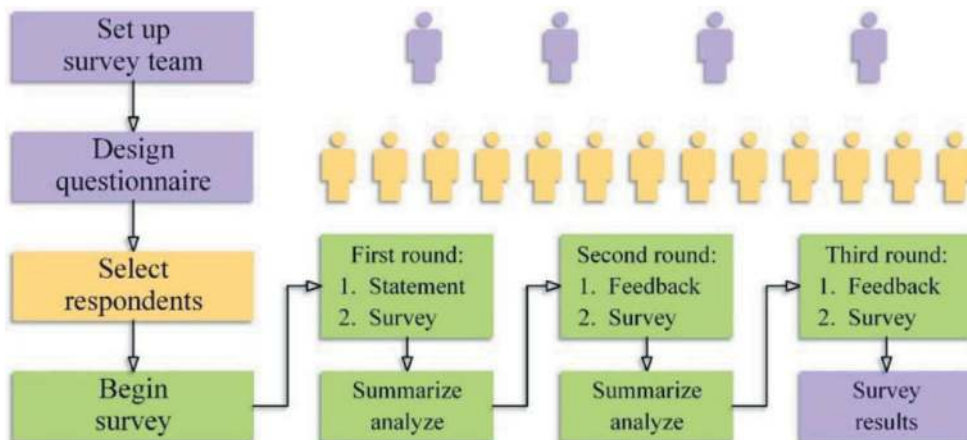

Figure 1. The survey process of the fuzzy Delphi method.

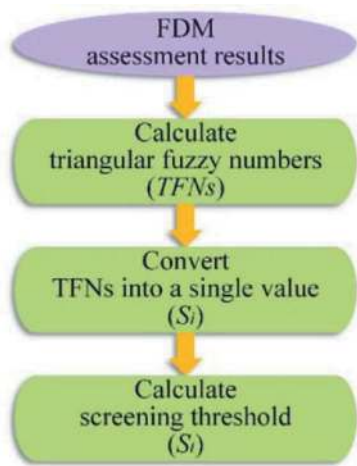

Figure 2. Calculation steps of the centroid method.

mean value was calculated as the green initiative threshold (Equation (3)).

$$S_t = \frac{s_1 + s_2 + \dots + s_n}{n} \quad (3)$$

3.2 Data sources

Inviting enough practitioners from related industries as respondents is the most critical step to ensure the reliability of the fuzzy Delphi method assessment results.

3.2.1 Study area

With the continuous progress of China's basic transportation construction, the central tunnel construction has been transferred from the plain eastern sight to the western mountainous area. Soon, many super long and deep mountain tunnels will be built in southwest China. Therefore, it is of great significance to explore whether *China's Green Transportation Facilities Assessment Policy* can motivate the green initiative of mountain tunnel builders. The respondents of this study came from twenty-one mountain tunnels under construction in southwest China. All the respondents invited to join this survey have years of experience in mountain tunnel construction. Therefore, their opinions and consensus are deemed professional and reliable.

3.2.2 Respondents

One hundred thirty mountain tunnel builders in southwest China were invited to complete the questionnaire. These respondents mainly come from four positions: project manager, technician, environmental inspector, and constructor (Table 5). The project manager is the core of mountain tunnel construction management, responsible for schedule, quality, safety, and cost. Each tunnel project should be staffed with 2~3 technicians responsible for writing construction plans, monitoring deformation, and supervising the construction process. The environmental inspectors have only been deployed in recent years. They are mainly responsible for reviewing pro-environmental plans, checking their effectiveness, and rectifying requirements. Among all the tunnel builders, the number of constructors is the largest, and they are directly responsible for various construction tasks. The work content of these four positions runs through the whole process of mountain tunnel construction. Therefore, the feedback from respondents in these four positions is honest and meaningful. The survey results can reflect whether *China's Green Transportation Facilities Assessment Policy* can drive the green initiative of mountain tunnel builders.

4 RESULTS AND DISCUSSION

This study transformed China's green transportation facilities assessment indicators into a questionnaire and used the fuzzy Delphi method to conduct the survey. The one hundred and thirty respondents who participated in the survey came from twenty-one mountain tunnel projects in southwest China. The respondent's work location and work content can ensure the professionalism and reliability of the survey results. After three rounds of survey and feedback, seven questionnaires with apparent errors or incompleteness were eliminated, and finally, one hundred and twenty-three valid questionnaires were obtained. The survey results will reflect the different driving effects of China's green transportation facilities assessment indicators on the green initiative of mountain tunnel builders.

Table 5. Position, educational background, and the work content of respondents.

Position	Educational background	Content	Numbers
Project Manager	Bachelor or master in management	Organization, management, schedule, quality, safety, and cost.	40
Technician	Bachelor or master in tunnel engineering	Construction plans writing, deformation monitoring, and process supervision.	30
Environmental Inspector	Bachelor or master in environmental engineering	Review the pro-environmental plans, check the effects, and give rectification requests.	30
Constructor	Bachelor of tunnel engineering	All site construction tasks.	30

4.1 Green concept

As shown in Figure 3, the green concept contains eight third-layer indicators, and the green initiative threshold of mountain tunnel builders is 7.27.

Only three third-layer indicators have scores above the threshold (1.1.1, 1.1.2, and 1.1.3). All three indicators are related to strategic planning. It shows that mountain tunnel builders believe that systematic strategic planning and supervision mechanisms from the government are the primary means to drive the construction of green transportation facilities. On the contrary, two indicators related to special funds received the lowest score of 6.72 (1.2.1 and 1.2.2). It is because the mountain tunnel builders doubt whether the government's special funds can be directly used in engineering projects, and it is difficult for the construction of public transportation to attract private investment. Three indicators related to education, training, and publicity scored close to the threshold (1.3.1, 1.3.2, and 1.4.1). It shows that these three indicators can also drive the green initiative of mountain tunnel builders, but the driving effect is limited.

Figure 3. Green concept.

4.2 Eco-environment protection

As shown in Figure 4, the eco-environment protection contains twenty-five third layer indicators, and the green initiative threshold of mountain tunnel builders is 7.01.

Seventeen indicators have green initiative scores above the threshold, and the remaining eight are below the threshold. All indicators related to habitat protection have been recognized by mountain tunnel builders (2.1.1 and 2.1.2). Especially indicator 2.1.2 got the highest score of 7.64. It shows that the mountain tunnel builders believe that the first consideration in protecting the eco-environment is to ensure wild animals' normal life and migration. The ecological and vegetation restoration indicators have obtained differentiated assessment results (2.2.1~2.3.2). The mountain tunnel builders are more willing to implement ecological and vegetation restoration by transplanting native species and strengthening daily maintenance

(2.2.2 and 2.2.5). Indicator 2.2.4 received the lowest score of 5.24. The construction and domestic waste harmless treatment requires the addition of new equipment, which means an increase in costs. All three indicators related to water protection scored higher than the threshold (2.4.1~2.4.3). On the contrary, only one of the three soil protection-related indicators scored above the threshold (2.5.3). In comparison, mountain tunnel builders have a higher green initiative in water protection. Reducing air pollution is also one of the core concerns of builders when building green transportation facilities. All the indicators related to pollution gas emission control and dust control have gained a high consensus (2.6.1~2.7.2). However, the method of reducing air pollution in sensitive areas by rationally arranging the location of the mixing station has not fully stimulated the green initiative of the builders (2.8.1 and 2.8.2). The land suitable for station layout in mountainous areas is limited, so it isn't easy to balance efficiency and environmental protection. Only one of

Figure 4. Eco-environment protection.

the four indicators related to sound and light pollution fell below the threshold (2.9.1~2.10.2). Compared with light pollution, noise generated by construction machinery is more difficult to prevent.

4.3 Saving resources

As shown in Figure 5, the saving resources contain sixteen third-layer indicators, and the green initiative threshold of mountain tunnel builders is 6.99.

The mountain tunnel builders first paid attention to the economical use of land resources. The land available for arranging stations in mountainous areas is highly scarce. Therefore, indicators such as using wasteland and abandoned land and centrally positioning pipelines have been recognized (3.1.2~3.1.3). The indicator related to earthwork excavation fell below the threshold (3.2.1). This is because the outline size of the tunnel depends on traffic planning and train selection. The mountain tunnel builders believe that the temporary ground should be strictly managed but have little initiative for restoring its original function (3.3.1 and 3.3.2). All the indicators related to the construction of drainage and storage facilities and sewage treatment scored higher than the threshold (3.4.1~3.5.2). On the contrary, mountain tunnel builders have little initiative to use water-saving equipment and methods in construction and daily life (3.6.1). The mountainous area has abundant surface water systems and water resources. The mountain tunnel builders prefer to prevent water pollution rather than save water. The mountain tunnel builders encourage recyclable materials such as fly ash and coal gangue in tunnel construction (3.7.1). However, there is little interest in recycling old pavement materials (3.8.1). Similarly, the mountain tunnel builders also questioned whether the utilization rate of the tunnel slag could meet the required standard (3.9.1). Finally, mountain tunnel builders are eager to use new materials such as polymer concrete, high-strength lightweight concrete, and natural asphalt to construct green tunnels (3.11.1).

4.4 Energy-saving and low-carbon

As shown in Figure 6, the energy-saving and low-carbon contain twelve third-layer indicators, and the green initiative threshold of mountain tunnel builders is 7.07.

The energy-saving warm mix asphalt technology scored the highest and won the greatest consensus among mountain tunnel builders (4.1.1). There are only one of the three indicators related to energy-saving construction technology scored below the threshold (4.2.1). Purchasing frequency conversion equipment means additional costs and mountain tunnel builders are more willing to save energy by increasing the existing equipment's utilization rate and full load rate (4.2.2 and 4.2.3). The use of energy-saving systems is the key to constructing green transportation facilities. Three indicators related to energy-saving equipment were scored above the threshold

Figure 5. Saving resources.

(4.3.1, 4.3.3, and 4.3.4). However, mountain tunnel builders have limited green initiatives for using intelligent devices (4.3.2 and 4.3.5). The failure rate of intelligent equipment is high, and it isn't easy to guarantee the stability of tunnel commuting. The use of renewable energy such as solar, wind, and geothermal has also failed to gain consensus among mountain tunnel builders (4.4.1). The lighting equipment is an exception (4.4.2). There is a lack of construction machinery that uses renewable energy as fuel, and if there is, it is expensive. The mountain tunnel builders are also not enthusiastic about using clean energy to replace coal and diesel in the mixing station (4.5.1). The main reason is the lack of a stable, clean energy supply and insufficient power.

5 CONCLUSIONS

This study conducted a questionnaire survey based on the fuzzy Delphi method among one hundred and thirty first-line builders from twenty-one mountain tunnels in southwest China. The purpose is to clarify the differentiated driving effects of *China's Green Transportation Facilities Assessment Policy* on the green initiative of mountain tunnel builders. The results showed:

- 1) Compared with private financing, education, training, and publicity, the government's strategic planning and supervision mechanism can better drive the green initiative of mountain tunnel builders.

Figure 6. Energy-saving and low-carbon.

- 2) The mountain tunnel builders believe that the key to eco-environment protection is wild animals' habitat protection, water protection, pollution gas emission control, dust control, and light pollution prevention.
- 3) The mountain tunnel builders believe that saving resources should focus on land planning, drainage and storage, and recycled and new materials.
- 4) Compared with intelligent equipment, energy-saving equipment, and technologies can better stimulate the green initiative of mountain tunnel builders. In addition, the widespread use of renewable energy is not recognized.
- 5) The study results will provide valuable suggestions for adjusting and improving *China's Green Transportation Facilities Assessment Policy*.

Planning and execution of horizontal directional coring method for future tunnelling works

Fahmi Mahony*, Kh Goh & C. Veeresh

Department of Geotechnical and Tunnels, Land Transport Authority (LTA), Singapore

ABSTRACT: The proposed Cross Island Line (CRL) is a high-capacity underground Mass Rapid Transit (MRT) system with a total route length of 56km. A section of the alignment crosses under one of Asia's busiest runways at Singapore Changi International Airport. Site investigation is an essential component for a better understanding of geotechnical uncertainty which is a key risk for underground tunnelling works. Ground investigations using conventional vertical bore holes along the alignment has limitations along runways and taxiways and closure of runway and taxiways affects the airport operations. To mitigate geotechnical uncertainty during future tunnelling, Horizontal Directional Coring (HDC) technology was adopted. In HDC, continuous cores along the future tunnel route allows comprehensive understanding of ground condition along the alignment. Due to limited amount of subsoil information, it is challenging to plan the HDC trajectory as the technology requires directional steering only in rock stratum. This paper presents various challenges, advantages and disadvantages in executing the HDC under runway 1 of Singapore Changi International Airport.

Keywords: Horizontal Directional Coring, HDC, Tunnel, Gravity Survey

1 INTRODUCTION

The geology along the tunnel alignment plays a dominant role in planning designing and constructing the tunnel, significant risks arise for tunneling construction are associated with uncertainty in the ground. Site investigation is an essential component for a better understanding of geotechnical uncertainty which is a key risk for underground tunnelling works. A section of the cross island (CRL) alignment under crosses the busiest runway at Singapore Changi International Airport.

Based on geological map of Singapore, Changi International Airport Runway 1 resides on Bukit Timah Granite formation. This is intrusive type of igneous rock formed more than 230 million years ago. The upper zone of the Bukit Timah Granite is generally weathered and has been decomposed into residual soils. Bukit Timah Granite has undergone weathering processes over time and the degree of weathering improves with depth. The upper portion of the Bukit Timah Granite Formation is mostly weathered and comprises completely weathered granite to residual soil. The slightly weathered and fresh granites are found at the larger depth of the Formation. The weathering of the Bukit Timah Granite is gradational with depth range and sharp

boundary between completely weathered layer (GV) and moderately weathered granite (GIII) is often observed. The rock head level is generally undulating with frequent valleys and commonly follows the topography.

Ground investigations using conventional vertical bore holes along the alignment has limitations along runways and taxiways and closure of runway and taxiways affects the airport operations. Alternative investigation methods using geophysical investigations are explored, microgravity survey has been carried out along the alignment where the access for bore hole drilling is limited. However, due to airport environment there are concerns on reliability of these investigations as the area is consists of numerous services and airport operations. To verify the gravity survey data and enhance the confidence level, Horizontal Directional Coring (HDC) has been considered.

In HDC, conventional boring process is adopted, and the main difference is the steerable core barrel mounted to a drill string attached to drill rig. The steerable core barrel makes it feasible to control the direction of coring in sub-vertical or horizontal direction along the alignment within the rock. In HDC, heat treated drilling rods are used which can withstand bending to between 5° and 9° for every 30 m (a radius of 200m) along the drilling trajectory. (See Figure 1).

Figure 1. Horizontal direction coring methodology (Veeresh et al 2018).

From the available literature review, it is noted that majority of past projects where HDC was carried out is mostly in hilly terrains focused on determining the rock quality, fracture zones by obtaining the continuous cores along the known tunnel alignment either placing HDC alignment above or on side of the tunnel with known geological information. In current project HDC is carried out in the Airport environment where subsoils information from direct drilling is limited the objective of conducting HDC was to determine the geological condition along the tunnel alignment and validate the geophysical information.

Information from microgravity survey rockhead profile results was used to plan the suitable HDC inclination angle, and curvature portion to determine the appropriate horizontal drilling trajectory. For HDC it is noted that the curvature must be in competent rock (GIII or better). The gravity survey helps to characterise rock profiles around the future alignment. This technique measures minute variations in the gravitational pull of the Earth by using a gravity meter and interprets the presence of massive objects and of voids in the ground. If there exist some material below the ground having density that is lower or higher than surrounding ground (such as a cavity or a subsurface cave), the gravity shows a relatively low anomaly. The denser rock material will have more gravitational attraction. Gravity survey requires at least few boreholes to help with processing and interpretation of the rockhead. See Figure 2 interpreted rockhead profile from gravity survey.

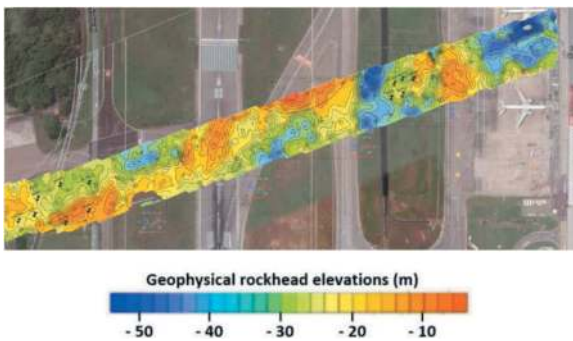

Figure 2. Interpreted rockhead profile.

After the identification of the drilling trajectory, a drilling tolerance envelope must be decided. Typical tolerance envelope for HDC trajectory is within

the range of 2m to 7m radius (Veeresh et al 2018). To ensure that drilling is travelling along the planned designed alignment and within the tolerance envelope, a survey equipment, Devitool™ from the HDC specialist was used to record the drilling trajectory in the borehole at regular intervals. The survey equipment uses three high-accuracy magnetometer and accelerometers to acquire three-dimensional borehole position, inclination, azimuth, tool face direction and magnetic dip angle.

2 ADVANTAGES AND CHALLENGES OF HDC

One of the main advantages is the continuous core sample along future alignment which provides valuable information on the geological condition and this reduces tunnelling risk during construction. Other advantages include, High drilling accuracy and able to drill up to 2km, pilot hole which can branch out to 30 multiple branches.

One of the main challenging aspects of HDC is the risk of a broken drill string and getting stuck in the borehole, this may cause the drilling to end prematurely and form a possible obstruction during tunnelling. This risk can be overcome by planning the HDC trajectory outside the tunnel envelope. Another major risk is encountering intermediate layers of soft ground along the alignment, in such situations it is difficult to control the direction of HDC and may have to abandon the drilling works. Localised grouting of soft ground is possible but if the soft stretch is longer it may be difficult to continue the HDC. From the past experience lengths of up to 40m of soft ground are grouted and drilling is able to continue.

Keeping in view the risk associated with HDC, trajectory should be planned with aim to reduce excessive curvatures which can potentially induce drilling stress on the drill rods, and alignment should be within rock strata as much as possible.

Figure 3. Broken drill string.

3 INVESTIGATION RESULTS AND DISCUSSION

From the gravity survey and available borehole data, the aim for HDC was to drill 1m above the north-east of the future tunnel while maintaining drilling within

a 5m envelope to ensure the trajectory does not intrude into the future tunnel alignment. See Figure 4.

Figure 4. HDC tolerance envelope.

The location plan for the site was strategically placed above the future tunnel alignment for better logistical planning and reduce unnecessary plan for curvature which induces stress on the drill rods. Stress on the drilling rods will impact the machine capability of drilling further. The plan was to terminate at 610m (horizontal distance) from the start location which was 225m away from the runway centreline. The end drilling point targeted before the apron of the cargo complex. The HDC undercrossed live runway, taxiway and drain box culvert. To mitigate the risk of casing stuck in the soft ground, various layers of casing with different sizes was installed, depending on the soil conditions. For examples, large size (140mm in diameter) PW-casing can be installed in loose sand layers, followed by medium-size (115mm in diameter) HW-casing installed in dense sand & residual soil layers, and finally the smallest (76mm in diameter) NW-casing in highly weathered rock layers. The joint screw of casings shall be checked to minimize the failure at the casing joints.

Drilling commenced with an 21° inclination section for approximately 60m before encountering the rock. This translated to approximately 22m below ground level. NW drill casing is then socketed 3m into rock to ensure the inclination degree is maintained before further coring was carried out up to 82m in drilling length before the curvature section using steerable barrel.

Drilling encountered highly fractured rock and multiple core loss between 104.8m – 112.5m. See Figure 5. Flushing and conditioning of borehole prevented the drill string to reach the bottom hole (114.8m). Grouting was proposed to overcome fractured zone. Upon comparing with the longitudinal section from the gravity survey results, drilling may have encountered a weak zone.

Grouting was proposed as mitigation measures between 104m – 114.8m. The single valve (one way) Van Ruth grouting and water control packer was set at 104m where good quality rock was observed. In theory the volume of grouted section was 49L. In actual, over 200L of grout was pumped into the hole and allowed to set for 60 hours. Packer was retrieved successfully when drilling resumed. Between 109m and 114m, fresh rock was sampled implying that the hole may have deviated from the from the original trajectory. Survey was conducted to verify the trajectory and found that hole had deviated slightly but still within the designed alignment.

Figure 5. Weak zone core sample.

Drilling continued as planned and successfully cored through underneath Changi Airport Runway 1 which was in operation. Between 321m and 324.6m, brittle rhyolite was encountered and grouting between this section was conducted for 4 times without success. Grout appears to have slipped into the fractured area without any sign of grout sample being retrieved after re-drilling. Drilling parameters were not stable with high torque and high-water pressure being observed. The water pressure for HDC must not exceed 40 bars or risk bursting the sliding packer that is fitted on the HDC barrel. The function of the sliding packer is to hold the core barrel by packing on the borehole wall to control the direction of the drilling.

It was then decided to conduct a side-tracking (branch out) without having to exit the entry point of the HDC. See Figure 6. Branching out or side-tracking can only be conducted at good quality rock section and shall begin with NQ core barrel placed at the apex of curvature along the drilling trajectory. Drilling must be conducted at low in rpm and water pressure for branch out to be successful.

The objective of branching out is to lower the trajectory within the tolerance envelope (See Figure 7) with hope drilling can be overcome previous weak zone and continue with the rest of the drilling as planned.

Branching out was conducted successfully (See Figure 8), however similar weak zone was encountered at 319m before the earlier 321m zone. Drilling experienced high rotation torque which prevented the hole from advancing further. Grouting was

Figure 6. Prominent peak at 237.4m.

Figure 7. Original hole based on last survey point vs projected trajectory.

carried out between 315m and 322.7m and grout volume pumped was 10 times more than the theoretical volume. When re-drilling was conducted, grout sample was encountered at 290m and towards the end of the hole the no grout sample was retrieved. Drilling again experience high rotation torque prevented the advancement of the drill hole. The hole was terminated prematurely, and the team explored the possibility of second side track and move the drilling trajectory towards the north-west of the future tunnel without the need for intrusion.

Extensive planning and discussion were held to ensure the success of side tracking while maintaining the principle of HDC drilling parameters. Before the side tracking was conducted, the original hole and the first side track hole had to be grouted from 180m onwards to the hole end. See Figure 9.

Figure 8. Side tracking core sample.

Figure 9. Grouted section (longitudinal section).

The left side tracking was conducted at the lowest apex of the drilling trajectory and the objective is to cross the drilling trajectory to the north-west envelope without having to intrude into drilling path of future tunnel. See Figure 10.

Figure 10. Moving the trajectory from the right to left envelope.

The side tracking when as planned and successfully drilled underneath the runway for 3rd consecutive time before entering to the north-west of the drilling envelope. Upon reaching 587m highly fractured zone were encountered where solid core recovery (SCR) range from 0% to 28%. SCR is referred to as length of core recovered as solid cylinders which is then expressed as percentage of the length of the core run.

Drilling continued with limited core recovery to 607.3m. As a result of the fractured area, the core barrel was jammed on three occasions despite conditioning the drill hole with higher viscosity drilling fluid to stabilise the hole. Higher force was applied on the machine and hydraulic pressure was closed to machine limit at almost 280 bars. The high force forces the machine to stop. The jammed took 5 days before it was finally recovered. This gives indication that further drilling may increase the risk of drilling string getting stuck or potentially break along the hole. Having considered drilling have achieved the intended end point, it was then decided to terminate the HDC. Specialist projected the coordinates based on the drilling trend and the last survey point indicated that drilling is still within the tolerance envelope.

The total drilling length including the two-side tracking was approximately 870m and 93% of the drilling was coring through granite. The final isometric view of all the 3 holes is shown in Figure 11.

Figure 11. Isometric view of the entire holes.

4 CONCLUSIONS

A section of the cross island (CRL) alignment under crosses the busiest runway at Singapore Changi International Airport. Ground investigations using

conventional vertical bore holes along the alignment has limitations along runways and taxiways and closure of runway and taxiways affects the airport operations. The HDC, which avoids any impact to airport operations is used to determine the geological condition along the future tunnel alignment. The HDC method has proved that multiple branching out or side tracking within the main hole can be carried even despite moving the trajectory against the natural deviation. In this study, HDC has branched out twice to explore deeper depth and moving the drill trajectory to the north-west of the future tunnel alignment. The gravity survey data has helped in determining likely depth of rockhead to plan HDC trajectory. HDC is successfully carried out under the runway without any impact to the operations of airport.

ACKNOWLEDGMENTS

The Authors would like to extend their appreciation to Changi Airport Group for facilitating the site work during the COVID-19 pandemic and ensuring that the works are carried out smoothly and safely.

Theory meets practice: Evaluating discrepancies between theoretical settlement projections and actual measurements in tunnelling projects with tunnel boring machines

Elena Navarro*

TYPSA/AZTEC, Austin, USA

Eduardo Salvador & Fernando Diez

TYPSA, Madrid, Spain

ABSTRACT: The construction of tunnels using tunnel boring machines (TBMs) is a complex process that requires accurate predictions of ground movement to ensure safety and avoid costly delays. However, discrepancies between theoretical projections and actual measurements are common, leading to significant challenges during construction. This paper presents a comprehensive evaluation of settlement projections in tunnelling projects using the East Crosstown West Extension (ECWE) Project in Toronto as a case study. The study compares predicted settlements during the design phase with actual settlements measured during construction using readings of instruments installed on-site.

The paper reveals important insights into settlement behaviour in different ground conditions, including rock, soil, and mix-face conditions. Maximum settlements at the surface, volume loss, and shape parameter values for each case were analysed. To evaluate ground movement during the design phase, the methodology involved calibration of Volume Loss and Settlement Trough using three-dimensional Finite Element Models (FEM) and calculation of greenfield settlement at 100 m intervals along the tunnel alignment by empirical models including parameters obtained from the FEM. Automated Data Acquisition and Monitoring System (ADAMS) was used during construction to collect and process data from various types of instruments, enabling us to monitor behaviour in real-time, predetermine trends, and trigger alarms. This system proved to be a powerful tool for evaluating ground movement during construction on tunnelling projects.

Overall, our findings highlight the importance of evaluating theoretical settlement projections against actual measurements and the need for accurate predictions of ground movement during tunnelling projects. The methodology and monitoring system presented in this paper contribute to the advancement of theory and practice in the field.

1 INTRODUCTION

Metrolinx (Mx) and Infrastructure Ontario (IO), two provincial government agencies are leading the project to deliver the Toronto subway expansion for the Ontario Ministry of Transportation. The Advance Tunnel for Eglinton Crosstown West Extension (ECWE) Project includes 6.3 km of internal 5.75 m diameter twin bored tunnels that include open cut excavations for the launch and extraction shafts. The tunnel runs from the Renforth Drive to the Extraction Shaft near Scarlett Road, through urban areas and challenging mixed-face (soil and rock) conditions.

Ground induced movements due to tunnelling and potential impacts depend upon the anticipated

magnitude of settlements, their spatial distribution, as well as the type and proximity of Existing Adjacent Structures (EAS), Existing Adjacent Utilities (EAU), and other facilities. TYPSA completed the tunnel design to the highest standards to ensure that the excavation of the tunnels does not cause impact on EAS, EAU, and the highway operations.

2 GEOTECHNICAL CONDITIONS

The schematic longitudinal profile of the bored tunnels includes the distribution of the rock/soils/mix-face conditions (soils and rock) along the tunnel excavation.

2.1 Rock conditions – sound Georgian Bay Shale

The bedrock within the confines of the tunnel zone can generally be described as slightly weathered to fresh shale, commonly referred as “Georgian Bay Shale”, of Ordovician age. The Total Core Recovery (TCR) in the bedrock typically reaches 100%, while the Rock Quality Designation (RQD) ranges from 48% to 100% with an average value of approximately 82%. Based on the RQD values, the quality of the rock mass can be described as ranging from fair to excellent. Average value of the UCS is over 15 MPa. Schistosity is almost horizontal. No major faults have been detected along the tunnel.

In general, tunnelling works are located within the sound rock except on the transition areas between rock to soils and vice versa (mixed-face conditions). The weathered rock thickness ranges from 0 m to 7.6 m.

Elevated horizontal in-situ stresses are a known characteristic of the Georgian Bay Shale. A design major principal horizontal stress of up to 4.0 MPa was recommended. Based on the available information and the wide range on the major principal stress, a sensitivity analysis of the influence of the horizontal in-situ stress on the induced movements (analysed in terms of the horizontal to vertical in-situ stress ratio, K_0) was performed using values from 1.5 MPa to 4.4 MPa.

2.2 Soils conditions

Native soil is typically silt and clay tills (cohesive and non-cohesive) with SPT-N values ranging between 7 blows per 300 mm penetration to 50+ blows per 150 mm penetration. The cohesive tills are typically stiff to very stiff and the non-cohesive tills are typically dense to very dense (competent soils).

2.3 Mixed-face conditions

Native soil is typically silt and clay tills (cohesive and non-cohesive) with SPT-N values ranging between 7 blows per 300 mm penetration to 50+ blows per 150 mm penetration. The cohesive tills are

typically stiff to very stiff and the non-cohesive tills are typically dense to very dense (competent soils).

2.4 Groundwater conditions

The soils typically present in the tunnel alignment have been identified as aquitards (tills) and water bearing (granular materials). Based on the rock quality and the hydraulic conductivity of the shale, negligible water ingress was assumed within the rock sections.

Figure 2. Mixed-face distribution of materials at Martin Grove.

Figure 3. Mixed-face distribution of materials at Royal York.

3 INDUCED SETTLEMENTS – APPLICATION OF THEORY

The methodology of the complete analysis included the following sequence:

- Volume loss (VL) and settlement trough calibration by numerical models (3D FEM) at selected

Figure 1. Geological longitudinal profile of the bored tunnels.

sections along the bored tunnel alignment (twelve sections in total).

- Greenfield settlement calculation performed at 100 m intervals along the tunnel alignment by empirical models including VL and the other parameters obtained from the 3D FEM.
- Zone Of Influence (ZOI) definition as per outermost 1mm settlement contour line.
- Estimation of induced movements (settlement, joint rotation, and angular distortion) for each EAS and EAU based on the estimated induced movements.
- Assessment of the magnitude of impact for all Existing Adjacent Utilities (EAU) and Existing Adjacent Structures (EAS) EAS and EAU.

The two main parameters for the ground movement analysis, other than the tunnel dimensions and depth, are the Volume Loss (VL) and the shape parameter (K). VL and K are empirical parameters that are dependent on ground properties, as well as the performance of tunnelling operations.

The settlement analysis was based on an empirical estimation using the usual Gaussian distribution curve (Figure 3), using parameters previously obtained from complex finite elements model (PLAXIS 3D) following good industry practice references such as Boscardin and Cording (1989), New and O'Reilly (1982 and 1991).

The settlement cross-sectional curve and the maximum settlement can be obtained using the following equations:

VL = Volume Loss

D = Tunnel Diameter

E_h = horizontal strain

i = Kz; Distance from the centreline of the tunnel to the inflection point,

(K: settlement trough shape factor; z: depth of the tunnel centreline).

S = Settlement at distance "y" from the centreline of the tunnel

Figure 4. Representation of settlement through using a Gaussian Curve (New and O'Reilly, 1991).

Different recommendations available in the bibliography, as well as numerous values of VL from

previous projects and references in Toronto area have been reviewed. However, 3D Finite Element Models (FEM) were developed at selected sections along the bored tunnel alignment to calibrate the VL and parameter K considering the conditions of ECWE Project. These models included the specific geotechnical conditions at each section, the construction sequence of the tunnel (at every ring excavation cycle), TBM lining and grouting, and the effect of the first tunnel on the settlements induced by the second tunnel.

A total of twelve sections in sound rock, in soils, and in mix-face conditions were analysed by 3D FEM for the Volume Loss (VL) calibration and settlement trough estimation. 3D Finite Element Models' design parameters and geometry:

- Long-term (drained/effective stresses) behaviour of cohesive materials and rock.
- Ground behaviour models:
- Soils: Hardening soil model with small-strain stiffness.
- Rock: Hoek and Brown model.
- Ratios between horizontal and vertical in-situ stresses of rock above 3.5 (up to 4.5).
- The diameter of the tunnel is taken as the external excavation diameter (6.58 m).
- The distance between the two parallel tunnels is 10.90 m (between axes).
- Depth of the tunnels and GWL and strata taken from the Geotechnical profile.
- Assumed horizontal ground surface, strata, and ground water level.
- Model boundaries are established to avoid affecting the results.
- 40 rings (68m excavation) and 96 stages in total.
- The settlement trough is obtained after the first and second tunnel excavation.

Figure 5. FEM model used to calibrate the settlement parameters VL and K.

The following values are measures and analysed:

- Maximum settlement S_{max} (mm)
- Volume of the trough A (m³/m)
- Ratio between the volume of the settlement trough and the total excavated volume (Volume Loss, VL)
- Shape of the curve and inflection point (parameter k)

Figure 6. Settlement after one tunnel excavation.

Figure 7. Settlement after two tunnel excavation.

- Influence of first tunnel excavation over the settlements induced by the second tunnel (parameter f_{2T}).

Figure 8. Parameters taken from the Gaussian Curve obtained on the FEM.

4 THEORETICAL SETTLEMENT PROJECTIONS

Three sections in sound rock, four sections in soil, and five sections in mix-face conditions were analysed by 3D FEM for the Volume Loss (VL) calibration and settlement trough estimation.

Tunnelling in rock:

- The high horizontal stress of the rock produces a slight heave (<1 mm) at ground surface.
- Settlements are found to be negligible (<1 mm) in all cases.
- No volume loss VL.

Tunnelling in soils:

- Settlements depend on the ground conditions encountered at the tunnel face (proportion of gravels and fine sands and silts) being higher on gravels formation since these materials are stable with lower TBM face pressure.
- Considering the TBM face pressures from the face stability analysis, all settlements obtained are lower than 10mm (7.5 mm at the most

Figure 9. Tunneling in rock – 3D FEM and settlement trough.

P_f (kPa)	S_T (mm)	V_{L1}	S_T (mm)	V_{LT}	K	f_{2T}
85	4.9	0.25%	7.3	0.26%	0.49	1.01
100	3.0	0.16%	4.6	0.16%	0.52	1.01
115	2.2	0.12%	3.4	0.12%	0.53	1.01

- P_f : Face pressure (EPB mode)
- S_T : Maximum settlement at surface after construction of the first tunnel
- V_{L1} : Volume Loss induced by the construction of the first tunnel
- S_T : Maximum combined settlement at surface after construction of the second tunnel.
- V_{LT} : Volume Loss induced by the construction of both tunnels
- K : Settlement trough parameter
- $f_{2T} = S_T / (2 \cdot S_{1T})$. Two-tunnels factor

Figure 10. Tunneling in Soils – 3D FEM and settlement trough.

unfavourable hypothesis). The second tunnel induces slightly higher settlements (around 10%) that the first tunnel.

- The volume loss VL when both tunnels are excavated varies within the range 0.15% to 0.30% depending on the adopted face pressure. VL is lower for fine sands and silts and higher for gravels.
- The shape parameter K is between 0.50 and 0.60 depending on the tunnel depth and type of soil.

Tunnelling in mixed-face conditions:

- In general, the calculations show similar results for soils (gravels or fine sands and silts). However, with over consolidated glacial tills the behaviour differs mainly on the ground movements caused by the second tunnel, most likely due to the decompression caused by the first tunnel.
- Considering the TBM face pressures from the face stability analysis, all settlements obtained are lower than 10mm (8.6 mm at the most unfavourable hypothesis). The second tunnel induces slightly larger settlements (around 10%) than the first tunnel.
- The volume loss VL when both tunnels are excavated is found to be around 0.10% - 0.15%.
- The shape parameter K has been found to be between 0.45 and 0.65 depending on the on the cover thickness and on the type of soils.

Where the tunnel is excavated in soils and mix-face conditions (rock and soil), settlement calculations have been performed at 100 m intervals by empirical models including VL and the other parameters obtained from the 3D FEM.

The settlement curves from each tunnel have been added up to obtain the maximum settlement envelope. Figure 12 summarizes greenfield settlement results at 100 m intervals along the tunnel alignment when excavation in soils and mix-face conditions.

- S_T : Maximum combined settlement at surface after construction of the second tunnel.
- V_{LT} : Volume Loss induced by the construction of both tunnels
- K: Settlement trough parameter
- $f_{2T} = S_T / (2 \cdot S_{1T})$. Two-tunnels factor

Figure 11. Tunneling in mixed face conditions – 3D FEM and settlement trough.

structures, utilities, THESL, roadways, highways, existing buildings, bridges, HONI towers and any other entity impacted by the Works.

Data obtained on a continuous basis from all monitoring instruments installed and transmits immediate notifications of exceedances of any Limits of Movement recipients.

- Limit of Movement: The maximum values of displacement, deflection, distortion, settlement, heave, rotation, slip, and strain that shall not be exceeded.
- Alert Level: The instrumentation reading indicating the maximum permissible ground or structural movement due to Construction Activities, the maximum groundwater level permitted during construction, the maximum allowable load or stress imposed on members of a support of excavation system, or the maximum permissible vibration level.

Figure 12. Settlement due to tunnel construction in soils and mix-face conditions.

- Review Level: The instrumentation reading at which requires the assessment of the need to modify construction means and methods to limit further movement.

The response action plan (RAP) provides action guidelines for instrumentation trigger events for all Monitored Facilities, including all infrastructure associated with each facility. The specific contingency plans implemented depends on the specific structure and situation encountered.

If the triggered level is confirmed, an Initial Assessment led by the RAP Implementation Team will make sure that the applicable teams and specialists are informed of the trigger event along with the potentially affected structures, or the potential implications of the event. This team will meet within 24 hours of the confirmed trigger event. The RAP implementation team will assess the mitigation measures to be implemented if deemed necessary as each event is evaluated in a case-by-case scenario.

6 INSTRUMENTATION AND MONITORING DURING CONSTRUCTION (ADAMS)

Ground settlements are a result of a combination of ground movements including in soils, ground movement towards the face and lateral ground movement towards the shield, tail and shield grouting pressure, and in-situ earth and water pressure; in rock, in situ stress relief is due to overcut and shield concavity that causes inwards movement prior to installation of the segmental lining and tail grouting.

The Earth Pressure Balance Tunnelling Boring Machines (EPB-TBMs) guarantee the stability and reduction of risk by creating a balance of pressure with its surroundings and the immediate support generated by the ring's installation and injection behind the completed liner rings.

Construction is supported by an extensive Instrumentation & Monitoring Plan to ensure no impact. Monitored facilities, including structures, buildings, roadways, pavement structures and non-pavement surfaces, along the alignment are monitored by the following instruments:

- BMP (Building Monitoring Points) on buildings and selected utilities.
- SMP (Surface Monitoring Points), MPBX (Multiple Point Borehole Extensometer) and ST (Surface Targets) for pavement surface, non-pavement surface and roadways.
- UMP (Utility Monitoring Point) and VM (Vibration Monitor) for selected utilities.
- RP (Reflector-Less Point).
- WEC has established an Automated Data Acquisition and Management System (ADAMS). ADAM is a GIS web-based system that receives, interprets, organizes, and stores real-time monitoring data obtained on a continuous basis from all calibrated monitoring instruments installed on the Project. ADAMS also transmits automatic notifications of exceedances of any Limits of Movement via phone and email to identified recipients.
- Baseline readings are obtained on a regular basis, at least twice a week, for a minimum of 1 month prior to the TBM being within 100 m of an instrument location.
- Automated instruments (MPBX, RP) collect data every 15 minutes and readings are uploaded to ADAMS in real-time.
- Manual instruments (BMP, SMP, ST, SPZ) are monitored at specified frequencies according to the proximity of the instrument to the TBM face. All manual readings are uploaded to ADAMS within 4 hours of the reading. Monitoring reports are prepared highlighting any response level exceedances, plots of active instruments and related construction activities including

the position of the TBM, monitoring results and identification of trends to predict future results.

GIMP instruments are periodically updated in ADAMS, and it is customized to suit the specific Review and Alert levels of each instrument. The system can be accessed online, and Construction personnel, engineers, consultants, and client representatives can access.

Daily Monitoring Reports (DMR) include the plots in seven (7) days of data acquisition prior to issuance. Baseline, Monthly and As-Built Monitoring Reports (BMR, MMR, ABMR) include complementary detailed comprehension of the instrumentation information.

7 PREDICTED SETTLEMENTS VS ACTUAL SETTLEMENTS

Table 1. Instrumentation and monitoring observed per reach.

Material & Stations ⁽¹⁾	Instruments ⁽²⁾	Dates of Monitoring ⁽³⁾
ROCK 96+950 to 99+200	ST-14E; MPBX-7E; RP-45 ST-10W; RP-24	From 21-7-2022 to 24-10-2022
MIX-FACE 99+200 to 99+600	MPBX-23E; SMP-63E; SMP-69E; SMP-78E; SMP-83E; ST-41E; ST-45E SMP-68W; SMP-74W; SMP-75W; SMP-83W; SMP-88W; SMP-93W; SMP-97W	From 9-11-2022 to 3-04-2023
MIX-FACE 99+600 to 99+800	ST-50E; ST-59E; ST-68E ST-36W; ST-45W; SMP-A11 _7; SMP-A11_8	From 31-1-2023 to 18-04-2023
SOILS 99+800 to 100+400	ST-68E; ST-77E; ST-86E; ST-95E; ST-105E; ST-104E; ST-118E SMP-A11_7; SMP-A11_8; ST-54W; ST-63W; ST-74W; ST-81W; ST-88W	From 7-02-2023 to 9-07-2023

- (1) Stations are chosen for the purpose of comparison behaviour of those ground conditions distinguished in this paper (rock, mix-face, and soils) and are limited to the extent of available monitoring at this stage of the construction (STA 100+400).
- (2) Instruments shown on the table are those that have been comparable to the theoretical analysis based on their location although there are many other instruments along the shown stations.
- (3) These dates are considered representative for the purpose of analyzing the influence of the TBM excavation and generally include a range of dates before and after each TBM passes by the reviewed instruments.

Table 2. Predicted settlements (theory) vs actual settlements (construction).

Material & Stations	TBM ⁽¹⁾	Settlement Prediction (mm)	Measurements ⁽²⁾ (mm)
ROCK 96+950 to 99+200	TBM-E	<1	-1.1 to -0.3
	TBM-E & TBM-W		-0.3 to 1.3
MIX-FACE 99+200 to 99+600	TBM-E	1.5-2.5	0.2 to 3.5
	TBM-E & TBM-W	3.0-4.0	0.2 to 4.0
MIX-FACE 99+600 to 99+800	TBM-E	2.0-3.0	0.4 to 0.8
	TBM-E & TBM-W	3.0-7.0	0.5 to 6.0
SOILS 99+800 to 100+400	TBM-E	2.0-5.0	0.4 to 2.6
	TBM-E & TBM-W	3.5-7.5	0.7 to 10.3

- (1) TBM-E refers to East Westbound TBM and TBM-W refers to West Westbound TBM (first and second TBM respectively).
- (2) Measurements shown are not intended to be maximum and minimum overall readings but a representative range during the analysed timelines. Measures associated with TBM loss pressure events if any are not considered for comparison purpose. Positive values (+) show settlement, negative values (-) show heave.

8 CONCLUSIONS

- **While TBMs are excavating in rock materials:** Both heaves and settlements have been observed as predicted during the design due to the high horizontal stress. Readings are negligible, below 1.0-1.5mm, and comparable with the design.
- **While TBMs are excavating in mix-face conditions (sound rock, weathered rock, and soils):** The lower range of readings shows values below settlement prediction while the upper range of readings shows values very similar (around +/- 1mm difference) to those predicted for both cases, when the first TBM has passed through and when both TBMs have passed through.
- **While TBMs are excavating in soils:** A wider range of readings are available which are in general lower than those obtained with the empirical approach and numerical models when only one of the TBM has passed through. However, once both TBMs have passed through, the upper range of representative measures reach higher values than predicted in average. Those differences do not usually exceed +/- 3mm though which means no concerns in terms of potential design impacts.

In summary, and based on the results, the actual measurements available at this stage indeed show accurate predictions of ground movement during tunnelling. Evaluating ground movement during the design phase using three-dimensional Finite Element Models for volume loss calibration has been key to make possible the settlement estimation to be aligned with the real ground behaviour while tunnelling. This has also allowed for optimization in terms of mitigation measures (no mitigation measures were proposed).

The Automated Data Acquisition and Monitoring System used during construction to collect and process data is also allowing an immediate and continue response to calibrate TBM parameters on real time and adjust tunnelling excavation to control and limit induced movements.

ACKNOWLEDGMENTS

The authors wish to thank the Contracting Authority and their Technical Advisors for their continue

collaboration, technical understanding, and agile design submission approvals and follow-up during construction.

Thanks also to WestEnd Connect Construction Joint Venture for their daily support, advise, and constructive supervision during design stages and easy teamwork during construction phase.

Finally, our greatest appreciation to all at TYPSA's team, which provided their expertise and unflagging efforts for the design, unbeatable leadership and guidance as well as providing daily feedback during construction to facilitate an effective engineering of record.

Geotechnical and tunnel engineer’s role on the success of major tunnel projects delivery

Jiping Pan*, David Och & Antoni Kuras
WSP Australia Pty Ltd, Sydney, Australia

Geoff Bateman
Sydney Metro, Sydney, Australia

ABSTRACT: Successful delivery of major tunnel project with minimum risks to all stakeholders begins at the early stages of the project inception from preliminary study to reference design. This paper presents authors’ experience as Technical Advisor (TA) role for Sydney Metro City & Southwest project, Australia with respect to managing Client’s expectations and community acceptance through technically feasible solutions with minimum delivery risks. The project faced several challenges related to indigenous, geological, geotechnical, and subsurface boundary constraints. Indigenous heritage sites were assessed with alignment modified prior to Tender; geological and geotechnical issues like rock conditions were addressed during the ongoing design phases; additionally, the presence of specific features like historical brickpits site, Sydney Harbour needed careful consideration in the planning to ensure the safety and stability of the tunnelling process. All these constraints have been carefully managed and mitigated to ensure the successful completion of the project while minimising any adverse impacts on the environment and local communities.

Keywords: Major tunnel project, TBM, Geotechnical and tunnel engineer, Technical Adviser, Tunnel alignment

1 INTRODUCTION

Sydney Metro is Australia’s biggest public transport project. By 2030, Sydney will have a network of four metro lines, 46 stations and 113km of new metro rail.

Sydney Metro City & Southwest is Stage 2 of this project extending metro rail from the end of Sydney Metro Northwest at Chatswood. It features a twin 15.5km tunnels along with seven new underground stations between Chatswood and Sydenham. The line is extended beyond Sydenham with an upgrade of the existing Sydney Trains heavy rail line to Bankstown.

Construction began in 2017 with the first tunnel boring machine (TBM) in the ground before the end of 2018. This line is due to open in 2024 with the capacity to run a metro train every two minutes each way through the centre of Sydney.

Transport for NSW engaged the design joint venture (DJV) of WSP and AECOM, with architectural support from Cox and HASSELL together with constructability support from Rail Planning Services as Technical Advisor for the Sydney Metro City & Southwest works.

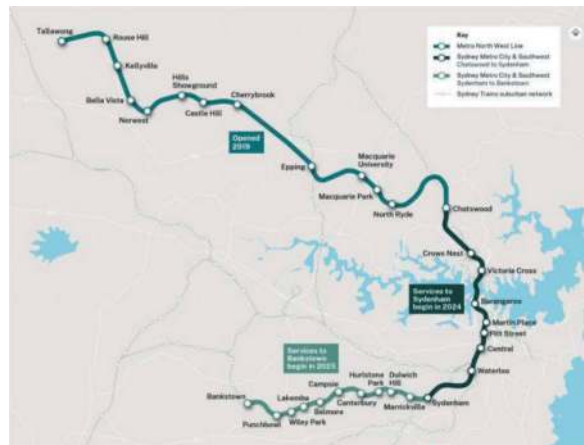

Figure 1. Sydney Metro – stage 1 & stage 2 alignment.

This paper explores the role of the Technical Advisor (TA) in identifying and mitigating risks during alignment optimisation in the project on behalf of Sydney Metro Authority, in particular for the tunnel and underground stations. It describes the

*Corresponding author: Jiping.Pan@wsp.com

typical challenges and associated solutions to manage the risks with due diligence, environments, heritage, and construction. It draws upon the author's experience of undertaking TA roles regarding geotechnical and tunnelling issues.

2 GEOTECHNICAL CONSIDERATIONS

Understanding the geology along the project alignment is a key to the successful and cost-effective delivery of the project, therefore, geotechnical site investigations are very essential in early stage of tunnelling projects.

Construction of underground stations and tunnels is a complicated process in any situation and involves huge costs which would multiply if proper planning were not exercised before starting the actual excavation. The excavation methods are intimately linked with the type of ground materials to be excavated. Choice of the right method will, therefore, be possible only when the nature of the rocks and the ground all along the alignment is fully known. This is one of the most important objectives of geological investigations.

2.1 Desktop study

A geotechnical desktop study has been undertaken to gather and collate relevant geotechnical information available along the proposed rail corridor. This study would provide basic information of the stratigraphy, identified and inferred vertical linear fault zones expected as well as gaps of geological information within the proposed rail corridor.

Findings from this desktop study include:

- Proposed running tunnels will be predominately within Hawkesbury Sandstone, which is typically a highly abrasive medium to coarse-grained sandstone with common clay seams;
- A section of the alignment from Sydenham to Redfern will encounter Ashfield Shale in tunnel;
- The proposed Central Station, Pitt Street Station, Martin Place station, Barangaroo Station and Victoria Cross Station will be constructed within Hawkesbury Sandstone;
- The proposed Waterloo Station and Crows Nest station will be constructed within Ashfield Shale (residual), Mittagong Formation and Hawkesbury Sandstone;
- Several identified and inferred vertical linear fault zones are expected along the project corridor;
- Relatively high horizontal in-situ stress levels within the Sydney Basin strata.

2.2 Geotechnical site investigation

Following the gap analysis of all existing available information (including the available borehole information collected in the desktop study) a suite of

geotechnical investigations was proposed. These investigations broadly included: geophysical survey under the Sydney Harbour; drilling of drilling of boreholes on land and under the Harbour; and field/laboratory testing. These investigations have focused on the harbour crossing, proposed stations locations, tunnel portal/dive sites and potential fault zones. The site investigations included:

- 36 “on-land” boreholes to depths of between 20 m and 64 m below the ground surface along the proposed tunnel alignment;
- 23 overwater boreholes under Sydney Harbour, in water depths of about 14 m to 23m;
- 30 overwater cone penetrometer tests (CPTs) probed the sediments along the proposed harbour crossing;
- Bathymetry and geophysical investigation under the Harbour
- In-situ stress testing in 4 on-land boreholes and 2 overwater boreholes;
- 14 groundwater monitoring holes.

2.3 Geological structures along the project corridor

Understanding the structural condition of the rock is important to tunnelling projects. This includes the extent and attitude of major structural features such as folding, faulting, unconformities, jointing and shearing planes.

It is obvious that with the help of above information, the engineers could propose a number of alternative tunnel routes to connect the two places, and in most cases, even decide about the general run of the tunnel.

The deformation of rock discontinuities is a fundamental component of the performance of a jointed rock mass. The rock structures or discontinuities within the Ashfield Shale, Mittagong Formation and Hawkesbury Sandstone and cross cutting dykes can be generally summarised in Table 1 and the typical geological conditions (Figure 2).

2.4 Geotechnical interpretive report

To provide geotechnical advice for the design of the tunnel alignment, locations of station caverns, tunnel portals, groundwater control, and construction associated risk management, a ProjectWise Geotechnical Interpretative Report (GIR) is prepared, which covers the following:

- Project wise topography and geology;
- Geotechnical profiles at the locations of the proposed stations, dive structures, portals and running tunnels;
- Characterisations of soils and rocks along the alignment;
- Characterisation of harbour sediments;
- In-situ stress regime;

- Geotechnical design parameters;
- Groundwater;
- Contamination.

These provided project specific geotechnical and geological information for the team in consideration of tunnel alignment, station locations, and groundwater control measures.

Table 1. Geo-structures identified along the project corridor.

Name	Description	Potential locations
Martin Place Joint Swarm	A concentration of structural features such as faulting, sub-vertical joint swarms. It has been recorded to contain closely spaced jointing, and zones of crushing and shearing.	In vicinity of Pitt Street Station and Martin Place Station
GPO Fault Zone	Multiple crush zones and closely spaced jointing and faulting with normal and reverse fault offsets. The width of the principle shear zones of the fault likely to vary from less than 10 m to over 20 m in width.	Tunnels between Martin Place Station and Barangaroo Station
Luna Park Fault Zone	Up to 3 m wide 'crushed' zones and closely spaced sub-vertical jointing and faulting/shear zones. The faulting shows normal and reverse movement as well as strike-slip movement. Widely spaced joints are encountered either side of the fault zone.	Crossover cavern at north of Barangaroo Station and tunnels under the harbour
Low Angle Thrust Faulting	Low-angle usually parallel to cross bedding will be encountered across the alignment associated with the sub-vertical geological structures.	Various locations
Dykes	Great Sydney Dyke, Ultimo Dyke and other Pittman Dykes, generally up to 6 m in width and comprises various intrusive materials such as basalt, alkali olivine basalt, or dolerite in various sources.	Central Station, tunnel at various locations

3 HARBOUR CROSSING

The Sydney Harbour crossing is a key element of Sydney Metro, City & Southwest. Limited geotechnical information existed, therefore, detailed geophysical/geotechnical investigations to facilitate early planning and design work were undertaken for three potential options to construct the harbour crossing, which would involve either full rock face excavation by Tunnel Boring Machine, mixed face

Tunnel Boring Machine or the installation of immersed tubes. Concurrently with the development of the concept design phases, site investigations were carefully staged. This approach allowed for real-time adjustments as both geological interpretation and the concept design evolved. A wealth of geophysical and geotechnical data was meticulously gathered to characterise the terrain beneath the harbour floor. This extensive data acquisition aimed to identify potential geotechnical challenges associated with tunnelling beneath the harbour.

The primary objectives of these site investigations were threefold: to delineate the seabed profile, determine sediment thicknesses, and predict the topography of the underlying rock (Figure 3), as documented by Och et al. (2017). The results of these investigations revealed a significant deviation from the originally anticipated rock profile. This deviation, based on prior technical literature, indicated that the underlying rock profile may, on average, be situated 12 metres deeper than initially presumed.

In response to these significant findings, a collaborative effort ensued between geotechnical engineers and tunnel engineers. They embarked on the task of devising a series of revised metro alignments. These revised alignments aimed to identify the most optimal route for the running tunnel, capitalising on the newly interpreted seabed and bedrock profiles. The overarching goal of this endeavour was to elevate the running tunnel alignment, ensuring the shallowest possible rail level at Victoria Cross Station, while maintaining the necessary ground and rock cover for the metro running tunnels beneath the harbour.

In the development of these alignment options, meticulous attention was given to various design criteria, encompassing track alignment, running tunnel cover requirements, and the placement of cross passages beneath the harbour. The application of these guidelines led to the generation of 12 alignment options, from which nine options were selected for further in-depth assessment.

Key factors considered in the option study for tunnel alignment under the harbour included:

- Depth to the next station;
- Placement of mined cross passages and low point sump;
- Spacing between cross passages;
- Sediment thickness with a minimum 1-meter rock cover;
- Speed restrictions;
- Minimum radius of curvature;
- Length of the tunnel beneath the harbour;
- Assessment of geotechnical risks related to trenching and deep excavation;
- Opportunities for locating a nearby ventilation shaft.

Figure 4 below provides a visual representation of the preferred alignment in conjunction with the geological conditions.

Figure 2. Graphical geological interpretation model, Sydenham (Downline) – Central – Chatswood (Upline).

Figure 3. Palaeogeographical rock surface -Seismic Reflection Survey (projected alignment in red) (Och et al 2017).

Figure 4. Interpretative geological long-section of the conditions along the proposed Sydney Harbour crossing (Och et al 2017).

The harbour site investigation including underwater drilling, seismic reflection survey provides sufficient geotechnical information for reference design and selection of construction method of harbour crossing from the three options described above (details were discussed by the authors in a paper presented to WTC 2017 (Och et al 2017)).

4 BUILDINGS, INFRASTRUCTURE AND UTILITIES

Construction of the running tunnels, station caverns and underground structures will cause ground movement with the potential to cause damage to the existing buildings, infrastructure and utilities. Buildings and infrastructure that falls within construction induced settlement troughs (zone of influence) will be affected to varying degrees depending on a number of factors including their relative position, form of construction and current condition. It is the responsibility of geotechnical engineer and tunnel engineer to minimise material adverse impacts on existing ground conditions or the performance of any existing infrastructure and utilities.

All existing buildings, tunnels, roads and utilities within the zone of influence of underground construction need to be evaluated for potential movement and distortion due to induced ground movement. In this context, the zone of influence is defined as the envelope within a 3mm settlement contour (i.e. commensurate with survey accuracy). Assets that fall outside of this zone generally do not need to be assessed.

4.1 Assets information collection

To enable the impact assessment, identification of the assets along the project corridor to establish a database is the first task to be carried out. Information in relation to buildings and infrastructure within the zone of influence has been obtained from the following sources:

- Walking through inspection along the project corridor;
- Aerial photography/imagery for the project area;

- As-built drawings obtained from public and private properties;
- Development applications from councils for future developments;
- Targeted building basement surveys;
- Roads and Maritime Services (RMS) including as-built information of existing road tunnels and future proposed road tunnels;
- Sydney Trains (as-built information from plan rooms);
- Utility authorities and companies.

In cases where as-built drawings are not available, preliminary assumptions have been applied in respect of the building foundation type and depth based on past project experience and engineering judgement.

4.2 Existing buildings

To be able to assess impacts of ground surface settlement induced by tunnelling works, settlement of contours along the alignment have been generated by green-field approach. This is considered as adequate at reference design stage. The approach taken to assess affected buildings applies analytical methods to filter buildings of concern. The processes have been divided into three phases of assessment:

- Preliminary assessment (level 1);
- Second order assessment (level 2) and
- Detailed evaluation (level 3).

The intent of the first two phases of evaluation is not to precisely quantify the effect of settlement, but to determine which buildings are potentially at risk of damage and thus require further evaluation. For this reason, only the preliminary assessment and second order assessment has been undertaken at the planning stage.

Well established and industry recognised criteria have been used at preliminary assessment - level 1 (CIRIA, 1996). The application of these criteria provides a means of demonstrating that Sydney Metro City & Southwest can be constructed without causing unacceptable effects to impacted buildings.

In total, about 1000 buildings were found to lie within the zone of influence of construction induced settlement (i.e., 3mm settlement contour). Of which, 253 buildings were identified within 10 mm or greater contour and were further taken forward for further review. Further assessments of these 253 buildings, 46 were identified as requiring a more rigorous level 2 assessment. This level 2 assessment also applies greenfield predictions of settlement to assess impacts. However, at this stage calculations are undertaken to estimate the angular distortion and horizontal strain that would occur beneath the foundations of critical buildings were they to follow the estimated settlement trough. The calculated angular distortion and horizontal strain are assessed in combination to determine an appropriate damage category based on the Boscardin and Cording (1989)

method. From the subsequent level 2 assessments all of these buildings were predicted to have negligible/slight risk ratings.

4.3 Brickpits

The history of brickpits in St. Peters, as well as across Sydney, is characterised by their pivotal role in the region's early brickmaking industry during the late 19th and early 20th centuries. These clay excavation sites were instrumental in supplying raw materials for the construction of countless buildings that define the city's architectural heritage. However, a significant issue arose when these brickpits were abandoned and repurposed as landfills, a common practice during the mid-20th century. The subsequent filling of these sites with various waste materials, including construction debris and industrial waste, has posed a significant challenge for future infrastructure projects, particularly tunnels due to their hidden locations and without the use of historical airphotos they would remain unidentified (Figure 5).

Figure 5. This image highlights the piles used to support the unit development (<http://www.waterway.com.au/projects/piling/sydney-park-village-piling>).

A noted finding was a property near to Erskineville that had a unit complex constructed above what was identified as a historic brickpit from historic air photography assessments. During early stages of reference design, a graphic was found during searches of piles used to found the complex on (Figure 6) but

further assessment could not confirm the depth these piles were piled to and therefore, was identified as a key risk.

4.4 Existing tunnels

Unlike building structures, there are no well-defined methods of risk assessment for existing tunnels. In part, this is because it is difficult to assess the effect of tunnel excavation on existing tunnels using empirical methods. As such detailed numerical modelling and analysis may need to be undertaken at a preliminary stage to judge the degree of damage that could be caused to existing tunnels from construction of adjacent underground metro infrastructure.

To develop the Reference Design critical sections have been identified that have warranted particular attention to prove, with a high level of certainty, the feasibility of their construction and method of support; as well as the acceptability of excavation impacts to existing nearby underground existing tunnels.

Fifteen existing tunnels in proximity to the Sydney Metro City & Southwest alignment have been identified as requiring assessment. Of these, six were analysed using numerical modelling given their close proximity to the Sydney Metro City & Southwest alignment. It has been concluded from the results that the impacts from the metro construction on these existing tunnels in terms of imposed movement will be acceptable.

Figure 6. Airphoto comparison (a) 2017 (TfNSW) and (b) 1943 (RTA – TfNSW) of the Erskineville – St Peters area highlighting brick pits and recent developments. (<http://www.waterway.com.au/projects/piling/sydney-park-village-piling>).

4.5 Utilities

A comprehensive staged assessment has been diligently conducted to evaluate the utilities associated with the Reference Design. The primary objective of this assessment has been to discern and highlight utilities of paramount significance. This determination has been influenced by several critical factors, including their functional importance, physical dimensions, spatial proximity to the metro alignment, and their heritage status.

In the context of the Reference Design, a subjective evaluation has been meticulously undertaken to appraise the anticipated repercussions arising from ground movements induced by metro construction activities. This evaluative approach has entailed the judicious application of engineering expertise and fundamental principles, complemented by insights gleaned from prior analogous projects.

Notably, established criteria widely acknowledged within the industry have been thoughtfully considered. These criteria encompass various aspects, such as the material composition of pipes and cables, the length of piles, the nature of joints, and the methodologies employed for backfilling. These parameters serve as essential yardsticks for gauging the relative risks associated with utilities.

A preliminary assessment was systematically carried out, encompassing a total of 95 utilities of substantial significance that lie beyond the purview of future metro stations and tunnel excavations. From this initial pool, a judiciously chosen subset of 15 utilities was identified for further, in-depth examination. The outcomes of this extended evaluation affirm that, while the majority of the scrutinised utilities are unlikely to suffer adverse impacts attributable to the Sydney Metro City & Southwest Project, certain exceptions do exist. Notably, major water tunnels, exemplified by the City Tunnel spanning from Potts Hill to Moore Park, and several other brick-lined stormwater tunnels of heritage significance necessitate meticulous protection measures.

5 INDIGENOUS HERITAGE AND BRICKPIT

The originally proposed metro alignment had running tunnels under the Newtown-St Peters area, which was referred to as the ‘Kangaroo Ground’. Local Aboriginal peoples, the Gadigal and Wangal, hunted kangaroo on the grasslands here, and fished and camped at the swamps, creeks and rivers that crisscrossed the area (City of Sydney, 2018).

The north-west part of the park is on the edge of a Wianamatta Shale from which brickmaking clay was extracted in the 19th and 20th centuries and buried below man-made reserves but identified in historic air photography.

To avoid the potential impacts on the indigenous heritage land, the tunnel alignment was revised from the initial location further north relative to the constructed location under Sydney Park Road (Figure 5).

6 DISCUSSIONS

The Sydney Metro City & Southwest project was a significant endeavour that involved the construction of new metro rail lines, underground stations, and tunnels in Sydney, Australia. We focused on the importance of a coordinated, multi-disciplinary approach in managing risks and making critical

decisions during the planning and execution of such a complex infrastructure project.

The success of the Sydney Metro City & Southwest project hinged on the collaboration of various disciplines, including geotechnical engineering, tunnel engineering, architecture, and heritage preservation. This coordinated effort ensured that risks were identified and mitigated effectively, and that the project aligned with the diverse requirements and challenges it faced.

One of the fundamental aspects of this multi-disciplinary approach was geotechnical considerations. Understanding the geological conditions along the project's alignment was crucial for cost-effective and successful tunnel construction. The geotechnical desktop study provided valuable information about the types of rock and soil encountered, potential fault zones, and in-situ stress levels. This knowledge was essential for selecting appropriate excavation methods and optimising tunnel routes.

Geotechnical site investigations followed the desktop study, involving drilling boreholes, conducting field and laboratory tests, and assessing the structural condition of the rock. These investigations provided data that informed the project's design parameters, including tunnel alignment, station locations, and groundwater control measures.

The Sydney Harbour crossing, a key element of the project, exemplified the need for a multi-disciplinary approach. Limited initial geotechnical information prompted detailed geophysical and geotechnical investigations to determine the best approach for tunnel construction under the harbour. The collaboration between geotechnical and tunnel engineers allowed

for the adjustment of alignment options, accounting for the reinterpreted seabed and bedrock profiles.

The consideration of existing buildings, infrastructure, and utilities was another critical aspect of the project. A multi-disciplinary team assessed potential ground movements and their impacts on surrounding structures. Buildings, tunnels, and utilities within the project's zone of influence were evaluated for risks and potential damage, with a focus on minimising adverse effects.

Furthermore, the project's engagement with Aboriginal Indigenous heritage and the recognition of these brickpits buried along the alignment underscored the importance of a multi-disciplinary approach. A coordinated effort between heritage experts, geologists, engineers, and environmental specialists ensured that the project respected and preserved cultural heritage and were not impacted by buried historical sites (Figure 7).

7 CONCLUSIONS

In conclusion, the Sydney Metro City & Southwest project exemplifies the significance of interdisciplinary collaboration in effectively managing risks and addressing complex challenges in infrastructure development. Geotechnical assessments and site investigations, alongside adaptive planning, played pivotal roles in overcoming major obstacles such as Sydney Harbour crossing, building basements and brickpits. Furthermore, the project's commitment to heritage preservation and cultural sensitivity highlights the value of a holistic approach in achieving its objectives.

ACKNOWLEDGMENTS

The authors extend their gratitude to the Sydney Metro Authority, and the collaborative efforts of the Technical Advisor (WSP AECOM JV) and Transport for New South Wales (TfNSW) team were instrumental in achieving these results.

ABSTRACT: Three innovative and very cost-effective concepts for the construction of tunnels using the TBM technique are presented: the TISB concept for tunnels in soft soil, in seismic areas; and the TMG and TMF concepts for railway and road tunnels, respectively. Some application examples are presented that show the benefits that can be obtained by using these concepts in creating sustainable infrastructure around the world.

Keywords: Traffic Tunnels, TBM, TISB, TMG, TMF, Sustainability

1 INTRODUCTION

Sustainability is a fundamental issue in the construction of infrastructure nowadays, whereby the use of natural resources to satisfy present needs should not compromise the satisfaction of the needs of future generations.

Thus, today, the concerns of decision-makers focus on building of infrastructure with increasingly reduced costs in terms of life cycle, that is, infrastructure that consume ever smaller amounts of materials and are as reliable as possible, to prevent incidents from occurring.

In this context, tunnels play a significant role, as they are increasingly used in the construction of transport infrastructure, for both railway and roadway networks.

The TBM (“Tunnel Boring Machine”) technique is currently most used, providing significant savings in terms of cost and construction time, making it common for a TBM to build more than 0.5 km of tunnel per month.

The TBM technique has also other advantages. In urban areas, for example, it allows the reduction of impact on the surface, practically eliminating the need for use surface space. In underwater tunnels, the TBM technique also allows the reduction of the environmental impact, allowing for non-disturbance of the sea bed.

With the technological progress that has taken place, there are now different types of TBMs (Open-Face, EPB, Mixshield, etc.), adapted to specific conditions, of the ground, which make possible to excavate in all types of conditions.

Therefore, the TBM technique is nowadays also the most promising for tunnel construction in the future. However, despite the progress made, the construction of TBM tunnels still faces important challenges.

With regard to rail and road TBM tunnels, major challenges are, among others: i) improving the reliability of structural safety when built on soft ground in seismic areas, ii) improving safety during operation, as well as iii) reducing construction costs.

To face these challenges, three new concepts were recently developed by the author: the TISB concept, that is, “Tunnel of Improved Seismic Behavior”; the TMG concept, that is, “Tunnel Multiple Gallery”; and the concept TMF, that is, “Tunnel Multi-floor”.

The TISB concept makes it possible to provide adequate structural safety to TBM tunnels built on soft ground in seismic areas, while the TMG and TMF concepts, for rail and road TBM tunnels respectively, allow, with adequate arrangements of the tunnel’s cross section and the adoption of innovative additional measures, a significant improvement in safety during operation and at the same time a significant reduction in construction costs.

This paper presents the most relevant aspects of the author’s book dedicated to this theme, entitled “Innovation in TBM Traffic Tunnels” (ISBN 9780367701635) (Pompeu-Santos, 2023), recently published, in March 2023, by Taylor & Francis (UK).

2 CHALLENGES IN TBM TUNNELS

2.1 TBM tunnels in soft ground in seismic areas

As in TBM tunnels the connections between precast segments have no tensile strength, ductility is low (they are a kind of “LEGO”), therefore they are suitable for stiff ground (rock, stiff clay, compacted sand, etc.), where stability is essentially ensured by the surrounding ground and the precast segments fundamentally serve as a finishing.

*Corresponding author: pompeusantos@sapo.pt

In the case of TBM tunnels built on soft ground (alluvia, soft clay, loose sand, etc.), in seismic areas, there is the risk of collapse due to horizontal movements of the soil during earthquakes, unless very thick precast segments are used.

Soil treatments, sometimes adopted to improve seismic behavior, are very expensive and sometimes being impractical, do not always guarantee structural reliability.

The adoption of seismic joints in the transitions to the stiff ground, as in the case of the Eurasia Tunnel, in Istanbul, Turkey (Figure 1) (Schmid et al., 2020), solves the problem in those areas, but not the effects of transverse displacements of the tunnel, nor the ovalization of the sections along the tunnel.

In addition, in the case of tunnels formed by two or three tubes connected by transverse tubes that act as cross passages between them, the relative displacements between the main tubes during earthquakes can risk the collapse of the connections to the transverse tubes.

To overcome these limitations, the TISB concept was recently developed by the author.

Figure 1. Eurasia Tunnel. Seismic joints.

2.2 Conceptual solutions and safety during operation of rail tunnels

In conventional railway TBM tunnels, after the construction of the outer wall, a filling is placed at the base, creating a platform for the circulation of the trains, with the two directions of traffic placed side by side.

However, to satisfy safety requirements (EU, 2008; UIC, 2003), the installation of two traffic directions side by side is only possible in short tunnels. In tunnels longer than 1 km, due to the chock of the piston effects of trains in opposite directions, their speed will have to be quite limited. Furthermore, it requires the adoption of complex ventilation systems (transverse or semi-transverse) to control the flow of smoke inside the tunnel in fire situations.

It has therefore become common, particularly in tunnels included in High-Speed lines, to adopt the dual-tube tunnel solution, in which two separate tunnels are built, each for one direction of traffic, and a system of cross passages, regularly spaced,

interconnecting the two tubes, for access by emergency personnel and the rescue of users in incident situations. In these situations, users will leave the incident train and move to the other railway tube through the cross passages, to later be evacuated via another train.

The safety measures in the dual-tube tunnels are generally quite complex. A remarkable case is the Gotthard-Base Tunnel, in southern Switzerland (Figure 2) (Anagnostou, 2013) opened to traffic in 2016, with tubes of 8.40m in inner diameter and 9.40m in diameter of the excavated section, and 57.1 km extension, the longest traffic tunnel in the world.

Figure 2. Gotthard-Base Tunnel. Cross-section.

In this tunnel, safety during operation is based on two large MFSs (“Multi-Functional Stations”), located about thirds of the length of the tunnel, which include emergency stops for trains in each tube, track crossings, ventilation shafts with giant fans at the ends and galleries with direct access to the outside. In the event of an incident, the evacuation of users is carried out using emergency trains permanently parked next to the tunnel portals.

Despite all these measures, the recent derailment of a train inside the tunnel meant that it will be out of operation for several months.

In long underwater tunnels, it is usual to use the three-tube tunnel solution, in which, in addition to the two railway tubes, a third tube is adopted, placed between the other two, to serve as a service gallery for the evacuation of users and the access for emergency services in incident situations, all three connected by cross passages.

This is the case of the Channel Tunnel, built in the 90s, with railway tubes with an inner diameter of 7.60m and an excavated section of 8.80m in diameter (Figure 3) (Getlink, 2021), and a length of 50.5 km, still today one of the longest in the world.

Figure 3. Channel Tunnel. Cross-section.

The tunnel is provided with longitudinal ventilation through ventilation buildings installed in the portals. To alleviate the piston effect of the trains, regularly spaced 2.0m diameter relief ducts were created, connecting the railway tubes, however, the system did not prove to be effective and was neutralized.

For fire-fighting, a classic system through fire trucks was originally adopted, which, after some setbacks, was replaced by a modern WFS (“Water Based Fire Fighting System”) based on high pressure water mist nozzles, installed in 4 “safe stations” in each of the railway tubes. In the event of an incident, the evacuation of users is carried out using wheeled vehicles specially designed for this tunnel, which circulate inside the service gallery. At thirds of the tunnel length two large caverns were also created for the installation of train crossings.

This tunnel has already suffered several incidents, some with serious consequences.

However, with the progress made in the technology of TBMs and the possibility of building tunnels with large diameters, the solution of the mono-tube dual-gallery tunnel also emerged, in which a single TBM tube, provided with a separating wall in the middle, houses two independent railway galleries, placed side by side. This is the case of the Groeneheart Tunnel, in the Netherlands, opened to traffic in 2005, with an inner diameter of 13.30m and an excavated section of 14.87m in diameter (Figure 4) (Bouygues, 2001), and a length of 7.2 km.

In the event of an accident or fire inside one of the rail galleries, users leave the incident gallery and enter the adjacent gallery through emergency doors regularly arranged along the separation wall, to later be rescued by another train. However, the escape doors open directly into the adjacent gallery, which can make it difficult to control smoke entry into that gallery.

Figure 4. Groeneheart tunnel. Cross-section.

The separation wall has openings at the top to relieve the piston effect of the trains. Ventilation is of longitudinal type, with jet fans. In operation for almost two decades, the tunnel has not yet experienced any significant incidents.

In short, different conceptual solutions (with three, two or one tube) and different safety concepts can be adopted in rail tunnels. In solutions with two or three tubes, safety systems are in general quite complex and expensive. The aforementioned mono-tube

solution proved to be very economical, although its safety concept has some weaknesses.

To overcome these limitations, the TMG concept was recently developed by the author.

2.3 Conceptual solutions and safety during operation of road tunnels

In conventional road TBM tunnels, after the construction of the outer wall, a filling is placed at the base, creating a platform for the circulation of vehicles (cars, trucks, etc.), with the two directions of traffic placed side by side. However, as in railway TBM tunnels, the installation of two directions of traffic is only possible in short tunnels with a single lane in each direction.

In fact, when there are two or more lanes in each direction, the required diameter would be so large that it would become impractical. Furthermore, in tunnels longer than 0.5 km, to comply with safety requirements: ventilation, firefighting, etc. (EU, 2004), placing bidirectional traffic on the same tube requires very complex and expensive technical systems.

Thus, as in railway tunnels, the double-tube tunnel solution is now commonly used, in which the tunnel is formed by two separate tubes, each for one direction of traffic, the two being interconnected by regularly spaced cross passages. In incident situations, users leave the incident tube and move through the cross passages to the adjacent tube, from where they will later be evacuated by conventional buses.

There are several remarkable cases of this type of solution, for example, the Changjiang Tunnel in Shanghai (China), opened to traffic in 2009, formed by two tubes with excavated diameter of 15.43m and internal diameter of 13.70m (Figure 5) (Huang, 2009), with 3 lanes each and efficiency indexes (ratio between the roadway cross-sectional area and the internal cross-sectional areal) of 0.45. In the middle of the lower part of each tube there are also galleries for the installation of an express train.

In this tunnel ventilation is of the semi-transverse type, with ventilation buildings at the portals and a duct along the upper part of the road galleries, in addition to jet fans, regularly distributed. The firefighting system is relatively complex, using fire trucks that enter through the portals of the non-incident tunnel tube.

Figure 5. Changjiang tunnel. Cross-section.

The evacuation system is also quite complex, given the need to make the evacuation of users from the road

galleries compatible with that of the railway galleries, being carried out through the non-incident tunnel tube, which is accessed through the cross passages.

With the development of TBMs with increasingly larger diameters, the mono-tube dual-deck tunnel solution also began to be adopted in road tunnels, in which a single large-diameter tunnel with an adequate arrangement of the cross-section houses two overlapping road galleries, each for one direction of traffic, which are connected to each other through vertical galleries, or to the outside through evacuation galleries. Safety systems are diverse and generally quite complex.

An outstanding example is the SR99 Tunnel, in Seattle (USA), opened to traffic in 2019, with two lanes in each direction, 17.50m in diameter of the excavated section (the second largest in the world) and 15.70m in inner diameter (Figure 6) (Jiang et al., 2019), and an efficiency index of 0.47. There are also cases of tunnels of this type with smaller diameters, but with limitations on the height of the vehicles that can use them.

A solution with three lanes in each direction was also developed (and the respective TBM was designed), the Orlovski Tunnel, in Saint Petersburg (Russia) with an excavated section of 19.25m in diameter, but it was not built.

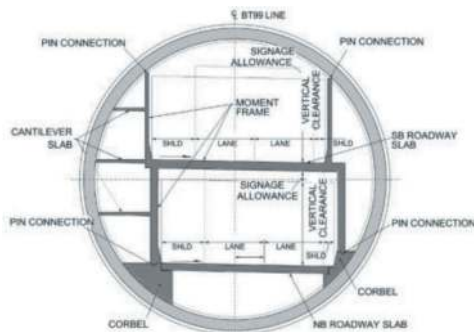

Figure 6. SR99 tunnel. Cross-section.

In the SR99 Tunnel, the ventilation system is of the semi-transverse type, with regularly distributed jet fans and four giant fans in the portals with a ventilation duct placed next to the road galleries. The fire-fighting system is a WFS, based on high pressure water mist nozzles and organized in sections. The evacuation of users in the event of an incident is carried out through escape doors that give access to longitudinal evacuation galleries, which lead to the tunnel portals.

In short, in road tunnels, in addition to the dual-tube solution, the mono-tube solution with superimposed road galleries is also being adopted. In both cases, the safety concepts are quite complex and expensive.

Regarding costs, although the cross-sectional areas of mono-tube and dual-tube tunnels are similar, the unit cost (ratio of the overall construction cost to the excavation volume) of tunnels with smaller

diameters is higher, in addition to the need to build a system of cross passages between the two tubes, so their cost will in principle be higher.

To respond to these challenges, the TMF concept was recently developed by the author.

3 THE TISB, TMG AND TMF CONCEPTS

3.1 The TISB concept

The TISB (“Tunnel of Improved Seismic Behavior”) concept is an innovative solution for TBM tunnels, when the referred tunnels are built in soft ground, in seismic areas, allowing the tunnel be provided with adequate resistance and ductility, without a significant increase in construction costs. It will also allow for the strengthening of existing TBM tunnels, using them as external formwork for the execution of the interior strengthening.

The TISB concept is illustrated in Figure 7 (INPI, 2008).

Figure 7. Illustration of the TISB concept.

In the TISB concept, the tunnel is formed by two concentric tubes; an outer tube (1), which is a conventional TBM tunnel, and an inner tube (2), which is subsequently built inside the outer one.

The outer tube (1) is thus formed by precast segments mounted by the TBM, while the inner tube (2) is subsequently cast, using the latter as outer formwork. Within the thickness of the inner tube (2) longitudinal reinforcement bars (5) and transverse reinforcement bars (6) are laid, both in two layers, which are confined by confinement bars (7), so as to provide the tunnel with adequate strength and ductility. Reinforcement bars (8) protruded from the precast segments connect the two tubes.

Where the tunnel can be subjected to significant vertical displacements (for example, due to an increase or decrease in the height of the overburden on weak soil), the tunnel will be provided with supports, regularly spaced along the tunnel axis. Those supports are composed of groups of piles (4) with great horizontal ductility, arranged in the longitudinal and transverse directions, which are anchored at the top in large blocks of jet-grouting (3) surrounding the outer tube (1), and at the base in the stiff ground below, so to resist vertical loads, while allowing horizontal movements of the tunnel during earthquakes, functioning as a kind of “movable bearings”.

The TISB concept thus leads to the obtaining of monolithic structures (joints are eliminated) with appropriate resistance in both longitudinal and transverse directions and great ductility under earthquakes. It will also be very effective if liquefaction and cyclic mobility phenomena occur. In addition, the tunnels will be provided great structural redundancy (robustness), which could be useful in the case of scenarios not foreseen in the design phase.

3.2 The TMG concept

The TMG (“Tunnel Multi Gallery”) concept, for TBM railway tunnels, allows, with a suitable arrangement of the tunnel cross-section, that a mono-tube tunnel provides the capacities there are normally offered by two or three parallel tubes and adopts an innovative safety concept, thus, significantly reducing construction costs and improving safety during operation.

The TMG concept allows in a mono-tube TBM tunnel the creation of two independent and isolated railway galleries and a service gallery at the bottom, inside which appropriate means are installed that create a very reliable system for local access of the emergency personnel and the evacuation of users to out of the tunnel in the event of an accident or fire inside the tunnel. The TMG concept is illustrated in Figure 8 (INPI, 2009a).

In the TMG concept, after executing the circular wall (1) by the TBM, a slab (3), placed slightly above the bottom of the tunnel and the entire width, and a separating wall (2), placed in the middle of the tunnel and its entire height, are built, so as to form two independent rail galleries, placed side by side (4) (5), one for each track, and a service gallery (6) below. In both sides of the tunnel, vertical access galleries (7), regularly spaced and provided with escape doors (8) are created, allowing for the safe passage of people between the railway galleries and the service gallery (6), in the event of an accident or fire inside the tunnel.

Inside the service gallery (6), emergency vehicles (9) of monorail type are installed, which are parked at the tunnel portals, to provide local access for emergency personnel and the evacuation of users out of the tunnel. In long tunnels large openings are also created, at adequate distances, in the separating wall, provided with sliding fire doors (10), to allow trains to pass from one traffic gallery to the other, when it will be necessary to isolate a section of a railway gallery.

A variant B to the basic TMG concept can also be adopted, in which the vertical access galleries (7), instead of being placed on the outer side of the railway galleries, are placed in the middle of the tunnel, at the separating wall.

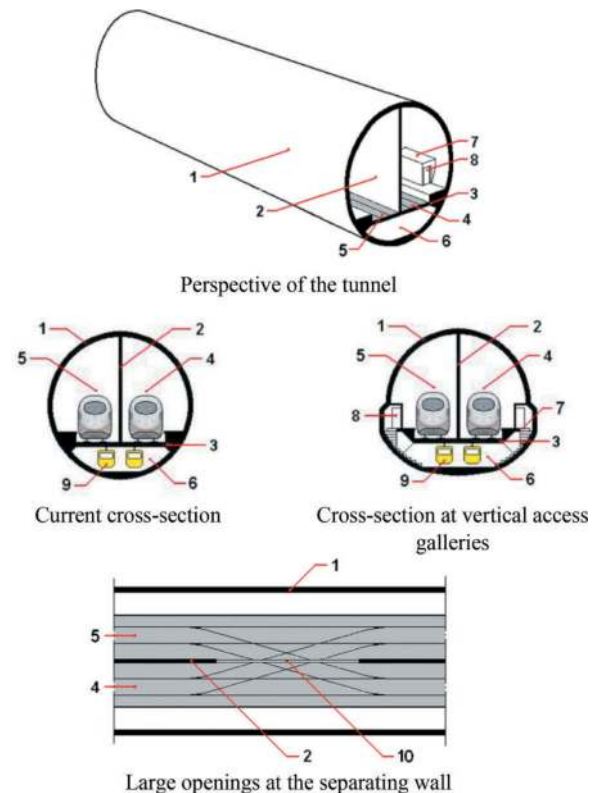

Figure 8. Illustration of the TMG concept.

Although in variant B there is a slight local reduction in the cross-section of the railway galleries, the need to make openings in the outer wall of the tunnel is avoided.

The variant B of the TMG concept is illustrated in Figure 9 (Pompeu-Santos, 2014).

Figure 9. Illustration of variant B of the TMG concept.

3.3 The TMF concept

The TMF (“Tunnel Multi Floor”) concept, for TBM road tunnels, allows, with a suitable arrangement of the tunnel cross-section, that a mono-tube tunnel provides the capabilities there are normally offered by two parallel tubes and adopts an innovative safety concept, thus, significantly reducing construction costs and improving safety during operation.

The TMF concept allows in a mono-tube TBM tunnel the creation of two independent and isolated road galleries and a service gallery at the bottom, inside which appropriate means are installed to create a very reliable system for local access of the emergency personnel and the evacuation of users to outside, in the event of an accident or fire inside the tunnel.

The TMF concept is illustrated in Figure 10 (INPI, 2009b; EPO, 2011).

Figure 10. Illustration of the TMF concept.

In the TMF concept, after executing the circular wall (1) by the TBM, two slabs (2) (3) are built at its full width, one placed roughly at half the height of the tunnel and the other placed slightly over the bottom of the tunnel, so as to form two superimposed road galleries (4) (5), one for each direction of traffic, and a service gallery (6) below.

In one of the sides of the tunnel, vertical access galleries (7), regularly spaced and provided with escape doors (8) in both road galleries, are also created, allowing for the safe passage of people to the service gallery (6), in the event of an accident or fire inside the tunnel. Inside the service gallery (6), emergency vehicles (9) of monorail type are installed, which are parked at the tunnel portals, to provide local access for emergency personnel and the evacuation of users to out of the tunnel.

3.4 Tunnelling based on TISB, TMG and TMF concepts

When using TISB, TMG and TMF concepts, some essential conceptual aspects are mentioned (Pompeu-Santos, 2023).

As for structural safety, tunnels based on TISB, TMG and TMF concepts will be analyzed as composite structures, considering the precast segments and the cast insitu elements working together to cope with actions, in accordance with the relevant structural codes.

As for the inner diameter of the tunnels, in the case of rail tunnels it will essentially depend on the speed of the trains, which however will only be relevant in tunnels on High-Speed lines (from 250 km/h), being 11.50m, 12.00m and 12.50m, respectively for speeds of 250, 300 and 350 km/h. Rail tunnels will be of two types: Alternative A tunnels, based on the basic TMG concept and Alternative B tunnels, based on variant B of the TMG concept. In the case of road tunnels, inner diameter will essentially depend on the number of lanes in each traffic gallery and their width and height.

Ventilation in both rail and road tunnels is of the longitudinal type, with jet fans regularly distributed along the length of the traffic galleries, which push the air in the traffic direction. They are activated (automatically) when the pollution particles exceed the established limits (in the road tunnels) and in the fire situations. In these situations, only the fans downstream the fire are activated. The service gallery of the tunnels has its own ventilation system, with ventilators operating at both ends, which are permanently active.

For fire-fighting, traffic galleries are equipped with active detection systems and WFSs (“Water Based Fire Fighting Systems”), with high pressure water mist nozzles distributed along the tunnel and grouped in sections of about 30m.

In road tunnels the nozzles are distributed along the entire length of the tunnel, being activated those of the sections adjacent to the fire. In rail tunnels, the nozzles are distributed along “emergency stations” (at least the length of the trains), spaced about 5 km apart, being activated the nozzles of the sections on the vicinity of the fire. The adoption of WFSs will also make it possible to reduce the level fire protection of concrete and technical equipment.

Safety in operation is based on the service gallery, which aims to: i) be a “safe place” for users in the event of an accident or fire, and ii) provide access to emergency services and the evacuation of users out of the tunnel. Therefore, even in very long tunnels, no access to the outside will be necessary along the length of the tunnel. Emergency services and users will never make use of the traffic galleries of the tunnel.

Both rail and road tunnels are provided with escape doors and vertical access galleries spaced about 400m (there is no significant advantage to using smaller

spacing), to provide escape for users, who are evacuated via EMEVs (“Emergency Monorail Electric Vehicles), which circulate inside the service gallery suspended from the roofing slab (Figure 11).

Figure 11. Lay-out of the emergency vehicles (EMEVs).

EMEVs” have (in principle) capacity for 20 people each and are grouped in “trains”, in numbers according to the needs. In road tunnels the EMEV “trains” have 2 units each while in rail tunnels its number is 5, in principle. The number of EMEV “trains” will be 2 or 4, in tunnels up to 10 km, or more than 10 km in length, respectively.

Rail tunnels are also equipped with large openings in the separating wall, spaced about 10 km, to allow trains to pass to the other track in case of need.

Costs of the tunnels can be estimated based on the unit construction costs of tunnels already built, taken into account their specific conditions. Given the specificities of the TMG and TMF concepts, compared to conventional rail and road TBM tunnels, cost reductions of around 25-30% can be expected.

4 SOME APPLICATION EXAMPLES

4.1 *Alternative solution for the Gibraltar Strait tunnel*

According to the official lay-out (Pliego, 2005), the Gibraltar Strait Tunnel will link Cape Malabata, near Tanger, north of Morocco, with Punta Paloma, west of Tarifa, south of Spain. It will be 39 km long, of which 28 km under the sea, and goes very deep, until elevation -400 (Figure 12). The maximum slopes will be of 2.5%. The maximum speed of the trains will be of 120 km/h.

The geological conditions along the tunnel consist mainly of formations called flysches, consisting of clayey materials and sandstone, which are overlaid by post-flysches formations, consisting of shallow granular deposits.

The construction of the tunnel faces major challenges. It has go very deep, more than 400 meters

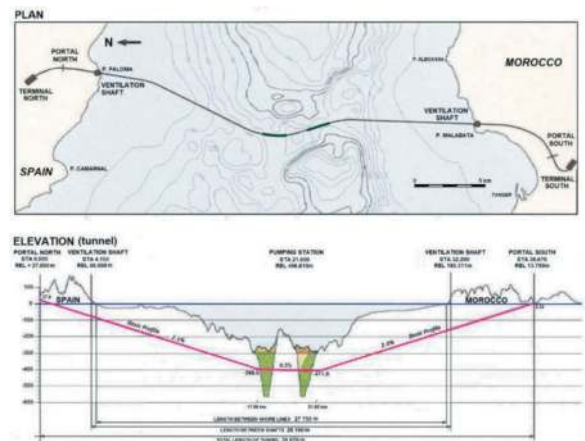

Figure 12. Gibraltar strait tunnel. Plan and longitudinal section.

below sea level, and to cross two paleo-channels in the middle, about 1 km wide each, mostly composed of deposits of clayey brescia and bioclastic sand, which are weak materials. To note also that the area is very seismic-prone, and severe earthquakes have been known to occur.

The basic layout of the tunnel is a three-tube solution, identical to the Channel Tunnel (see, Section 2.2), with railway tubes 7.5m inner diameter and a service tunnel 4.8m inner diameter.

Based on TISB and TMG (variant B) concepts, an alternative solution was developed by the author (Figure 13) (Pompeu-Santos, 2016).

In the alternative, the tunnel is a mono-tube TBM tunnel 11.5m inner diameter, inside which two independent railway galleries, placed side by side, and a service gallery below, are created (Figure 13). The cross-section of each railway gallery is about 36 m², identical to that of the railway tubes in the basic layout.

Figure 13. Gibraltar Strait Tunnel. Alternative solution cross-section.

In the section of the tunnel along the paleo-channels, the tunnel cross-section is enhanced with an interior cast insitu concrete vault, creating an inner tube with a wall thickness of 0.25m (Figure 13). The inner tube is reinforced with

longitudinal and transverse reinforcements dully confined, in order to provide the tunnel with adequate ductility under earthquakes.

Vertical access galleries are created in the middle of the tunnel (Alternative B tunnel) (see Section 3.2), with escape doors on the emergency walkways of both railway galleries, spaced about 400m apart. The service gallery is equipped with EMEV type emergency vehicles (see Figure 11), to allow local access for emergency personnel and the evacuation of the users to outside in the event of an accident or fire inside the tunnel.

As mentioned above (Section 3.4) ventilation of traffic galleries is longitudinal, with jet fans distributed along the upper part. For fire safety, the traffic galleries are equipped with WFSs installed along 7 “emergency stations”, spaced about 5 km. The separating wall is provided with 3 large openings spaced about 10 km, so that trains can change tracks.

It can be seen that the alternative solution is much more cost-effective; the cost is much lesser and the safety in operation is much higher.

4.2 Proposal for a road tunnel under the Tagus River in Lisbon

A new crossing of the Tagus River in Lisbon, Portugal, is being looked for a long time, to allow the closure of the Lisbon’s inner ring, being located west of the existing 25 de Abril (suspended) Bridge, on the Algés-Trafaria corridor (Figure 14) (Pompeu Santos, 2020, 2023). Several solutions have already been suggested, namely an immersed tunnel.

Major challenges to be faced are the very-prone seismic conditions of the site (to be remembered the 1755 Lisbon earthquake, one of the most destructive in history) and the bad characteristics of the ground.

The site is characterized by the existence of alluvial deposits of large thickness along the river bed, composed of various complexes of mud and sands, which extends from elevation -20 until elevation -75.

Figure 14. Location of the Algés-Trafaria tunnel.

Underlying the alluvial deposits there are bed-rock formations composed of basalts and limestone, which extend through the north bank. On the south bank there are Miocene formations composed mainly of sands and clays (Figure 15).

Figure 15. Proposal for the Algés-Tráfaria tunnel. Longitudinal section.

Based on the TISB and TMF concepts, a TBM solution was developed by the author (Pompeu Santos, 2020, 2023).

Given the orographic conditions of the ground, the tunnel will be 5.0 km long, 2.25 km of which under the river, and maximum gradients of 4.8% (Figure 15).

The inner diameter is 14.20m, whereby, using pre-cast segments 0.55m thick ($\approx Di/25$) and a gap of 0.15m to be filled with jet-grouting, the excavated diameter will be 15.60m (Figure 16), a common size today.

Inside the TBM tunnel, two superimposed road galleries with 4.85m of free height and a service gallery 2.00 m high are created. Each road gallery has two lanes 3.50m wide and 4.35m high (0.50m for signage installation), an emergency lane 2.50m wide and an inner edge 0.70m wide, in addition to emergency walkways in the two sides 1.20 m wide.

These features give the tunnel an efficiency index with an impressive value of 0.56, much higher (25 to 30%) than most TBM road tunnels built.

To improve the seismic behavior of the tunnel, in the section where it crosses the alluvial layers, it will be enhanced with an inner tube of confined concrete cast insitu with 0.25 m wall thickness, which also incorporates the cast insitu concrete elements already foreseen (Figure 16).

Each road gallery has 12 escape doors, placed on one side of the tunnel, approximately 400m apart, which provide access to the service gallery below, through vertical access galleries.

The vertical access galleries will be built through local dismantling of the precast segments of the TBM tube and casting new concrete walls in-situ. In the cases where there is water pressure around, jet-grouting injections will create a kind of “cake” to allow work to be carried out safely.

As mentioned (Section 3.4) ventilation is longitudinal by pairs of jet fans, distributed along the upper part of the road galleries. For fire safety, traffic galleries are equipped with WFSs, with nozzles installed along their entire length, which are grouped in sections. For safety during operation the users

Figure 16. Proposal for the Algés-Trafaria tunnel. Cross-sections.

escape to the service gallery through the vertical access galleries, from where they are moved to outside through emergency vehicles of the EMEV type.

The cost of the tunnel was estimated from the unit construction costs of TBM road tunnels, taking into account the specific conditions of the tunnel, leading to a cost of around 400 million euros, a much lower value (about 1/3) than the estimated cost of an immersed tunnel in that location.

5 CONCLUSIONS

Building sustainable infrastructure, that is, infrastructure with increasingly lower costs and greater reliability in terms of its life cycle, is a major concern for current decision-makers.

As shown, the TISB, TMG and TMF concepts are innovative developments that allow obtaining very reliable and economical solutions in tunnel construction using the TBM technique.

Thus, these concepts can be of great benefit when applied to the construction of tunnels in rail and road networks around the world, significantly improving structural safety and safety during operation, and reducing construction costs and, consequently, materials consumption, contributing to more sustainable infrastructures.

ABSTRACT: Underground space use is a widely accepted solution to sustainable urban development. The orderly use of urban underground space requires deliberate preliminary layout planning, otherwise ad hoc underground space uses will inevitably confront many challenging issues in planning, design, construction and investment processes. Conventionally, the layout planning of urban underground space relies merely on the subjective judgements of urban planners. Such an approach increases the risks of unreasonable layout planning in the master planning process that involves hundreds of land parcels and heavy workload. To address the deficiency in layout planning, this paper proposes a new approach for the master planning of urban underground space use driven by multi-source spatial data, analytical hierarchy process method and geographic information system. In particular, the data-driven layout planning approach will facilitate laying out the integrated land use purposes, development depth and key areas of underground space use. Taking the city of Zhengzhou, China as a case study, this paper will first interpret the general considerations of underground space use planning focusing on integrated use and development depth, then use multi-source spatial data, including urban planning data, land use data, metro system data, population data, real estate data, etc., to demonstrate the applicability of the proposed approach to achieve deliberate layout planning of urban underground space use.

Keywords: Underground space use, layout planning, spatial data, integrated use, development depth

1 INTRODUCTION

Underground space plays a key role in urban development in particular terms of sustainability and resilience (Bobylev, 2009; Qiao et al., 2022; Sterling and Nelson, 2013). Taking China as an example, the newly built underground space infrastructures nationwide summed up to 1.07 billion square meters during 2016–2020 (CSCCAE et al., 2020), and the amount of urban underground space (UUS) uses in Chinese mega cities such as Beijing and Shanghai have already exceeded 100 million square meters. Such a huge amount of both built capital and future increments beneath a city is likely to cause management chaos with many challenging issues in planning, design, construction and investment processes. Therefore, deliberate preliminary layout planning is required for the orderly use of urban underground space.

The planning of UUS use in China originated from the planning of civil defense facilities dating back to

1990s. since 2000s, the planning of UUS for civil uses began to spread in major Chinese cities. As of 2020, 191 out of 341 prefecture cities in China had completed or were preparing for UUS planning. Nevertheless, the conventional layout planning of urban underground space relies merely on the subjective judgements of urban planners. For instance, common planning criteria include that UUS use should be arranged surrounding metro stations in urban core areas, a higher UUS development density should be introduced to an area with high floor area ratio, etc. However, such subjective approaches could increase the risks of unreasonable layout planning in the master planning process. This is because that the master planning of UUS use generally involves hundreds of land parcels and heavy workload, and that the layout of UUS use are attributed to by multiple factors hence subjective judgements are difficult to perform.

In this context, data-driven and intelligent planning approaches are proposed to address the deficiency in

*Corresponding author: iamqyk@163.com

conventional layout planning of UUS use (Peng et al., 2023). This paper is also intended for this direction. Specifically, it proposes a data-driven approach for the master planning of urban underground space use aided by multi-source spatial data, analytical hierarchy process method and geographic information system. In particular, the data-driven layout planning approach will focus on the key aspects of UUS use layout, including the integrated land use purposes, development depth and key areas of underground space use.

The proposed approach will be illustrated with a case study of the Chinese city of Zhengzhou. The UUS planning of Zhengzhou began in 2017, and completed the first version of review draft in 2018, in which UUS layout planning was mainly performed by the aforementioned subjective judgements. However, there was a planning revolution around 2019 in China with the objective of establishing territorial spatial planning system. For this reason, the first review draft was not put aside and the planning process was suspended. It was not until 2021 that the planning was restarted. In this round, multi-source spatial data, including urban planning data, land use data, metro system data, population data, real estate data, etc., was used to facilitate the deliberate layout planning of urban underground space use under the framework of territorial spatial planning system. Compared with the first draft in 2018, the data-driven approach was deemed as more efficient, convincing and scientific. Against this background, this paper will take the city of Zhengzhou as a case study to demonstrate the applicability of the proposed approach to achieve deliberate layout planning of urban underground space use, which will provide references for the data-driven and intelligent UUS planning.

2 GENERAL CONSIDERATIONS OF UNDERGROUND SPACE USE LAYOUT PLANNING

In practice, there are at least two levels of UUS planning: master planning and regulatory detailed planning. Unlike UUS regulatory detailed planning that is often treated as a statutory and contractual instrument for guiding and regulating developers' behaviors in the use of UUS, UUS master planning puts more emphasis on outlining the development strategies and priorities in terms of integrated use type, scale, location, and depth (Peng et al., 2021). Since this paper focuses on the layout planning of UUS use, this part only introduces the general considerations of UUS planning from the perspectives of integrated use type, location, and depth.

2.1 *Integrated UUS use*

UUS is usually used as civil defense, public service, transportation, parking, municipal and industrial storage facilities. In the level of UUS master planning which is mainly drafted at land parcel scale, it is quite common that the underground space below a land parcel will be planned for multiple uses either

integrated horizontally or vertically. This is also a major characteristic of UUS planning distinctive from surface planning. In general, the degree of UUS use integration can be divided into the following three categories based on the conditions of land use properties, locations, development requirements and other relevant factors.

- (1) Comprehensive integration, refers to the UUS planned with diverse use types and direct connections with metro stations and surrounding underground buildings. It mainly exists in the key areas and nodes (such as central business districts and commercial centers) of UUS development, and is usually characterized with a UUS use combination form of public service + parking + transportation + utility tunnel + others. Another distinguishing feature is the required high connectivity.
- (2) Compound integration, refers to the UUS planned with mixed use types but low connectivity. It is usually characterized with a UUS use combination form of public service + parking + transportation + others. The interconnectivity between planned UUS and surrounding underground buildings is encouraged under this category.
- (3) Simple use, refers to UUS with relatively single use type and lack of connectivity. It is the major category of planned UUS use in UUS master planning.
- (4) Restricted use, refers to UUS uses are not encouraged for common uses such as commercial and parking. Special uses, such as relic storage and exhibition, transportation tunnels, should be well-reasoned before and during planning process.

2.2 *Development depth*

Different UUS planning levels have different purposes and approaches for development depth control. UUS master planning expects to control and optimize the use of UUS from the surface down to 100 meters or even deeper below a city, while UUS regulatory detailed planning pays more attention to the number of underground floors to be built by private developers or public sectors.

As regards UUS master planning, due to the differences in development stages, demands and geological conditions, cities varied in the vertical stratification standards of UUS development. For example, Beijing, one of the largest Chinese cities, divided its underground space into four layers: shallow layer (0–10 m), sub-shallow layer (10–30 m), sub-deep layer (30–50 m) and deep layer (deeper than 50 m); while Tongren, a less-populated city, was planned with three layers: shallow layer (0–10 m), sub-shallow layer (10–30 m) and deep layer (30–50 m). Evidently, the definition of deep underground layer is different between Beijing and Tongren. Similarly, such a difference also exists between international jurisdictions, such as Tokyo (40 or 10 m below the bearing layer of

foundation piles) and Singapore (30 m). In addition, there are some cities delineated different depth limits for the shallow layer. Prior approximately 2016, the adoption of 10 m was popular among Chinese cities to define the shallow underground layer. But with the demand for UUS grew, particularly the underground parking demand, more residential compound and commercial centers were built with three or more underground floors. This tendency drove more cities to adopt 15 m as the limit of shallow layer of UUS use.

Considering the aforementioned facts and the Standard for Urban Underground Space Planning (GB/T 51358-2019, 2019), this study adopts the following vertical stratification standard: shallow layer (0–15 m), sub-shallow layer (15–30 m), sub-deep layer (30–50 m) and deep layer (deeper than 50 m). Different depths correspond to different major categories of UUS uses. Specifically, shallow layer is more suitable for UUS uses intended for frequent daily activities of inhabitants, sub-shallow layer favors underground transportation facilities due to worse accessibility, sub-deep layer is usually planned as a long-term development reservation, and deep layer is often reserved for special underground facilities.

The development depth of a land parcel is influenced mainly by two factors: the degree of UUS use integration and the amount of UUS development demand. For the first factor, a higher degree of integration implies that more underground floors are required to accommodate various facilities types because the same type of facilities tend to share the same floor. For the second factor, it is apparent a larger development depth can bring more space to accommodate a higher UUS demand. To determine the demand of land parcel, we can refer to the findings of Peng et al. (2019), which used Osaka as a case and revealed that UUS demand or developed UUS area is strongly related with passenger flow rate and land price.

3 METHODOLOGY

The methodology for data-driven UUS layout planning involves the determination of planning decision supporting model, weight calculation method and index system.

3.1 Planning decision supporting model

Through the analysis in Section 2, it is clear that the UUS layout planning for integrated UUS use and development depth is a typical problem of multiple criteria decision analysis (MCDA), which is usually solved by Eq. (1).

$$S = \sum_{j=1}^n \left(\sum_{i=1}^n A_i B_i \right) C_j \quad (1)$$

Where, S is the calculation value of the planning objective ($0 \leq S \leq 1$); A_i is the quantitative value of the

i -th index; B_i is the weight of the i -th index; C_j is the weight of the j -th theme.

After obtaining the calculation value S , the layout planning can be made by setting reclassification criteria to the calculation value. Specifically, the layout of integrated UUS use and development depth will all be reclassified into four categories as mentioned in Section 2.

3.2 Weight calculation method

As a useful decision-making management tool, analytic hierarchy process (AHP) was introduced by Saaty (1980) to deal with multiple criteria problems. AHP follows a procedure of (1) determining the judgment matrix, and (2) calculating the priority vector of the judgement matrix to obtain the weights of multi-criteria.

3.3 Index system

As analyzed in Section 2.1, the degree of UUS use integration is influenced by land use properties, locations, development requirements and other relevant factors. Therefore, this study established the index system listed in Table 1 for UUS layout of integrated UUS use. The index system consists of four indicators, namely urban centrality, surface land use, rail transit and area functionality. Following the AHP procedures, the weights of these four indicators were calculated as 0.48, 0.09, 0.16 and 0.27, respectively based on the judgment matrices determined by experts from Tongji University and Zhengzhou Urban Planning Design & Survey Research Institute. Table 1 also lists the sub-indicators used in this study. It can be seen that these sub-indicators are all qualitative expressions. To make it computable in GIS platform, it is necessary to find a suitable scoring approach to translate these qualitative expressions into quantitative values that should reflect the relative importance of sub-indicators. Therefore, AHP is used again to transform them into quantitative scoring values, which are normalized in the field of ‘score’ of Table 1.

Section 2.2 mentioned that influential factors of the development depth include the degree of UUS use integration and the amount of UUS development demand, and the latter is strongly related with passenger flow rate and land price. The first indicator is derived from Table 1. However, the data of passenger flow rate is usually quite difficult to obtain or to forecast, particularly for cities just about to develop urban rail transit systems. To solve this problem, we need to find other data types to replace this data. According to Peng et al. (2019), the number of transfer lines is highly correlated with passenger flow rate (Pearson Correlation = 0.902). Moreover, the passenger volume is also related with local population. Therefore, we can replace passenger flow rate with the sub-indicators of population and the number of transfer lines. Similarly, we replace land price with the sub-indicator of real estate price. As listed in Table 2, the sub-indicators for development depth planning is weighed as 0.4, 0.2, 0.2 and 0.2, respectively based on AHP method.

Table 1. Index system for integrated UUS use planning.

Indicators	Weights	Sub-indicators	Scores
Urban centrality	0.48	City centers	1
		City sub-centers	0.48
		District centers	0.23
		Others	0.07
Surface land use	0.09	Commercial service	1
		Culture, sports, medical	0.58
		Green, plaza, transportation	0.58
		Residential	0.13
		Others	0.09
Rail transit	0.16	Within 300 m of a station	1
		Within 500 m of a station	0.55
		Within 800 m of a station	0.32
		Others	0.08
Area functionality	0.27	Level I	1
		Level II	0.51
		Level III	0.25
		Level IV	0.13
		Others	0.06

Indicators	Sub-indicators	Weights
Integration degree of UUS use		0.4
UUS demand	Population	0.2
	Real estate price	0.2
	Number of transfer lines	0.2

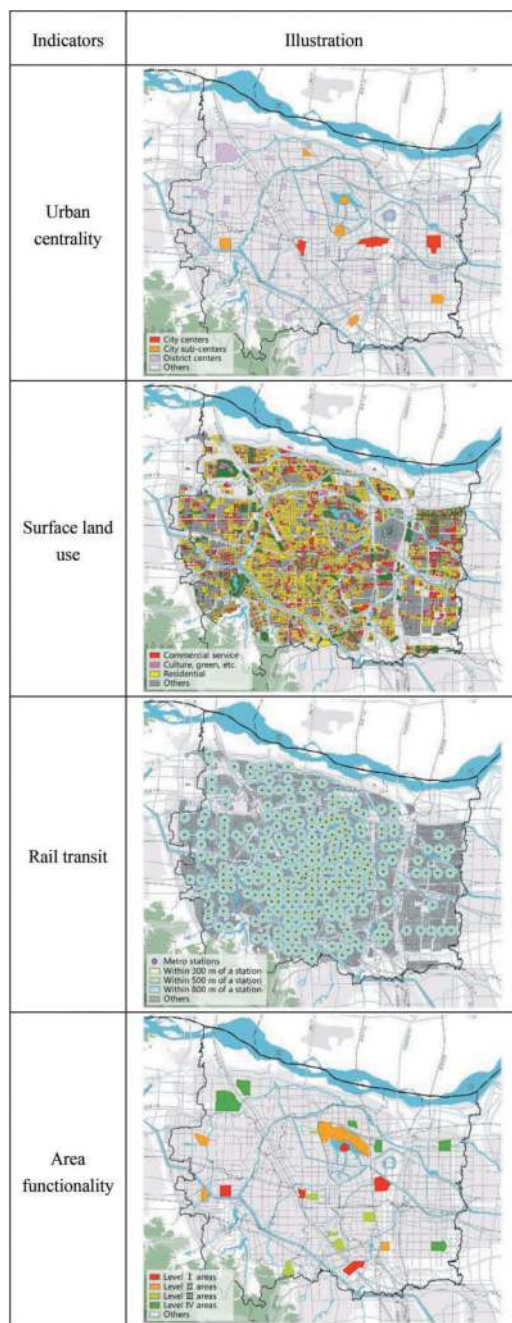

4 A CASE STUDY OF ZHENGZHOU

4.1 Overview of the case study area

Zhengzhou, the capital city of Henan Province, is located in the central and northern part of Henan Province. It has a history of 3,600 years and is one of the eight ancient capital cities of China. The urbanization of Zhengzhou in the modern sense began after the founding of People's Republic of China. With the construction of Longhai Railway and Beijing-Guangzhou Railway, two of the most important artery railways in China, Zhengzhou has gradually become an important city with the best transportation location, vast hinterland market, abundant human resources and rich historical and cultural heritage in the Central Plains. As of 2020, the city's GDP reached 1.2 trillion yuan (\$187 billion) with a population of over 12.6 million. The amount of underground buildings in Zhengzhou's main urban area reached 43.8 million square meters.

With the advent of the new century and the proposal of Belt and Road Initiative, Zhengzhou has risen to become a national central city and the core city of the Central China City Cluster, which puts forward higher requirements for its urban development in particular terms of compact, liveable, green and resilient city. These requirements were also viewed as the objectives of UUS planning in Zhengzhou. The total area of UUS planning set in 2021 was 1,239 square kilometres with a planned population of approximately 8 million.

Table 3. Multi-source spatial data for integrated UUS use planning in Zhengzhou.

4.2 Layout planning for integrated UUS use

Based on the methodology introduced in Section 3, we collected the required multi-source spatial data for integrated UUS use planning. The data is listed in Table 3, which were mainly obtained from planning authorities.

With the aid of GIS platform and AHP, the calculation results of the planning objective of integrated UUS use were derived as shown in Figure 1, based on which the main urban area of Zhengzhou was divided into four categories as shown in Figure 2.

Figure 1. Calculation results of the planning objective of integrated UUS use.

Figure 2. Reclassification results of integrated UUS use in Zhengzhou.

4.3 Layout planning for development depth

The required multi-source spatial data for development depth planning was collected and presented in Table 4. The calculation results of the planning objective of development depth were derived as shown in Figure 3, and reclassified into four categories as shown in Figure 4.

Table 4. Multi-source spatial data for development depth planning in Zhengzhou.

Indicators	Illustration
Integration degree of UUS use	
Population	
Real estate price	
Number of transfer lines	

4.4 Overall layout planning for UUS use in Zhengzhou

Based on the layout planning of integrated UUS use in Figure 3 and that of development depth in Figure 4, we can delineate the key areas for UUS use and development in Zhengzhou as shown in Figure 5, which includes four city-center-level areas and 17

Figure 3. Calculation results of the planning objective of development depth.

Figure 4. Reclassification results of development depth in Zhengzhou.

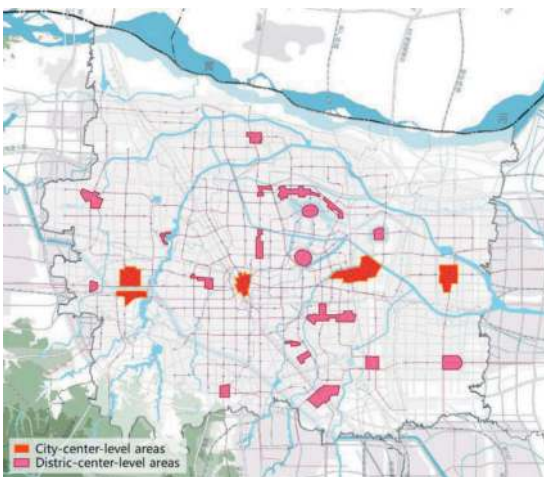

Figure 5. Overall layout planning of key areas of UUS use in Zhengzhou.

district-center-level areas. Furthermore, these results can also provide valuable references for mapping out the planning structure of UUS use in Zhengzhou.

5 CONCLUSION

In the era of smart city development, newly emerged urban planning tendencies are driving urban underground space (UUS) planning to shift from conventional approaches to data-driven technologies.

This paper presents a straightforward approach of data-driven layout planning for UUS use, which is comprised of a planning decision supporting model, i.e. multiple criteria decision analysis, an AHP-based weight calculation method and an index system. The index system for integrated UUS use planning consists of four indicators, namely urban centrality, surface land use, rail transit and area functionality, while that for development depth include integration degree of UUS use, population, real estate price, number of transfer lines. The case study of Zhengzhou, China proved that the proposed data-driven approach for UUS planning is practical.

However, it should be mentioned that this paper just showed a tentative attempt for data-driven UUS master planning. In fact, there are a lot of research work to be done in the future. For instance, UUS use can be influenced by more complicated factors, and these factors should be incorporated into this approach. Moreover, intelligent planning algorithms need to be developed to integrated these factors among which the relations are likely to be nonlinear. Nevertheless, findings of this paper can still provide some insights for UUS planning.

Tunnelling in a green country – Brenner Base Tunnel study case: Decision and solutions in construction lot H41 Sill Gorge-Pfons

Ivan Zamberlan* & Christian Schwarz*
Brenner Basistunnel BBT SE, Innsbruck, Austria

ABSTRACT: In the construction lot H41 Sill Gorge-Pfons of the Brenner Base Tunnel, decisions have been taken in order to reduce the pressure on the environment and the regional population living in the project area. In cooperation between the contractor and the client, innovative and eco-friendly logistical solutions for the transport of spoil as well as for the manufacture and transport of tubing were implemented.

The contractor decided to optimize the production of segmental liner by building a factory directly on the construction site, avoiding transportation on the existing highway. They made a reinforced earth to increase the available area built with spoil material. An automatic tubing production system using local quarry material on the site was established.

Using the exploratory tunnel built in an earlier stage of the project, the client decided to transport the spoil to a deposit site located further from the construction site but with a minor impact on the environment and the resident population. A large-capacity conveyor belt system approximately 30 km long was built, allowing a completely automatic underground material transfer.

The conveyor belt runs through three different construction lots and therefore three different contractors, each of whom must provide management of their own section, are involved. This presents a challenge to all participants for an optimal coordination among the three different contractors to provide smooth service of the conveyor belts and consequently undisturbed TBM advancements.

The reduction in the number of trucks coming to the construction site via the congested highway and the introduction of the conveyor belt system lead to a minor CO₂ emission. These decisions achieved great benefits for the environment and for the regional population.

1 INTRODUCTION

The Brenner Base Tunnel is a straight, flat railway tunnel connecting two countries (Italy and Austria) in the heart of Europe. The BBT runs for 55 km between Innsbruck (in Austria) and Fortezza (in Italy). Thanks to the low gradient of 4 ‰ - 7 ‰ and the relatively flat course of the line, the tunnel cuts the route length between Fortezza and Innsbruck by 20 km, from 75 km down to 55 km. Since suitable expansion of the line is not possible, due to the steep ascent to the Brenner pass at 1,370 meters above sea level and the many curves in the current route as it winds through the landscape, a railway tunnel, the Brenner Base Tunnel, is being constructed at the very base of the Brenner massif. The construction of

the Brenner Base Tunnel is segmented in several lots to allow a great parallelism of work and optimized tender (Insam et. al, 2022) (Figure 1).

2 THE TUNNEL SYSTEM

Two single-track main tubes run between Innsbruck and Fortezza, set about 40 to 70 metres apart. This distance is necessary to keep the rock mass stable. Smaller tunnels connecting the two main tubes are located every 333 m. They are used for logistics but also for emergency rescue.

A peculiar feature is the exploratory tunnel, which runs from one end to the other. This tunnel lies between the two main tunnels and about twelve metres below them. The exploratory

Figure 1. BBT route, the different lots are marked with different colors, on the left the city of Innsbruck and on the right the city of Fortezza is located.

Source: BBT SE

tunnel is meant for geological prospection, as a service and logistics tunnel during the construction phase and as a maintenance and drainage tunnel during the operational phase (Figure 2). Each 20 km an emergency stop is located, which provides a dense number of cross cuts between the main tunnels and a direct exit to the surface.

In total, the tunnel system for the Brenner Base Tunnel will comprise about 230 km of tunnels.

3 EXCAVATION METHODS

The choice of excavation method depends on the geology of the mountain, on geotechnical findings and forecasts, and on construction logistics and economic considerations.

For the BBT project the drill and blast method and the mechanical excavation are used in a ratio of 50% and 50% circa.

In total 9 TBMs, mainly shielded TBMs, but also open gripper TBM, are used. The far-reaching stretches of the main tunnel are excavated with shielded TBMs and tunnel support using precast concrete tubing rings are installed.

Figure 2. BBT tunnel system.

4 BUILDING IN A PROTECTED ENVIRONMENT

4.1 General considerations

The construction of the Brenner Base Tunnel is accompanied by comprehensive environmental measures.

Austria and Italy are implementing numerous environmental measures during the construction of the Brenner Base Tunnel also because there are strict environmental regulations. The high-capacity rail line itself is contributing to the protection of the Alps. Even the construction process is as environmentally friendly as possible.

A series of decision are taken in order to reduce the impact of the construction phase. Dust and noise at the construction sites are kept as low as possible, tackled in terms of minimization and mitigation.

4.2 Noise reduction

Firstly, the deployed equipment has a low level of emitted noise, in the tunnel and on the surface. Further, the turbines used to ventilate the tunnel are housed in their own caverns built in the rock. However, noise emission is not entirely avoidable, so noise protection baffles and walls have been erected to protect against noise pollution. Where construction sites are located close to populated areas, construction hours are limited to consider the needs of the local residents. This is the case on the surface as well as underground when excavation underneath a village the excavation has to be stopped during the night hours.

4.3 Air pollution control

Air pollution caused by construction site traffic is also minimised. Firstly, all vehicles and construction machinery must comply with the latest technical standards. However, several additional motorway slip roads have been provided in the project area: they allow the construction site to

be supplied exclusively over the primary road network, thus effectively eliminating additional traffic through local residential areas. A dedicated access tunnel, the Saxener tunnel (1km ca.), was built for the construction site in Wolf near Steinach am Brenner. All site traffic exits the A13 Brenner motorway at the Plon road maintenance depot and travels through the Saxener tunnel directly to the construction site in Wolf. The town of Steinach is therefore not burdened with construction site traffic.

Further, a dedicated railway siding was built for the Wolf construction site in 2016. Construction materials and machinery can be directly delivered and discharged by train. In the upcoming construction lot H53 this railway siding will be used intensively, especially for the haulage of tubbings.

On the construction site itself air pollution is mainly caused by dust. All site roads and temporary storage areas on the construction sites are watered down to reduce dust. Vehicles and construction machines are cleaned regularly. Material transport within the construction sites takes place largely via conveyor belts, on which the material is also sprayed with water to avoid dust. Further, a strategic placement of facilities on the construction site avoid dust beforehand. In the Innsbruck area the quite strong *foehn* wind is a common phenomenon. E.g. the placement of the handling area of the dry components for cement and mortar in a wind shielded area is a smart, cheap, and effective measure.

5 SPOIL MATERIAL: COST OR RESOURCE?

5.1 Conditions at the Brenner Base Tunnel

The construction of the Brenner Base Tunnel involves the excavation of about 21.5 million cubic meters of spoil. Depending on the quality, this will either be landfilled or recycled. The processing and recycling of the material helps to preserve resources. The processed material can be used for the production of concrete for inner linings and base slabs as well as shotcrete. Since the tunnel spoil is very diverse due to varying geological conditions, the amounts of recyclable tunnel spoil also vary as construction proceeds. When more material is processed than is required for re-use, it is used as aggregate to produce concrete in other sectors.

The processing into concrete aggregates is done *in situ* on the construction sites in dedicated gravel plants and concrete production factories. Doing so, the environmental impact is reduced threefold:

First, the amount of aggregate delivered to the construction site is reduced.

Second, the volume of deposits necessary and the impact on the landscape is reduced.

Third, the amount of spoil transported to the landfills are reduced.

5.2 Reinforced earth

At the construction site Ahrental the material properties of the spoil do not allow a use as aggregate neither for segmental liner nor shotcrete, so it has to be deposited. The capacity of the landfill directly at the Ahrental portal is about 2.5 M m³. In the previous construction lot H33 the deposit Ahrental was mostly filled and some room was left for logistical reasons to the current lot. This deposit was built predominantly with the classic 2:3 slopes and mostly considered as a deposit only.

However, in the construction lot H41 the deposit is reshaped in a meaningful manner to optimise the logistics and infrastructure for construction site in an intermediate state of the landfill and emphasize its additional value as a construction site. The current contractor desired a remodelling of the shape of the deposit, i.e. a steepening of the slope in order to create a larger surface on its top. The steeper slope, however, comes with further reinforcement for stability reasons (Figure 3).

Since it was planned to fill the deposit entirely by the end of the construction lot this measure describes an anticipation of works. The larger surface creates the conditions to build directly on the construction site the factory for the segmental liner, that would not have been possible otherwise, due to the confined construction area.

Therefore, this is a win-win-situation, for the BBT SE company on the one side, by reducing the transportation impact on the environment for the segmental liners and avoiding the costs for the reinforced earth. On the other side the contractor, has reduced its cost for the purchase and constant supply of segmental liners and gained the independence of logistic risks on public streets. Overall, this measure is cost-neutral and beneficial for all parties.

Figure 3. Crosssection of the reinforced earth.

Source: ARGE H41 Sillschlucht – Pfnos

The construction of the reinforced earth allowed for the creation of an additional 5,300 square metres (Figure 4; dark brown) of construction site area, which was used to house the segmental liners store.

These, piled in stacks of 12 pieces each, add up to a total weight of around 120 tonnes. The reinforced earth also houses one of the two lanes of the overhead crane dedicated to the handling of segmental liners (red). The maximum height of the reinforced soil is 23 m with a filling volume of approximately 40,000 m³.

Figure 4. Plane view of tubbing factory (yellow) and tubbing storage (red) on the reinforced earth.

Source: ARGE H41 Sillschlucht – Pfans

The two main tube headings towards the south in the construction lot H41 are excavated by two quasi identical single shield tunnel boring machines. In the east tunnel 8398 m and in the west tunnel 8108 m of tunnel has to be drilled and equipped with segmental liners. The tubbing design defines 6 segmental liners and a length of 1,95 m per ring, which results in ca. 50,800 elements in approximately 2.5 years. These figures describe the work load of the factory and the constant logistic effort to stack produced new liners, handle them and load them for transport to the heading, which requires a finely planned logistics just for the tubbing transport.

6 CONVEYOR BELT LOGISTICS

6.1 Logistics at the Brenner Base Tunnel

The construction of the Brenner Base Tunnel is segmented in several construction lots awarded to various contractors in individual tenders. However, the BBT SE as the client summarizing all lots and aims at generating value in cooperation between the lots, especially in logistics this is beneficial.

In the proximity of the city of Innsbruck only little percentage of the spoil is deposited, with one bigger landfill of 2.5 M m³ volume and some smaller ones. These landfills were mayorly used during

a previous construction lot and only little is left for the current construction lot. The biggest landfill of the Brenner Base Tunnel is located in the Padaster valley near the neighbouring lot in Wolf, which is capable of taking the spoil of its own lot and excess material from another lot.

The two portals of the two construction lots Ahrental H41 and Wolf H52 are only 20 km apart and linked by a highway and a federal street. However, these streets are already prone to congestions and a smooth transport is key to the success of any construction, but to this in particular. In addition, the legal constraints are, that transport by truck is forbidden during the night and on weekend, which conflicts with a 24/7 progress on the construction site. Furthermore, the environmental aspect is considerable.

The two lots are already linked since the breakthrough of the exploratory tunnel happened more than 3 years ago on 06.07.2020 and this was incorporated in the logistic management of the lot.

6.2 Logistics at construction lot H41 Sill Gorge-Pfans

Aim of the logistics for the spoil transport was to create safe, redundant, eco-friendly, high capacity system, which is capable of handling four main headings and deliver spoil to two landfills (Ahrental and Wolf/Padaster valley). In the construction lot H41 Sill Gorge-Pfans the two main tunnel headings in the east and west tube to the north are excavated by the drill and blast method and stretched over about two or three kilometres respectively. The two main tunnel headings to the south are excavated by two quasi identical tunnel boring machines (also called “TBMs”) and stretch over more than eight kilometres in each tube. Due to the different excavation method the spoil is differently composed in its grain size distribution. A drill and blast heading creates a rather wide graded spoil composition, whereas a TBM heading produces a rather narrow graded spoil. By leading the spoil through crushers the grain size curve is homogenized and the material is suitable for the transport by conveyor belt.

Another criterion for the conveyor belt logistics at the construction lot H41 was to enable the merge and separation of material flow without interfering in running conveyor belts. This is crucial in order to have really independent headings, whose performance does not depend on the state of the conveyor belt. Finally, the established conveyor belt system comprises 4 sources of material (headings), 2 distribution hubs, and two exits (portal Ahrental and Wolf/Padaster valley).

Under consideration of the above-mentioned boundary conditions the contractor H41 developed the following solution transporting the spoil through the exploratory tunnel (Figure 5).

In the lot H41 alone the length of all conveyor belts sums up to more than 34,7 km distributed over

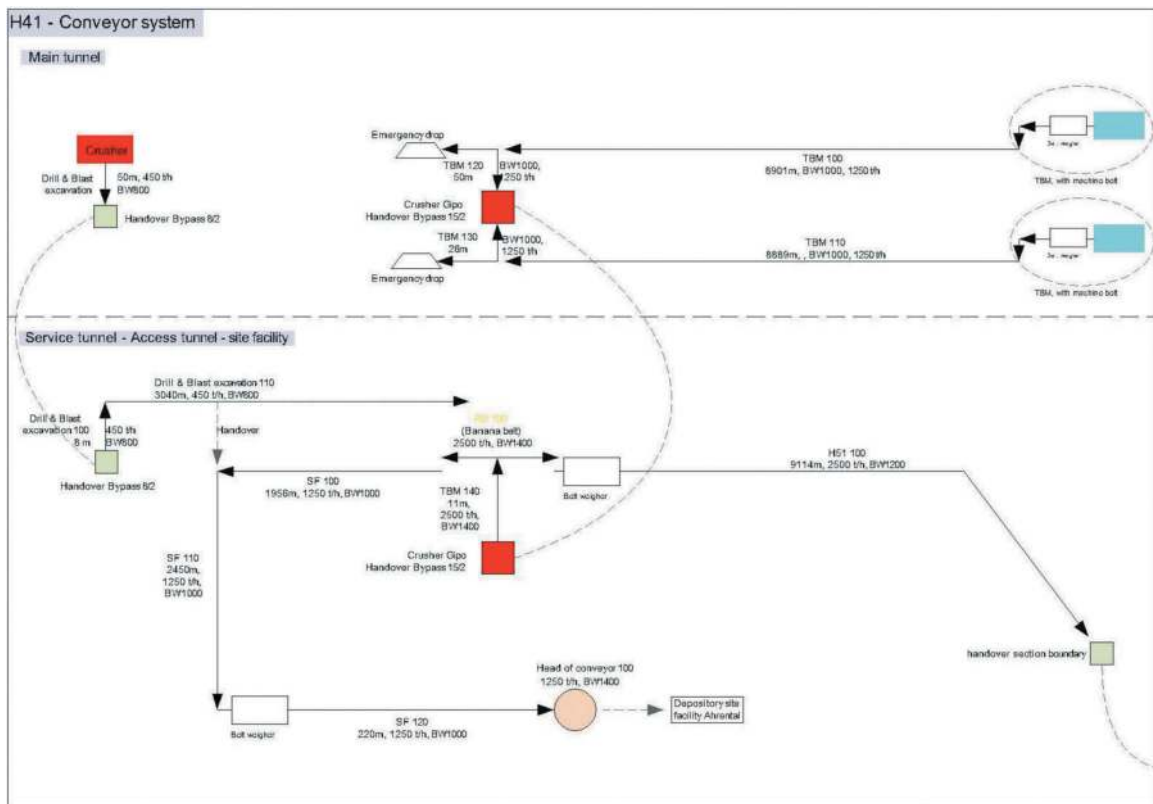

Figure 5. Conveyor belt system of the construction lot H41.

Source: ARGE H41 Sillschlucht – Pfon

20 conveyor belts. The maximal capacity towards the lot H52 in the south is 2,500 to/h and to the construction site Ahrental 1,250 to/h. During the construction phases 4.5 M to will be transported to Padaster valley via the conveyor belt in the exploratory tunnel and about 1.0 M to will be discharged at the construction site Ahrental.

6.3 Logistics at construction lot H52 Hochstegen

At the underground border between the lots H41 and H52 the spoil passes to the contractor of H52, who has to transport it to the surface and finally into the Padaster valley deposit without further manipulation. In addition to this, the lot H52 is in operation as well with its own headings. Its spoil has to be transported as well with the same conveyor belt system from the underground to the surface and then to the Padaster valley.

In the construction lot H52 17 belts are operated and sum up to about 26 km. Their design varies from a about 9 km long flat conveyer belt equipped with 3 boosters, to about 4 km long ascending (+300 m) conveyer belts equipped with 3 boosters, and a set of shorter conveyer belts for distribution purposes underground and on the deposit to the different heads (Figure 6).

In the future the upcoming lot will incorporate the conveyer belts for its two TBM drives into this system.

6.4 Joint logistics

Each conveyor belt system is a complex arrangement on its own, but all systems have to operate together as a unique system, rather than two systems joint together. However, the construction lots are awarded by independent tenders and therefore the contractors and their conveyor belt manufacturer are not the same. The detailed planning of the logistic concept (e.g. the conveyor belt system) is done by the contractor and the underlying conception may differ. BBT SE as client of both contractors took care of the tender process and it is still taking care of the execution process, to make sure that the relevant parameters in both lots are identical. These are mainly the capacity of the conveyer belt, the regulation and interdependence of the individual conveyer belts (e.g. emergency stop, regular de- and acceleration). Regular meetings and exchange of experiences between the client and both contractors and their conveyor belt manufacturer are crucial during the total duration of the construction phase (BMA, 2022).

Further challenge will be the transition of contractors from lot H52 to H53 on the same construction site Wolf, right after completion of H52. No service interruption of the conveyor belt system is allowed during this phase, since the lot H41 will continue to excavate and transport material to the lot border to (then) H53.

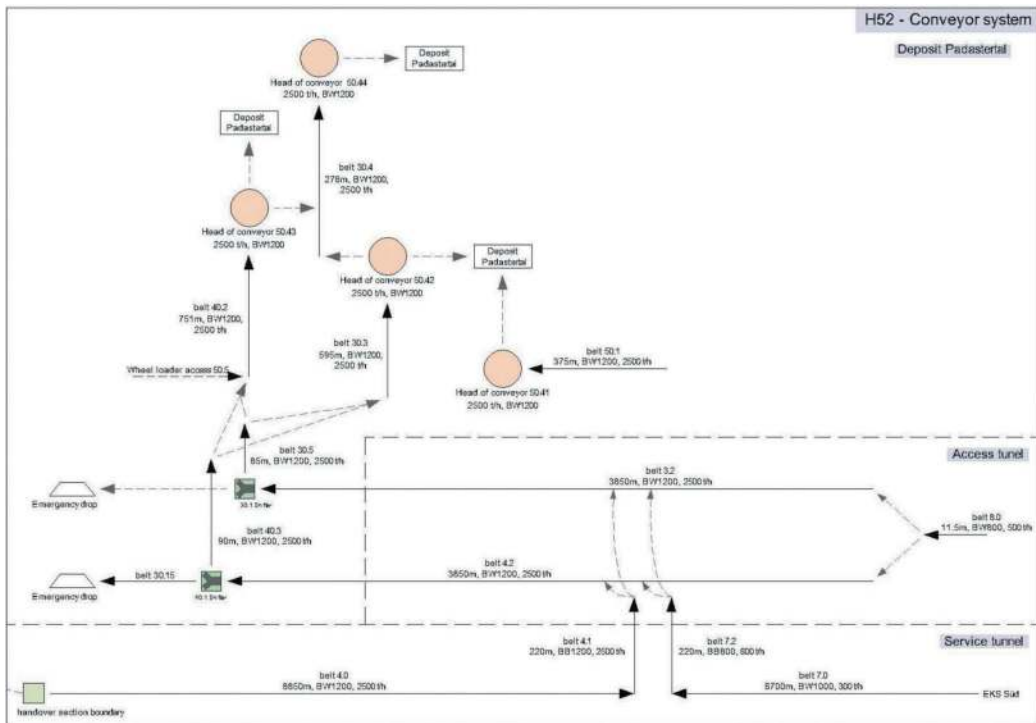

Figure 6. Conveyor belt system of the construction lot H52.
Source: BBT SE based on AN H52 Swietelsky Tunnelbau GmbH & CoKG

This is a win-win solution for both the client and the contractor. BBT SE reduces its costs, thanks to the optimised material flow. The deposit capacity near portal Ahrental is limited and the transport length and costs would increase if a truck rather than a conveyor belt logistics is implemented. Furthermore, the public acceptance would rise, as this is a more sustainable solution. The contractor will gain a 24/7 available constant flow of spoil out of its headings, due to the redundancy within the systems. In case of unavailability of the conveyor belts from the neighbouring lot, the material flow can be diverted and discharged to the other construction site, and vice versa.

Further, a safer work environment, due to the reduced number of trucks in the tunnels is created. The amount that is expected to be transported in Padaster valley is about 4,5 M tons. To remove this amount of material about 180.000 full loaded trucks would be necessary. Assuming a full load truck emission of 0.9 kg/km and an unloaded truck emission of 0.7 kg/km, this would result in an emission of 7,200 tonnes of CO₂.

A further 1 M tonnes of spoil material is planned to be transported to the Ahrental portal by conveyor belt. This material is used to complete the deposit and shape its final form for its purpose after the construction. The majority of the surface will be given back to the original owners and a small part will serve as an access and emergency area for the emergency stop Innsbruck.

6.5 Padaster valley

Another advantage of using the spoil material, that would otherwise not be reusable, is in the form of the final arrangement of said material. The Padaster valley was originally a wild, inhabited V-shaped valley, with no significant economic activities due to its narrow, closed shape (Figure 7).

Figure 7. View of the Padaster valley spoil disposal site at the beginning of construction.

Source: BBT SE

Once the deposit will be completed, the valley will be resettled in a U-shape, which also allows the creation of pastures and the establishment of economic activities within the valley. This results in a significant increase in the economic value of the area affected by the deposit works. The creation of the deposit was also the reason for carrying out work to secure and revitalize the Padaster stream. A holding basin was created in the stream to secure the settlement at the mouth of the valley.

Figure 8. View of the Padaster valley spoil disposal site during the construction.

Source: BBT SE

At the moment the preparatory construction works like the excavation of the spoil removal tunnel and the completion of the holding basins are over. The disposal of the tunnel spoil is currently ongoing (Figure 8). These works are accompanied by the construction of a basal and peripheral drainage lines together with extension and maintenance of an extensive geotechnical and hydrological surveyance system.

After the completion of the disposal of the tunnel spoil, the Padaster valley will be completely restored. Firstly, the entire valley will be replanted, with different site-specific composition of seeds, depending on altitude and water saturation in the soil and a variety of trees and bushes, depending on the specific location. E.g. reforestation or meadow. Finally, the Padaster stream, which runs underground during the construction phase, will be brought back to the surface again and will create a worthy habitat (Figure 9).

7 CONCLUSIONS

In conclusion, with these two examples, an attempt has been made to show that important measures to

Figure 9. Model of the Padaster valley spoil disposal site after completion.

Source: BBT SE

protect the environment can be taken at large construction sites, without this necessarily entailing higher costs. Through careful management, safeguarding the environment and gaining public support at the same time is possible. In the next few years, more and more attention will be devoted to the protection of the environment in the entire construction industry. Especially in the realisation of large projects, this will be crucial to maintain public support in terms of environment protection.

ACKNOWLEDGMENTS

The authors would like to thank all their colleagues at the BBT SE for their support and effort. Further acknowledgement to the contractor for providing additional figures and information.

Technical challenges and countermeasures of plateau railway tunnels

Yong Zhao & Tingyu Zhu

Tibet Railway Construction Corporation, Lhasa City, China

Gaoming Yan

School of Civil Engineering, Beijing Jiaotong University, Beijing, China

ABSTRACT: With the implementation of the Chinese strategy to become a strong transportation nation and the rapid development of our social economy, the national railway network is gradually extending to mountainous areas with relatively weak transportation infrastructure, such as the Qinghai-Tibet Plateau. This has led to the need for the construction of a large number of ultra-long and deeply buried tunnels in the plateau region. The extremely complex and variable environmental characteristics and engineering geological conditions in this area pose significant challenges to the safe construction and long-term operation of these tunnels under construction or planned. In light of this issue, this paper provides a detailed analysis of the major technical challenges faced in the construction of railway tunnels in high-altitude areas. These challenges mainly include disasters caused by crossing active fault zones, high ground stress rock bursts and large deformations in soft rocks, disasters caused by high permeability and sudden water and mud inflows, as well as the high-altitude (water) temperature damage. To address the aforementioned challenges, this paper proposes disaster prevention and control strategies and mechanized intelligent construction technologies from both theoretical and technical perspectives to cope with tunnel construction challenges in the extreme plateau environment. The results can provide a reference for the efficient construction and safe operation of ultra-long and deeply buried tunnels in high-altitude areas.

Keywords: Plateau Railway Tunnels, technical challenges, countermeasures, intelligent construction technologies

1 INTRODUCTION

The Qinghai-Tibet Plateau is an important ecological security barrier in our country. However, the relatively weak transportation infrastructure hampers the development of the Qinghai-Tibet Plateau region. Accelerating the construction of a regional highway network and railway network in the Qinghai-Tibet Plateau is of great significance for the development of Tibet and the long-term stability of the country. With the continuous advancement of major national strategies such as “Building a Strong Transportation Nation” and “Western Development,” a large number of significant transportation infrastructure projects are gradually being carried out in the Qinghai-Tibet Plateau and surrounding areas. Tunnel engineering, due to its safety and environmental characteristics, has been widely used in transportation infrastructure construction. There is an urgent need to construct a large number of ultra-long and deep-buried tunnel projects, such as a plateau railway tunnel line where the tunneling

rate is as high as 82.6%. The Qinghai-Tibet Plateau region is the most geologically, topographically, and morphologically complex area in the world. Under the strong coupling of internal and external forces, the tectonic plates along the route are the most active, with the most intense fault activities, the strongest earthquake intensities, the most significant topographical changes, and the most developed natural disasters (Figure 1). All of these pose extremely severe challenges for tunnel engineering.

The extreme environment of tunnel construction on the Qinghai-Tibet Plateau is mainly reflected in three aspects: environmental characteristics, geological features, and engineering characteristics. In terms of environmental characteristics, most areas are located at altitudes between 3000 and 5000 meters. Influenced by high altitude, significant terrain differences between mountains, and the impact of monsoons and westerly winds^[1], these areas exhibit characteristics of high cold and oxygen deficiency, with complex and variable weather conditions.

Figure 1. Plate tectonics and movement in the Qinghai-Tibet Plateau.

From a geological perspective, the Qinghai-Tibet Plateau is located in a zone of compression and collision between the Indian Plate and the Eurasian Plate. The relatively rigid Indian Plate continues to push strongly in northeast direction. On the northern side, oceanic crusts successively diminish and close, continental crusts collide and merge, and the relatively plastic Qinghai-Tibet region is strongly uplifted and compressed, forming complex land crust blocks with converging and nested structures^[2-3]. This geological context results in extremely high ground stress, high seismic intensity, frequent earthquakes, the presence of ultra-high-pressure water, and high ground (water) temperatures in tunnel engineering in the Qinghai-Tibet Plateau region. Table 1 lists some representative plateau ultra-long and deeply buried tunnel that have been constructed in the Qinghai-Tibet Plateau region.

Table 1. Ultra-long and deeply buried tunnels that have been constructed in the Qinghai Tibet Plateau.

Tunnel projects	Length/m	Altitude /m	Problem
Galongla Tunnel	3310	3700	Fault, water inrush Water-rich moraine layer,
Milin tunnel	11560	3076	high ground stress, high ground temperature
Gangmulashan tunnel	11660	3128	Rockburst, high ground temperature
Bayu tunnel	13073	3465	Rockburst
Gongduoding tunnel	13590	3116	Water inrush, rockburst, high ground temperature
Sangzhuling tunnel	16449	3581	High ground temperature, rockburst
Muzhailing tunnel	16670	3116	Fault, large deformation, water and mud inrush
Guanjiao tunnel	32690	3500	Karst and fault, water inrush

In terms of engineering characteristics, the depth and length of tunnels in the Qinghai-Tibet Plateau region far exceed the standards specified in current regulations. Taking a certain plateau railway under construction as an example, there are as many as 15 tunnels with lengths exceeding 20 km, the longest of which is 42.4 km. There are 31 tunnels with depths exceeding 1000 meters, and their cumulative length accounts for over 70%. Compared to traditional short and medium tunnels, as tunnel depth and length increase significantly, the deep and complex geological environment differs greatly from the shallow rock conditions. Ground stress, ground temperature, and underground water pressure will significantly increase, resulting in distinctly different engineering characteristics for deep tunnels.

2 DISASTER OF TUNNELS CROSSING ACTIVE FAULT

2.1 Technical challenges

Active faults, typically refer to faults that have been active since the Quaternary period (Late Pleistocene) and are likely to remain active in the foreseeable future^[4]. Crossing these active faults poses immeasurable hazards to tunnels. During earthquakes, the fault movement results in longitudinal and transverse displacement of tunnels, reducing the arch effect and making the tunnel structure prone to overall collapse. For instance, in the 1906 San Francisco earthquake with a magnitude of 8.3, the tunnels crossing the San Andreas Fault experienced localized displacements of up to 240 cm. The Wenchuan earthquake in 2008 led to severe damage in tunnels near the fault zone, including lateral displacement, secondary lining collapse in upper sidewalls and crowns, as shown in Figure 2. The Longxi tunnel experienced relative vertical displacement of about 100 cm due to the earthquake. In 2022, the Menyuan earthquake caused

Figure 2. Seismic damage in transverse fault tunnels.

overall shifts and twists in the Daliang tunnel and Qilian Mountain Tunnel. Particularly in the Daliang tunnel, the structure was severely damaged, with a relative displacement of 2.8 meters, a vertical deformation difference of 0.6 meters in the track, and approximately 350 meters of the tunnel structure severely damaged, causing track deformation and rendering the tunnel completely unusable.

The Qinghai-Tibet Plateau has a complex stress distribution, widespread active structures, intense seismic activity, and numerous active fault zones. Taking a certain plateau railway as an example, it crosses 11 active fault zones, including the Xianshuihe fault, Jinsha River fault, and Jiali-Polong fault. Therefore, when constructing tunnels in the Qinghai-Tibet Plateau region, it is essential to employ scientific tunnel design, rational construction methods, and stringent safety management measures to minimize the risk of tunnel disasters caused by the sliding and creeping of tunnels crossing active fault zones.

2.2 Engineering strategies

2.2.1 Advanced forecasting techniques

For complex geological tunnels, a comprehensive advanced geological forecasting approach combining long, medium, and short distances, along with physical drilling, is followed. Various forecasting techniques complement and verify each other. Long and medium-distance advanced geological forecasting involves the use of integrated geophysical methods such as seismic wave method, electromagnetic method, and induced polarization method. Various devices such as TSP, HSP, GRP, TRT, and TST are employed. Advanced drilling methods include advanced geological core drilling and deepening blast hole method, with a minimum drilling length of 50m for complex geological conditions. Especially for the detection of fault and other disaster-causing structures (as shown in Figure 3), an expert team led by Shucaï Li and others has developed high-energy, wide-frequency controllable excitation methods and seismic source prototypes^[5,6]. The detection range has been increased from 100m to 130m. A constrained full waveform inversion method has been proposed, overcoming the theoretical bottleneck of precise wave velocity calculation and achieving accurate fault detection.

Figure 3. Detection imaging of fault-induced disaster structures.

2.2.2 Aseismic measures

Due to the severity of damage caused by faults to tunnels, construction is primarily based on the principle of avoiding active faults, which is also the most effective measure against fault-related tunnel damage. However, due to requirements for track smoothness, it is unavoidable to encounter tunnels crossing active faults. Currently, there are several strategies for seismic reduction in tunnels crossing active faults. One is to improve surrounding rock conditions, which can reduce the relative displacement between surrounding rock and tunnel structure. Methods include grouting reinforcement of surrounding rock. Three commonly used methods for grouting reinforcement are full-ring interval grouting, full-ring grouting, and partial grouting^[7]. The second is to alter lining structure properties. Techniques such as enlarging the tunnel across faults, segmenting the lining, and setting joints between sections can be employed. For example, the Wushaoling railway tunnel, constructed in 2004, adopted a construction plan involving an enlarged section size at the fault crossing area^[8]. The third is to introduce seismic isolation structures. These structures are placed between the tunnel and surrounding rock to reduce seismic energy transfer between the surrounding rock and lining. In complex geological sections, lightweight and flexible seismic isolation materials can be placed between the surrounding rock and lining structure. These layers can absorb seismic energy, reducing the seismic impact on the tunnel lining^[9]. Common materials for these isolation layers include rubber or foam concrete. The isolation layer can be placed between surrounding rock and lining or between initial support and secondary lining.

Considering the current design for seismic resistance in tunnels crossing faults, there are very few examples specifically addressing the design of large cross-section tunnels crossing active faults, and these designs have not been validated in major earthquakes. Reinforcing surrounding rocks and seismic damping layers significantly influence the seismic response, whereas their effect on fault displacement is relatively small^[10]. Setting flexible joints reduce uneven tunnel deformations and mitigate damage to tunnel structures caused by fault displacements. However, these designs cannot guarantee the requirements for tunnel alignment, especially for railway lines. They also present challenges for structural waterproofing. Therefore, the principle of “reserving space, optimizing sections, segmental design, and operational monitoring” should be applied in fault zones. In future research on seismic resistance in tunnels crossing active faults, factors such as fault displacement, fault damage zones, surrounding rock pressure, and strong seismic effects should be considered. The main design approach should focus on active prevention and control by enhancing the structural adaptability and deformation capacity. The research should propose a multi-level variable seismic reduction structure system for tunnels crossing active faults to minimize the impact of fault displacements and seismic effects on the tunnel.

For operational tunnels, active fault segments should be closely monitored. This includes routine monitoring requirements along with additional health monitoring during the operational phase, including tunnel settlement and deformation, lining deformation, and structural stress (initial support and secondary lining contact pressure, secondary lining reinforcement stress, concrete stress). Furthermore, research should be conducted on monitoring, early warning technology during fault seismic events, emergency dispatching of train operations, and rapid restoration plans to ensure safe operation.

3 HIGH PERMEABILITY, SUDDEN WATER INRUSH, AND MUD INRUSH

3.1 *Technical challenges*

The climate characteristics of multiple periods of change, high altitudes, sparse rainfall, and heavy snowfall on the Qinghai-Tibet Plateau have created unique surface features such as large ice lakes and plateau-type karst formations. Taking a certain plateau railway as an example, there are as many as 227 major faults along the tunnel alignment, extensive plateau karst sections spanning 58 km, and predicted water pressure reaching 7 MPa. This complex environment makes the tunnels highly susceptible to major geological disasters, such as sudden water inflow and mudslides, as shown in Figure 4.

The prevention and control of sudden water inflow and mudslide disasters in the complex and high-energy environment of the plateau railway face the following challenges.

Geological environment is extremely complex. The geological environment within the tunnels is extremely complex, and the mechanisms and evolution patterns of water inflow and mudslide disasters are not clear. There is an urgent need to break through the disaster identification technology to clearly understand the mechanisms causing these disasters from the source.

In high-risk sections, the danger of manual monitoring is high. There is a pressing need to overcome real-time online monitoring technology and intelligent early warning platforms to achieve automatic monitoring and intelligent warnings.

There is a need to develop new materials, technologies, and intelligent equipment suitable for high-pressure environments for large-flow water sealing, rock reinforcement, and active prevention and control of water inflow and mudslide disasters.

There is a lack of scientific management tools for risk assessment. Innovation is needed in dynamic and accurate risk assessment methods, breakthroughs in safety management, and emergency rescue technology systems.

These above challenges have brought a series of technical difficulties to tunnel construction in plateau regions.

Figure 4. Sudden water inrush in the tunnel.

3.2 *Engineering strategies*

The key to actively controlling sudden water inflow disasters in deep and long tunnels on the plateau lies in the correct balance between “draining” and “blocking”. Specific response strategies should be classified based on geological conditions and stratum types.

For karst strata on the plateau, considering various information sources such as different karst forms, water pressure, water volume parameters, and safety distances, a construction control optimization scheme based on a disaster control decision-making model is developed. This scheme integrates key indicators such as pressure relief amount, drainage point layout, and pressure relief timing to propose construction control techniques for sudden water inflow and mudslides. It establishes proactive sealing and drainage standards, accompanying construction processes, and suggests dynamic responses and optimization methods for key parameters at multiple levels and stages.

Regarding fractured zones and faulted zones, a multidimensional evaluation approach, including the stability of fractured zone surrounding rocks and the performance evaluation of anti-inrush structures, is implemented. This approach involves a tailored grouting reinforcement technology system, focusing on the stability of fractured zone surrounding rocks. It incorporates environmental modifications, rock mass improvements, and the enhancement of structural water-resistant properties. Ultimately, a comprehensive and proactive control technology system is established, integrating advanced drainage and pressure reduction with proactive grouting reinforcement for effective control of sudden water inflow and mudslides in tunnels within fractured zones and faulted zones.

4 ROCKBURST AND LARGE DEFORMATION DISASTERS UNDER HIGH STRESS ENVIRONMENT

4.1 *Technical challenges*

The Qinghai-Tibet Plateau is located in the compression-collision zone between the Indian plate and the Eurasian plate. The region experiences intense modern tectonic movements and internal and external dynamic forces, resulting in significant geological features such as strong crustal

deformation and concentrated crustal stress. The high-stress environment in these high-altitude areas is exceptionally prominent. For example, the maximum ground stress in the Bayu tunnel of the Lalin railway is 52.4 MPa. In a certain large railway tunnel construction sites, the estimated maximum ground stress is around 75 MPa, while in planned large hydropower station tunnel sites, it is approximately 100 MPa. The exceptionally high levels of ground stress are evident. In such high-stress environments, tunnel is affected by construction unloading, making it susceptible to disaster risks such as rock bursts and significant deformations^[11]. Rock bursts are dynamic instability disasters characterized by the brittle fracture of intact hard rocks. Based on the timing of occurrence, rock bursts can be classified into immediate-type and delayed-type. Immediate-type rock bursts typically occur within 6 to 8 hours after excavation, while delayed-type rock bursts occur over a longer period, often spanning weeks, months, or even longer. For example, in the Gangmula tunnel of the Lalin railway, certain sections of the tunnel bottom experienced sudden rock bursts even two years after operation, causing the floor to uplift by 38.9 cm and interrupting rail traffic for 11 days. Since rock bursts often accompany the ejection of surrounding rock fragments, the crater depth of intense rock bursts can exceed 3 meters. Considering the sudden and random nature of rock burst occurrences, effectively avoiding harm to personnel and equipment during the construction period and ensuring the long-term safety of support structures pose significant technical challenges. Large deformations refer to significant plastic deformations occurring in fractured and soft rock, characterized by high values, rapid rates, long durations, and high support loads^[12]. Large deformations can lead to engineering problems such as cracking, spalling, and even intrusion limitations in support structures. For instance, in the Muzailing tunnel, some sections experienced deformations exceeding 2 meters, leading to a high support replacement rate of 30%. Therefore, comprehensive and effective control of surrounding rock deformations becomes a key aspect of deformation disaster control technology.

4.2 Engineering strategies

Considering that rock bursts and large deformations disasters are closely related to high-stress environments and the stress state of surrounding rocks, the prevention and control techniques for these two disasters can be implemented based on the principle of “prevention as the main focus, combined prevention and control, actively improving the stress state of surrounding rocks, and strengthening timely and reliable rock support”. “Prevention as the main focus” focuses on accurate prediction and warning of high stress environment and disaster characteristic indicators, evaluating the risk of disaster occurrence, and improving the pertinence of disaster prevention and control measures. At present, the prediction and warning technology for rock burst mainly focuses on the precise perception of rock

burst surrounding rock fracture information and accurate identification of fracture process^[13], and the first high-precision microseismic intelligent monitoring system in the world has been developed. It can accurately concretize the probability of rock burst events, achieve quantitative warning and evaluation of rock bursts, and solve the problem of “undetectable, inaccurate, and incomplete measurement” of rock bursts. Figure 5 is a typical application case of rock burst microseismic prediction and warning technology in tunnels. In terms of in-situ stress environment prediction technology, we actively develop new technologies such as parameter inversion while drilling with rock drilling rigs and borehole acoustic testing to solve the problems of traditional technologies such as long time consumption, large process interference, and delayed feedback. “Combined prevention and control” focuses on comprehensive prevention and control of the entire tunnel area and construction process. It is mainly manifested in the use of “prevention” measures for the surrounding rock in front of the palm. This includes improving the ground stress conditions through advance hole stress release before excavation, using advance hole loosening blasting to reduce the brittleness of hard rock, and using advance grouting and pre-support to improve the quality of soft rock. These measures alleviate the risk and degree of disaster occurrence. The surrounding rock behind the face of the tunnel is mainly treated with “treatment” measures, which include optimizing construction methods and providing timely support to the surrounding rock to ensure effective disaster management. Specific measures include controlling the excavation cycle size, implementing energy dissipation protection nets. Additionally, employing large-section excavation, enhancing the mechanical properties of supporting materials or components, and shortening the closure time for support structures are used to control the early deformation rate of soft rocks. The core of disaster prevention and control technology is to actively improve the stress state of the surrounding rock, which means to enhance the self-stability of surrounding rock and achieve the goal of self-stability of surrounding rock through the active improvement of the stress state of surrounding rock. For example, using electronic digital detonators, directional shaped charge blasting, and precise control blasting of tunnel contour helps alleviate the stress concentration in the excavation contour of surrounding rock. Utilizing high-performance support materials and components and pre-stressed anchor rods (cables) provides effective support force for the surrounding rock^[14], timely improving the stress state of the surrounding rock and enhancing its ability to resist deformation (Figure 6). “Strengthening the timely and reliable support of surrounding rocks” emphasizes the timeliness of support time and the reliability of quality, mainly achieved through large-scale mechanized rapid construction technology, such as the mechanized supporting construction technology of the entire tunnel process, which can achieve mechanized and unmanned operations of various types of support such as sprayed

concrete, prestressed anchor rods, and steel supports. The rapid construction technology of the anchor mesh support system based on the drilling injection anchor mesh integrated machine can achieve the full process mechanization of rock burst energy dissipation protection net, pre-stressed anchor rod and other support operations. The technology has been preliminarily applied in the Duoji tunnel (Figure 7), reducing the laying time of the energy dissipation protection net from 5 hours manually to 5 minutes. this significantly improves the rock burst protection capability of the support and the safety of construction personnel.

Figure 5. High precision microseismic intelligent monitoring system.

Certainly, deepening the understanding of the disaster mechanisms in the surrounding rocks of tunnels in the high-stress environment of the Qinghai-Tibet Plateau, studying long-term perception, monitoring, and early warning of rockbursts, especially delayed-type rockbursts, optimizing excavation profiles, adapting support designs, and developing fully mechanized and unmanned robotic construction technologies for tunnels, are still pressing technical directions that need to be addressed.

Figure 6. High performance support system.

Figure 7. Mechanized Construction of Anchor Mesh Support.

5 HIGH GEOTHERMAL TEMPERATURE DAMAGE

5.1 Technical challenges

The Qinghai Tibet Plateau is rich in geothermal resources. In most areas, the ground temperature ranges from 40 to 60°C, and in certain areas, it can even reach up to 90°C [15]. The construction of deep buried long railway tunnels in the region will inevitably be plagued by high geothermal temperatures. For example, during the construction period of the Sangzhuling tunnel on the Lalin railway, the highest ground temperature recorded was 89.9°C. In the construction of Layue tunnel, high-temperature hot water gushing up to 92.6 °C occurred. High geothermal temperature can be divided into two types based on the type of heat source: high rock temperature and high water temperature. The impact of high geothermal temperature on the thermal damage of tunnel engineering is mainly reflected in two aspects [16]. Firstly, it deteriorates the construction environment inside the tunnel. The high temperature and high humidity construction environment can affect the efficiency of construction workers and equipment, leading to efficiency reduction. The high water temperature environment can also induce the risk of burns and other injuries to construction workers. The second is the deterioration of the mechanical performance of the support structure. High temperature environments can deteriorate the mechanical properties of materials such as sprayed concrete and anchor grouting materials, leading to a decrease in the mechanical performance of the support structure and endangering its safety.

5.2 Engineering strategies

The prevention and control measures for high-temperature heat damage in tunnels can be implemented in accordance with the principles of “deepening geology, controlling heat sources, combining drainage and water sealing techniques, comprehensive cooling, monitoring and warning, and system guarantee”. “Deepening geology” refers to the use of comprehensive exploration techniques in all aspects to grasp the distribution patterns and characteristics of ground temperature in the tunnel site and excavation area, providing guidance for targeted control in the future. Detection techniques mainly include outside detection and inside detection. Outside detection can use the integrated exploration technology of “space, sky, and earth” to grasp the distribution range and characteristics of high-temperature areas, while inside detection can use three-dimensional geological radar, transient electromagnetic, and deep circulation blast holes. The combination of “long distance medium distance short distance” techniques such

as borehole temperature measurement and infrared photography of the surrounding rock of the face can refine the distribution and development degree of heat sources. “Controlling heat sources” refers to the use of targeted heat source control measures based on different types of heat sources to reduce the heat dissipation of the heat source. For high-temperature water, control measures such as drilling and sealing, centralized drainage are mainly used. For hot water drainage pipes, insulation treatment is required (Fig. 8). For high-temperature surrounding rocks, spray insulation concrete is mainly used for heat source control. “Combining drainage and water sealing techniques” refers to the treatment based on the development level of high-temperature hot water. When the hot water is $\leq 50^{\circ}\text{C}$, the inflow is $\leq 60\text{m}^3/\text{h}$, or the hot water is $\leq 70^{\circ}\text{C}$, the inflow is $\leq 30\text{m}^3/\text{h}$, a centralized drainage method can be used. In other cases, blockage is the main method, such as curtain grouting, sequential grouting, top water grouting, and so on. It is necessary to develop grouting materials specifically designed for sealing high-temperature hot water tunnels. These materials should enable rapid solidification under high-temperature and high-pressure water environments, effectively sealing water pathways in the surrounding rocks. “Comprehensive cooling” refers to the use of techniques such as enhanced ventilation, localized cooling, and the integration of cold water to achieve targeted cooling control for different geothermal levels and various regions (Table 2). “Monitoring and warning” involve comprehensive, fully automated, and intelligent monitoring and sensing of high-temperature environments inside the tunnel. This system provides feedback and guidance for engineering measures based on the collected data. “System guarantee” ensures construction safety by strengthening occupational health training

for workers, enhancing individual protective measures, providing well-equipped rest rooms and medical facilities inside the tunnel, and establishing emergency plans and their simulation mechanisms. Meanwhile, a new high-temperature support structure needs to be adopted, consisting of materials such as heat-resistant sprayed concrete, high-temperature waterproof board, insulation layer, reinforced lining, to ensure the long-term stress safety of the structure in high-temperature environments.

Figure 8. Heat source control.

Table 2. Cooling measures for different sections of high geothermal tunnels.

Surrounding rock and high temperature groundwater temperature	$t < 40^{\circ}\text{C}$	$40^{\circ}\text{C} < t < 60^{\circ}\text{C}$	$60^{\circ}\text{C} < t < 80^{\circ}\text{C}$	$t > 80^{\circ}\text{C}$
tunnel working face section	Use local fans	Use local fans, ice cooling (temperature 60°C , ventilation distance 4000m, ice consumption: 40 tons/day)	Use local fans, use a refrigerator to cool down	Use local fans, use a refrigerator to cool down
Tunnel body section	Drain with cover, thermal insulation air duct	Local grouting, thermal insulation drainage ditch, thermal insulation air duct	Full section grouting, thermal insulation drainage ditch, thermal insulation air duct	Full section grouting, thermal insulation pipe drainage, thermal insulation air duct
The section outside the tunnel	1~2 wind turbines, 1~2 air ducts to enhance ventilation	Use 2~3 turbines and 2~3 air ducts to enhance ventilation	Use 3 turbines and 3 air ducts to enhance ventilation	Use 3 turbines and 3 air ducts to enhance ventilation

Note: When the rock temperature and groundwater temperature exceed 60°C , a refrigerator is required for mechanical cooling

6 CONCLUSION

The complex climatic conditions and active geological structures in the Qinghai-Tibet Plateau have led to various technical challenges in the construction of these ultra-long deep-buried tunnel projects, including high seismic intensity, high ground stress, high seepage pressure, high geothermal heat, inadequate ventilation, and so on. These challenges seriously threaten the safety of the construction and long-term operation of the projects. This paper summarizes the main difficulties encountered in completed and ongoing tunnel projects in the Qinghai-Tibet Plateau region, as well as the current main prevention and control techniques. It proposes a disaster response concept centered around “active prevention and control”, construction techniques led by mechanization and intelligence, and long-term safe operation and emergency support technologies. These provide technical support and theoretical references for the safe construction and long-term operation of ultra-long deep-buried tunnels in the Qinghai-Tibet Plateau.

Observational method and calibration of design safety factors to optimize technical-economical solutions in tunnelling projects

Andrea Antiga*, Massimo Lorenzi & Antonello Lucia
More Engineering Srl, Milan, Italy

ABSTRACT: Tunnel design is a practice involving countless uncertainties and many failure modes. Often, the knowledge of the geological structure, the hydro-geological conditions, the mechanical properties and the behaviour of the soil/rock is only fulfilled during construction. The reduction of uncertainties progresses during excavation. For these reasons, a solution based only on the knowledge available at the time of the design phase can be unsafe or uneconomic. Conversely, information collected during excavation can be used to adapt the original design to comply with the actual conditions following an “observational approach”.

The paper will also provide some reflections on the potentials of the Observational Method in underground works also with reference to its use into projects according to a “lump sum” logic.

Keywords: observational method, risk, lump-sum, claim

1 INTRODUCTION

Doubtless, tunnel design involves much higher uncertainties than any other civil engineering work. A lot of tunnel projects reported significant cost overruns and contractors claims in percentage much greater than other civil construction works.

To be underground means that the context is difficult to know. To realize what “difficult to know” means we have to compare a tunnel with a surface structure.

Even in a comprehensive exploration program we can test only a small fraction of the total ground to be affected by the tunnel construction. We can recover a relatively miniscule drill core volume that is less than 0.0002 % of the volume of rock mass that one has to consider in tunnel design.

It is therefore obvious that ground conditions account for the largest element of technical and financial risk in tunneling projects. Risk minimization implicates decisions about what is required to excavate the ground, to control the ground during the process of excavation and to support that ground as the tunnel advances; each of these decisions are closely related to one’s knowledge of ground conditions and one’s expectations about how that ground will behave and/or react to the process of tunneling.

From a design viewpoint, uncertainties can be categorized into two macro-categories: parameter uncertainty and model uncertainty. Each source of uncertainty can potentially result in unsatisfactory performance with associated casualty and economic loss,

so it is necessary to explicitly evaluate and quantify parameter uncertainty and model uncertainty.

In order to design safe structures, safety factors are used in most design codes in different formats. Ideally, these safety factors are calibrated such that they ensure sufficient reliability for a wide range of cases.

In the recent decades, tunneling design codes have developed considerably. The tunneling engineering practice has developed from experience-based decisions to rational design criteria. In many aspects, geotechnical design Codes have followed developments in structural engineering. Besides design approaches based on reliability theory (i.e., the probabilistic approach) has developed considerably.

Tunnel design rules are usually borrowed from the geotechnical ones.

2 FORESEEABLE AND UNFORESEEABLE UNCERTAINTIES

When we deal with ground conditions the “unknown” usually exist in inverse proportion to the amount and quality of the geotechnical investigations.

In the development of a project of an underground work we can distinguish various levels of knowledge about hazards and uncertainties and consequently about a risk event’s occurrence.

We can have:

1. uncertainty associated to the tunnel section in which specific situations, nevertheless certain, will

*Corresponding author: a.antiga@more-engineering.it

- occur; for example, it is not known the actual distribution of rock types along tunnel alignment, the extent of fault areas, the exact area of sudden water in flows, etc. but it is certain that they will happen;
2. uncertainty associated to the precise intensity with which certain situations, expected by type (and as maximum value), will occur; for example, having to go through a certain rock mass, there are uncertainties about the maximum magnitude of the acting loads and of the consequent convergences, even though it is possible to assume a priori the extreme situations of reference;
 3. uncertainty related to the possible occurrence of completely unforeseen situations. In this category we must include unfortunate geological feature, the presence of which was missed during the design stage and requires partial or total redesign of the project; we have also to include a type of geomechanical behavior that was not predicted in the design.

We can define the first two uncertainties as “expected tunneling hazard”. Usually, only foreseeable uncertainties, which can be quantified, are directly considered in design. We can prepare the tools for dealing with them during the design phase and therefore they are manageable during construction and lead to the modification of quantities within a specific standard solution already identified in the project. The third is an uncertainty that we could qualify as “unforeseeable”. It can make the typical solutions imagined in the project no longer valid (i.e. it affects the final reliability). It cannot be easily quantified and should be implicitly considered in the design assumptions.

It must be highlighted that it is practically impossible to completely remove uncertainty inherent in tunnel design. It is equally true that increasing awareness of these existing uncertainties and their consequences is a basic input of a reliability view.

Lack of awareness of the uncertainties can result in unsuitable design solution and therefore designers must focus on thinkable consequences of design assumptions.

It is always important to remember that an “expected tunneling hazard” is a controlled hazard and small unforeseen hazards can be worse than big foreseen hazards.

The three first and fundamental steps in the development of a tunnel project are: (1) characterization of the underground layers and geometry, (2) choice material parameters (3) choice of a suitable computational model.

Different designers would make different choices in these three phases leading to conclusions between optimistic or pessimistic and consequently the reliability of the resultant designs can significantly diverge.

2.1 Geological and geotechnical/geomechanical uncertainties

The first obvious, but not always respected, rule to mitigate the “geo” uncertainties is to prepare a plan of investigation in an appropriate manner.

The most effective strategy to reduce geotechnical risk is to minimize the unforeseen and site investigations are the basis on which the risks associated with the project are identified; on the other side without enough information from site investigations the inherent risks would be unacceptably high. It would be obvious to conclude that a lot of time and economic effort need to be concentrated in site investigations.

An effective site investigation program is of major significance to obtain the necessary information essential for construction; we should increase our knowledge about possible hazard to be ready to treat them in a right way. Hence, an in-depth site investigation program would ensure that the project sees fewer change; resources dedicated to site investigations should be considered as an investment and when it comes to the geotechnical scope of work established for a tunneling project, one should not be thinking about reducing costs.

Nevertheless, a balance needs to be identified in determining the extent of site investigation. Soil investigations can be carried only to the extent that is judiciously possible, compatibly with time and budget available. It is necessary to establish a balance between the resources spent through site investigations and the losses prevented by them. Anyway, we can surely state that a good investigative program is helpful in reducing costs of works in percentage much higher than the cost of the additional exploration (Figure 1).

Figure 1. UK Highways Agency – Increase in construction cost vs ground investigation cost.

With an adequate geological and geotechnical knowledge, it is possible to better refine the project in the context of the uncertainties of type 1) and 2) and reduce as much as possible the uncertainties of type 3).

We should remember that residual uncertainties can lead to excessively conservative design approaches, higher provisions for risks and higher exposure to the risk of contractual claims. Any apparent economy in terms of cost could result in bigger residual geotechnical risks.

2.2 Model uncertainties

Model uncertainty can be defined as the ratio of the actual quantity to the quantity predicted by a model (Lacasse & Nadim, 1996).

In tunneling practice, site investigation is used as a basis for the definition of a ground model that is an idealized representation of the real geotechnical/geomechanical conditions. Site variability is considered by specifying different soil layers and through the choice of characteristic values of soil parameters. Creating a ground model involves the combination of the data gathered during the ground investigation with previous local experience and subjective judgement.

For design based on calculations, three main types of calculation models can be distinguished: analytical, semi-empirical and numerical.

An additional challenge of modern codes, as EC7, is that it is not prescriptive of the type of analysis to be used in design and encourages the use of numerical analysis. However, it does not specify as to the partial factors should be applied in numerical analysis. For example, the introduction of partial factors on soil strength, or partial material factors, implies that the soil's characteristic strength should be reduced by the relevant partial factor, and this can be achieved in two different ways: at a suitable stage during an analysis, or at the beginning of an analysis. They give different results but there is no guidance on which of these two approaches is more appropriate to apply (Potts & Zdravkovic, 2012).

Another tricky phase in the utilization of numerical models is soil-structure interaction in a semi-probabilistic framework (please refer to §4). When this is carried out with non-linear constitutive models of soils, the stiffness of soil depends on the characteristics of resistance and would be altered in presence of their factorization with partial factors. Furthermore, in these analyses, factoring the resistance soil parameters would modify the soil stiffness-resistance ratio by altering the distribution of stresses. Even the factoring of loads would involve an unnatural alteration of the conditions of plasticization of the soil and, consequently, an unrealistic redistribution of stresses.

For these reasons, the soil-structure interaction analyses must be carried out without any factorization of these parameters, thus using their characteristic values. The safety margin is then introduced by appropriately factorizing the stresses resulting from the interaction analysis.

This aspect is well explained in the recent Italian Codes (NTC 2018). It is not well addressed in most other Codes, first the Eurocode 7, and involves potential critical issues in numerical modeling with soil-structure interaction; this can, for example, occur when “design approach 3” (for which the entire calculation is performed with the design values of the actions and the design shear strength) is used.

Moreover, the existence of wide variety of calculation methods is one of the main constraining factors of harmonizing design practice and procedures.

It is difficult to obtain targeted safety level when a calculation model is used with a set of code-given partial factors, without consideration of the degree of reliability of different models.

The inherent uncertainties resulting from simplifications should lead to redundant conservatism. On the other side, advanced calculation methods require a great number of parameters and factors that can make those methods not appropriate for practical applications.

Lambe (1973) highlighted that using advanced models which parameters are based on unrepresentative number of soil tests may be even less reliable than using simplified models for which the amount of data is enough.

From a practical point of view, the appropriate model can be described as one offering the most favorable balance between the reliability of prediction and the necessary data for its application.

It is important to keep all these in mind when choosing a model to be used in the calculation and also to pay attention to EC7 that states “It should be considered that knowledge of the ground conditions depends on the extent and quality of the geotechnical investigations. Such knowledge and the control of workmanship are usually more significant to fulfilling the fundamental requirements than is precision in the calculation models and partial factors”.

The choice of the geotechnical model, the calculation scheme, the constitutive law of the soil, must be commensurate with the quantity and quality of the geotechnical data, since the reliability of the result is conditioned by the weakest link in the chain.

3 DESIGN BY CALCULATION

In the design phase, to deal with the uncertainties, the typical approach, known as ‘predefined design’, is to attempt to eliminate the uncertainty by assuming a conservative condition, derived from the data available before construction.

Various possible methods, inherited by design of structures, can be used to consider uncertainties and to ensure an adequate margin of safety; the main ones are:

1. the global safety factor method,
2. the semi-probabilistic method (partial safety factors)
3. the probability-based calculation method.

In all three cases, the final design is determined prior to construction, based on ground parameters that take account of uncertainties inherent in natural soil/rock.

The development of the safety philosophy in geotechnical design went through a first phase where “global safety factor method” was adopted (nowadays practically abandoned) to move toward reliability-based methods (i.e. probabilistic-based method).

In the European countries, the main documents providing guidance on the method of reliability assessment and the reference reliability levels in the geotechnical field are EN 1990 and EN 1997.

The main aim of the Eurocodes has been to harmonize the design practice across Europe and provide unified framework for design. Unusual or high-risk structures are beyond their scope.

For tunnel design the codes are very poor and designers refer to geotechnical rules.

Eurocode EN 1997 states that it contains rules for “tunnels in hard non-fractured rock and not subjected to special water tightness or other requirements”; for other tunnels it is necessary to consider alternative provision and rules, but no specific indication is given.

Furthermore, there is no consensus on the choice of a commonly accepted targeted safety level. Reference levels of safety factors provided in Eurocodes may be subjected to a change in the national normative annexes. Moreover, in the respect of a general mandatory framework, Eurocodes allow for the use of different approaches to ensure sufficient reliability level.

The Italian Codes (NTC 2018) are congruent with Eurocodes.

3.1 *Global safety factor design*

Traditionally, geotechnical and tunnel design have been based on “global safety factor” method that has been sustained by a vast amount of experiences. It introduces a safety factor that is defined as a ratio between total resistance and total force and must be kept a value, higher than 1, given by experience. Values for different applications are empirically based and represent commonly accepted representation of the safety level for a given structure.

The use of global safety factor has been associated mostly with Allowable (working) Stress Design framework.

Although this approach can be easily and intuitively understood it doesn't represent an objective measurement of reliability as it does not directly account for various uncertainties. In theory, large uncertainties, arising from data and model, require large safety factors. However, the safety factors established in design Codes are not calibrated to consider different levels of uncertainty.

Since it is not a logical and reliable approach numerous studies have been undertaken in recent years to develop probabilistic approaches that deal with uncertainties in a methodical way. In the last few decades, efforts have been made to substitute “global safety factors”, i.e., deterministic design, with reliability-based design.

3.2 *Probabilistic-based design*

The “probabilistic-based design” (i.e. “reliability-based design”) is a way of handling foreseeable uncertainties by an explicit introduction of “probability density functions” (PDF) of know variables, i.e. relating to loads, material parameters and resistance.

One of the main characteristics is that parameters are defined over a range of values, not as a specific value, as in a deterministic approach.

In civil engineering the probabilistic method (level 3) is practically impossible to use, both for the number of independent random variables, and for the difficulty of knowing the PDF.

It would be possible to use a simplified probabilistic method (level 2), reducing the number of independent random variables to those that have the greatest effect on the value of the dependent variables. However, in current practice even level 2 methods are difficult to apply, since the designer does not have the data and knowledge of statistics and probabilities to apply it.

In any of the previous cases, the main downside is of course the lack of necessary data, especially, concerning PDF of geotechnical parameters.

Nowadays most design are based, for safety analysis, on the probabilistic method of “level 1” (or “partial safety factor” or “semi-probabilistic”) and on the concepts of Limit State, as a demarcation between desired and adverse states of the structure.

This is the method formally used by the Technical Codes for Construction in most of the world countries (i.e. Eurocode 7, NTC, 2018 etc.).

4 OBSERVATIONAL METHOD

Observations have been used by engineers to deal with uncertainties and to observe the performance of structures since the early days of civil engineering.

Terzaghi & Peck (1948) discussed the first thoughts and ideas behind this process in geotechnical engineering. They suggested a new design procedure where information obtained during the construction phase is used to optimize the design.

The interest for the application of the observational method has increased in Europe during the last couple of decades, mainly due to the drive for competitiveness in the construction industry, as well as an increasing demand on reducing time and costs.

According to Nicholson et al (1999) the observational method is: “A continuous, managed, integrated, process of design, construction control, monitoring and review which enables previously defined modifications to be incorporated during or after construction as appropriate. All these aspects have to be demonstrably robust. The objective is to achieve greater overall economy without compromising the safety.”

Eurocodes 7 and the Codes of the main European countries state that Limit States could be verified by mean of the “the observational method” when prediction of geotechnical behavior is difficult.

It states that before construction is started “the range of possible behaviour shall be assessed, and it shall be shown that there is an acceptable probability that the actual behaviour will be within the acceptable limits”. This asks for a probabilistic approach and makes the rigorous application of the method difficult. In the Italian Code (NTC, 2018) the word “acceptable probability” is not present (!) so the use of this approach is easier.

The approach is based on a design that is improved step by step during excavation by means of observations and data collection on soil-structure interaction that allow to acquire useful elements for a better understanding of the geological and geotechnical reference model.

An Observational Method design assumes that the ground conditions will be near to a “reference value” of the predicted conditions, but alternative designs or contingency measures are prepared in case conditions should turn out to be worse than predicted.

Essentially, it is a method for reducing the risk in the construction phase based on preventive design analysis.

This approach identifies that uncertainty has two components, risk and opportunity: the ground conditions could turn out to be better than expected or worse and therefore brings enormous potential in terms of reducing risks and optimizing the costs of the works. The basic idea behind the OM is to balance reliability with economy by allowing design modifications at the construction phase, where design is done for expected conditions, but steps are taken to safeguard against the occurrence of less favorable ones. The most important aspect distinguishing the OM from just “learn-as-you-go” approach, often confused by engineers, is the preparation of fallback scenarios for every predicted unfavorable situation considered previously.

These scenarios should be realistic and possible to implement without delay and all possible modes of failure should be accounted.

During the design implementation a rigorous monitoring and observation strategy is used to check and confirm the actual conditions found during construction. Performance indicators are selected for monitoring, related to the critical risks. Peck (1969) stressed the importance of making right observations regarding measuring phenomena governing the behavior of the project; measuring the wrong quantities may cause significant problems. The issue noticed by Peck (1969) still rings true now that, not infrequently, less effort goes to the significance of data obtained from monitoring than the preparation of formal reports and documents based on them.

The choice of the calculation parameters for the “reference design” is one of the most debated item and conditions the possibility that the Observational Method is cheaper, with the same safety conditions, compared to a traditional approach. There are, essentially, two approaches (Figure 2):

1. based on ‘most probable’ conditions. Contingency measures are prepared before construction and are implemented if observed behaviors exceed critical limits;
2. based on a “most unfavorable” set of parameters. Observations during construction are used to actively optimize the design.

There are, obviously, intermediate approaches.

Peck (1969) adopted the “most probable” conditions and then reduced the design to “moderately conservative” parameters, where triggers were

exceeded. CIRIA [4] considers a “safer” approach to design by adopting a “progressive modification” of the design starting with the design based on “moderately conservative parameters”, and then reverting to “most probable” conditions through field observations. CIRIA uses the terms “most probable” and “most unfavorable” to describe the range of soil conditions as illustrated in Figure 2.

Figure 2. Gaussian distribution.

The “most probable” is a set of parameters that represent the probabilistic mean of all the data.

The “most unfavorable” parameter represents the 0.1% fractile (it represents the worst value that the designer believes might occur in practice).

The “moderately conservative parameter” is not a precisely defined value. It is a cautious estimate of a parameter, worse than the probabilistic mean but not as severe as the most unfavorable. In assessing these parameters, the designer should carefully consider the quality of the site investigation data and assess its suitability. It could be associated to the “characteristic value” of geotechnical parameters that Eurocode 7 defines as a “cautious estimate of the value affecting the occurrence of the limit state”. It should ideally result in prediction of the upper 5% fractile.

The establishment of the initial design based on the “most probable” ground conditions drew most concerns. Muir Wood (2000) underlined as sometimes the concept of “most probable” situation is mistakenly associated with the situation that will be overcome with little probability; actually, most probable is equivalent to 50% probability. Almost all subsequent authors, suggest starting with an initial “moderately conservative design”, to be relaxed to a “most probable” condition during construction, should the observed behavior warrant it.

In the observational approach, the suitable limits of behavior, is a “serviceability” calculation. These provide the predictions that can be monitored and reviewed.

Since a tunnel is excavated “step by step”, we obtain a lot of information on tunnel behavior during the construction and we can improve the original design during excavation: the application of the observational method is a standard method in tunneling design and construction. It is also true that often the application is not formally congruent with all the Code’s indications and it would be better to speak of observational approach.

5 THE POTENTIAL OF THE OBSERVATIONAL METHOD

The use of the Observational Method allows, in general terms, a reduction of the risk present in the construction of an underground work.

If we compare an “Observational Method design” with a “predefined design” we must highlight that less conservative ground parameters should be applied.

In a “predefined design” we proceed using the “most unfavorable” (worst scenario) set of parameters; in the case of the Observational Method we should proceed using a less unfavorable set of parameters (“most probable” according to Peck, “moderately conservative” for other authors).

Basically, we can work with safety factors lower than those used in a predefined design without reducing the real safety of the project. This is made possible by the knowledge acquired gradually during the work.

To clarify this concept, let us analyze the Figures 3 and 4 in which Gaussian distribution of load and resistance is represented. If one design based on the “most unfavorable” set of parameters and apply a similar factor of safety that we would for the most probable condition, we will fall in the first category described by Peck (1969), i.e. a wasteful or over-conservative design (Figure 3). On the other hand, designing for the “most probable” decreases the degree of conservatism and would be more economical (Figures 3 and 4). However, as Peck stated, it is, to some extent, a gamble; otherwise, if not there would be no need of using the word “probable”.

Figure 3. “Most unfavorable” set of parameters.

Figure 4. “Most probable” set of parameters.

By adopting an observational approach and a working hypothesis of the most probable conditions, one could say that it is at least a risk-controlled “gamble”.

The objective of the observational method is to deal with uncertainties, and not reduce factors of safety, so if we properly monitor the ground behavior during excavation, contingencies may then be put in place if we realize that our “gamble” has failed (Oliveira 2015).

6 RISKS ALLOCATION

Noted that residual “geo” uncertainties and consequently “geo” risks tend to prevail despite robust site investigations and advanced calculation models, a contract should incorporate a mechanism to determine how to deal with residual risks and should give a clear allocation of risks for the case they occur. It is also clear that uncertainties of types 1, 2 and 3 (with reference to chapter 2) must be treated in a different manner and the choice of the contractual form implies a different allocation of risk to the Owner or Contractor. In general, in simplified terms, we can identify two most common forms of contract: 1) unit prices contract and 2) lump sum contract. The use of one or the other contractual form involves a different way of managing uncertainties and any unforeseen events (Klee 2015). In unit prices contract it is easy to deal with large variations of quantities in a reasonable manner, as regulation mechanisms are built into the contract. The experience shows that unit prices contracts are suitable to deal also with ‘unexpected geological conditions’, as long as the ‘unexpected’ element results only in variations in the quantities of work activities, that is for uncertainties of type 1) and 2). This means that all necessary work activities must have quantities and preferably also ‘standard capacities’ for regulation of the construction time. If “truly unforeseen” geological features (that is uncertainties of type 3), for which there are no methods and quantities available in the contract, occur the unit prices contract must be supplemented by special agreement. Unit price contract allocates all or most of the risk for the ground conditions to the Owner. For this reason, for underground construction where the impact of changed ground conditions can be very severe, Owners in many cases are reluctant to shoulder all the geological risk. For purposes of financial planning, many Owners prefer awarding lump sum (i.e fixed price) contracts. Fixed price contracts, with all risk for ground conditions allocated to the Contractor, may have an apparent predictability of cost, which may be attractive to the Owner. However, this type of contract imposes risks on the Contractor that may at best be difficult to quantify, at worst disastrous if the “truly unforeseen” occurs (i.e type 3). Such risks may become an Owner problem, no matter the contract text, if the Contractor is not able to bear the loss and complete the project. Therefore, also lump sum contracts for underground projects may not provide the intended predictable cost. ‘Adjustable fixed price’ contracts, combining unit rate and fixed price, may prove to be more suitable than fully fixed price

contracts, and easier to handle than unit prices contracts. According to the FIDIC ITA Task Group 10, risk allocation and risk dependent costs can be shown in a simple way as in Figure 5. It suggests that a fair risk allocation is likely to produce the lowest construction cost (FIDIC-ITA 2014). It is evident that, from a contractual point of view, the types of uncertainties described above must be addressed in a different way. In the case of uncertainties of (type 3), one must think a subdivision of the risk that involves in a decisive manner the Owner. History shows that the attempt to transfer the total geotechnical risk to Contractor does not liberate the Owner of his final responsibilities. In the event of a high level of losses, the Contractor will look for all possible ways to terminate the contract in advance; this can impact on the total costs, quality, safety of the entire project. Fair risk sharing between the Owner and the Contractor helps to reduce potential claims and therefore the total project costs. We can say that for the uncertainties of type 1) and 2) we cannot speak of unforeseen or unforeseeable.

In other words, there is the certainty of not knowing exactly anything, but moving in known areas for which the actors (Owner and Contractor) can evaluate and quantify the existing risk.

Figure 5. FIDIC Task Group 10. Lowest construction cost.

In any case, these uncertainties do not allow to precisely define the cost of the work. Therefore, it is necessary to find contractual mechanisms that distribute the risk of this non-definition on Owner and Contractor in a different way, also attributing a “risk premium” to the higher risk that one of the two is willing to charge. The theoretical ideal allocation of risk in a contract is that point where the sum of the risk premiums is minimized, the point where each party takes on the risk for which it is best placed to control and manage those risks. For the uncertainties of type 1) and 2) a lump sum contract could be assumed. It is necessary to define the risk assignment limit to establish what conditions were expressly or impliedly “foreseen” within the contract. This can be done by the Geotechnical Baseline Report (GBR) (ASCE 2007).

The Geotechnical Baseline Report is a document where contractual statements describe the geotechnical

conditions predicted (or to be assumed) to be met during construction. It has to be viewed as a tool for defining those conditions that should be considered ‘reasonably foreseeable’ (i.e. uncertainties of type 1) and 2)).

The contractual statements are referred to as “baselines”, and they should be considered as the reference point for risk evaluation and pricing. In fact, the tenderer needs to know ‘with a sufficient degree of certainty’ the risk that he is going to price, while the employer needs to know what he is going to pay for. Both parties must evaluate the cost of known conditions and to estimate the contingencies that should be included either in the contract price or in the Owners’ budget.

The “baselines” serve as contractual references to establish where conditions encountered during construction that are significantly more adverse, onerous and time consuming, may be considered as ‘unforeseen’ (i.e type 3).

Risks associated with conditions consistent with or less adverse than the “baselines” are allocated to the Contractor, and those more adverse than the baselines are accepted by the Owner (Figure 6).

Figure 6. Baseline.

It is important to describe the possible range of property values or ground behavior. The recommended approach is to indicate the expected range of conditions and uncertainty, but then state a specific baseline (upon which bidders may rely) that has been established for contractual purposes. The baseline may be expressed as a maximum value, a minimum value, an average value, a histogram distribution of values, or a combination of them.

The Owner may decide to allocate certain risks and costs to the Contractor by baselines that are more adverse (higher “risk premium”). This will usually result in an increased bid price. Alternatively, the Owner may choose to share the risks and costs through less adverse baselines and utilization of either alternative payment provisions or a change order process, if the more adverse conditions materialize. To be useful for risk allocation, a geotechnical baseline must clearly establish the boundaries of those conditions that are expected and define how they are measured. The GBR has come into use in some countries, and there are encouraging benefits of its use. The British Tunnelling Society and the Association of British Insurers, which represent insurers and re-insurers on the London-based insurance market, issued their the “Code of Practice for

Risk Management” and the GBR concept is adopted in this code (BTS ABI 2003).

7 FINAL CONSIDERATIONS

In summary, the adoption of Observational Methods helps in mitigating the geotechnical risks.

It is therefore established that by proceeding with an observational approach, two important advantages can be obtained.

1. Verification, during construction, of the solutions defined during the design phase.
2. Calibration of the input parameters and the consequently of the safety factors in consideration of the knowledge acquired during the works.

In general, only the advantage 1 is exploited, i.e. the predefined design solutions are refined. Therefore, its potential, above all in terms of possible reduction of the overall costs of the work, is generally not fully exploited in the planning and construction phase. It is standard practice to limit its use to refine the application of the stabilization interventions and construction methods defined by a “predefined” design.

In other words, a “basic” design is developed based on the available data, and then in the construction phase this design is adapted to the real conditions found on site without modifying the safety factors as it would be possible by the greater information that are gradually acquired.

Depending on the specific problem, the parameter uncertainty, or model uncertainty or both can be updated through back analysis.

Generally, The OM is applied in the context of a unit prices contract with all risks are accepted by the Owner, without fully exploiting the opportunities provided by the method.

Therefore, there is a large “not exploited” reservoir of potential optimization of the total cost of the work. It is often suggested that cost uncertainty should be allocated to the party best able to anticipate and control that uncertainty, usually replacing the term ‘uncertainty’ by ‘risk’ although variability, ambiguity and systemic uncertainty may also be involved.

On this basis, a tentative conclusion is that lump sum contracts are appropriate when sources of uncertainty are controllable by the Contractor, i.e. types 1) and 2) that are within baseline. An interesting analysis of Ward and Chapman (2011) concludes that a lump sum contract is usually risk efficient in allocating Contractor controllable uncertainty. An important conclusion is that even where Owner and Contractor share similar perceptions of project cost uncertainty, fixed price contract may be inefficient for the Owner, if the Contractor is more risk averse than the Owner. In this situation, the Contractor will require a higher premium to bear the risk than the Owner would be prepared to pay for avoiding the risk. It is equally true that in the case of lump sum contracts all the uncertainties, even within the baseline, are the responsibility of the Contractor and consequently the Contractor may be driven to maintain a high ‘risk

premium’ and then do not convenient offer for the Owner. For this reason, this type of risk should be mitigated by appropriate contractual architecture. On the other hand, under a fixed price contract, the Contractor is motivated to manage project costs downwards to formulate a competitive offer; it should be able to generate, an ‘opportunity discount’ for example, by increasing efficiency or using the most cost-effective approaches. With the use of the Observational Method, one could exploit precisely this enhancement linked to the good work of the Contractor.

The definition of aggressive baselines involves high risks for the Contractor and the consequent attribution of a higher “risk premium” (i.e. expensive offer for the Owner).

This premium could be balanced by allowing the Contractor to use an Observational Method with optimization of the interventions. By exploiting the potential of the Observational Method, the Contractor could be able to manage all the risk (within the baseline) and could generate benefits for both Owner and Contractor. For that purpose, it is strategic to build a sufficient flexibility into the contract so that design can be adapted during construction according to “geo” properties encountered within an observational approach. With the use of the Observational Method, the Owner could use a more aggressive baseline because thanks to the possibility of refining the “safety factors” (without reducing the overall safety of the work) there is a possible premium for the Contractor. This could allow for more aggressive lump sum bids and therefore an overall advantage for the Owner. Ultimately, we want to highlight how moving within the limits of the uncertainties of type 1) and 2) then definable by the Geotechnical Baseline Report and controllable, the contract could also be a lump sum thus attributing all the risk to the Contractor. Within the baseline, the Contractor would have the possibilities to evaluate and quantify the risk and considering a possible refining of the “safety factors” (made possible by the greater knowledge acquired during construction and therefore without reducing the overall safety of the work).

It must be emphasized that for a “right” use of the Observational Method, that wants to enhance all the potentials of the same, it is necessary that Owner and Contractor provide a team of expert designers able to support the mutual interests. The processes of design and construction need to be integrated, and close co-operation is required between all those involved in the project. Definitely, increasing investments in engineering design would allow a control of cost and time overrun and a certain reduction of the overall cost of the project.

Design of Ontario Line South Tunnel

Mehdi Bakhshi*, Verya Nasri & Toufic Maalouf
AECOM, New York, USA

ABSTRACT: The Ontario Line is a 15.6-km stand-alone rapid transit line with fifteen stations that will connect the Ontario Science Centre to the Exhibition (Ontario Place) with numerous connections to the broader transit network. The southern stations and tunnel, also known as Ontario Line South (OLS), will be the first portion of the Ontario Line to be designed and constructed. OLS consists of 6.7 km of twin bored tunnels between the Exhibition portal to Don Yard portal (west of the Don River), seven new stations, six underground and one at-grade stations to be integrated with existing underground stations. The tunnel will be excavated by a 6.8-m hybrid shielded rock TBM, capable of operating in open mode when in relatively competent rock and operating in EPB mode when the tunnel is passing through potential buried valleys. TBM excavation will be supported by a precast fiber-reinforced concrete segmental lining system. This paper presents geological conditions in the Georgian Bay formation, alignment, excavation sequence, design of lining, and geotechnical instrumentation and monitoring for the OLS bored tunnels.

Keywords: Concrete, Fiber, Lining, Rock, Segment, TBM

1 INTRODUCTION

Ontario Line is a 15.6-km long rapid transit project. The project will consist of fifteen proposed new stations that will have several connections to the existing stations. Ontario Line South is the south underground portion of the project that runs from Exhibition portal to Don Yard portal, as shown by red line in Figure 1. The tunnel length between the two portals is approximately 5.9 km. This portion will consist of five underground stations (King Bathurst, Queen Spadina, Osgoode, Queen, Moss Park and Corktown). These stations will be connected by two twin TBM tunnels. The TBM tunnel is lined with fiber-reinforced concrete. While the project includes cut-and-cover structures such as portals, headwalls, shafts, station, and

Figure 1. Overview of Ontario Line South (OLS) project.

underground station structures constructed using the sequential excavation method (SEM) with a roadheader, this paper will exclusively focus on the design and construction of the main tunnels.

2 GEOLOGICAL CONDITIONS

The site geological conditions consist of the following layers. The shallowest layer is a granular fill layer underlain by modern alluvial deposit and coarse textured lacustrine deposit. These deposits are underlain by glacial till deposits (plastic and non-plastic). These native deposits are underlain by the bedrock. The interpreted stratigraphic profile indicates that the bedrock surface generally slopes down from approximately 80 m at the west to about 65m at the east end except a buried bedrock valley with lowest bedrock surface of about 40 m that was identified in the vicinity of the Don River. The rock belongs to the Georgian Bay formation which consists of shale, limestone, dolostone and siltstone. The fractured rock layer is called Type 16 in this project consists of decomposed or highly weathered shale and Type 17 rock is the competent rock found underneath. The horizontally bedded Georgian Bay Formation regionally contains consistent sets of vertical or sub-vertical discontinuities and horizontal to sub-horizontal bedding discontinuity. Location of tunnel

*Corresponding author: mehdi.bakhshi@aecom.com

with respect to the geological layers are shown in Figure 2. The majority of the tunnel will be excavated in type 17 competent rock.

3 TUNNEL EXCAVATION METHOD

The selection of the Earth Pressure Balance (EPB) TBM excavation method for OLS was based on a comprehensive analysis of geotechnical, settlement, groundwater, wear, and gassy conditions. The project alignment intersects Type 17 and 16 bedrock units, resulting in the majority of the tunnel being excavated in excellent rock face conditions. Nevertheless, pressurized TBMs excel in controlling settlement and face stability when encountering discontinuities like joints and shear faults. Furthermore, they are the optimal choice for addressing geotechnical conditions, such as the potential presence of buried valleys, especially on the eastern side of the project alignment. This selection not only facilitates the implementation of an optimal face stability pattern but also ensures settlement levels below attention thresholds near tall and heritage buildings in Downtown Toronto. Given the groundwater level and low hydraulic conductivity, groundwater pressure does not affect the choice of TBMs. However, addressing groundwater is more effective with pressurized TBMs compared to open-shield TBMs. The selected TBMs are pressurized single shields equipped with cutter discs, as indicated by geotechnical reports that suggest a very low wear potential for the rock mass, reinforcing the suitability of the TBM excavation method. Additionally, geotechnical investigations have confirmed the presence of methane and hydrogen sulfide gas within the shale bedrock, necessitating that the TBM excavation method meet the requirements for a “gassy tunnel”. OLS tunnels will be constructed in an easterly direction, starting from the Exhibition Portal, passing through Queen Station, and concluding at Don Yard

Headwall. At Don Yard, the shields are abandoned in the ground, and the TBMs are disassembled from within the tunnels.

4 SPACEPROOFING

The selected configuration for the OLS project consists of two twin-tube tunnels with an inner diameter of 6.05 meters (Figure 3). The inner diameter of the tunnel’s precast segmental rings is determined by various factors, including the Vehicle Dynamic Envelope (VDE) on curves, track structure, duct banks, electrical conduits, walkway platforms, track center spacing, overhead catenary envelope, and fire life safety cabinets and equipment. Construction tolerance is considered 100 mm.

5 PRECAST SEGMENTAL LINING

The TBM tunnel will be lined with a watertight circular one-pass lining system with precast concrete segmental rings. These rings are available in two types, each designed with a different width to accommodate varying minimum curve radii. Type 1 rings have a width of 1.7 meters suitable for minimum curve radius of 200m, while Type 2 rings are 1.2 meters wide suitable for a minimum curve radius of 141m. Both ring types have a thickness of 270 mm, ensuring structural capacity for all governing load cases. As depicted in Figure 4, each ring is composed of seven ordinary segments, one large key segment, and one reverse-key segment. The key and reverse-key segments have dimensions similar to ordinary segments, leading to a 6+0 ring configuration. Ordinary segments have an arc angle of 60 degrees, while the reverse-key segment features an arc angle of 63 degrees, along with a slightly greater

Figure 2. OLS tunnel profile.

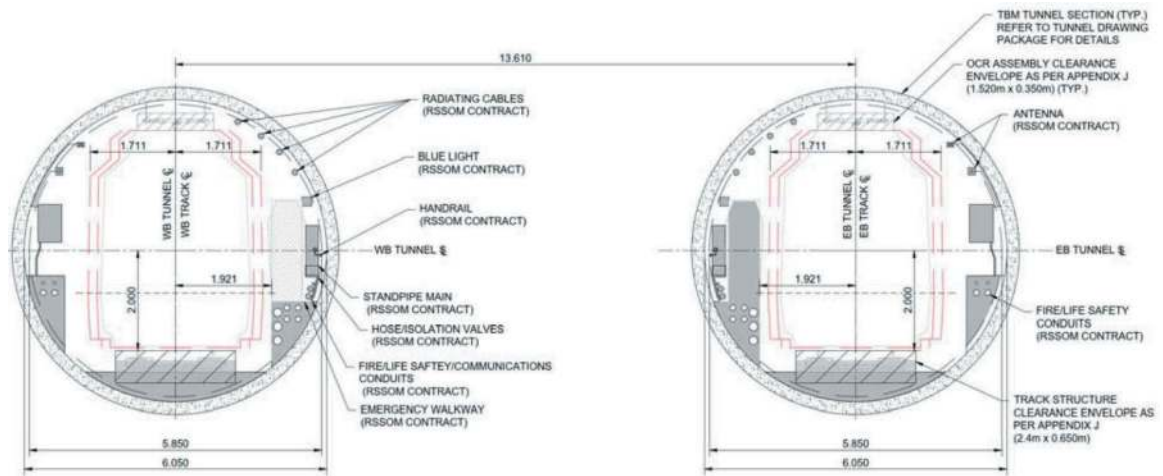

Figure 3. Tunnel spaceproofing.

curved length than other ordinary segments. Consequently, the key segment features an arc angle of 57 degrees and a slightly shorter curved length compared to the ordinary segments. To create staggered longitudinal joints, the angles between the joints of ordinary segments and the tunnel axis are set at 8 degrees. For key segment joints, this angle is slightly adjusted to 10 degrees. Rings are tapered to negotiate alignment curvatures. The calculation of the ring taper takes into account the smallest curve radius along the alignment, the ring's length, and the tunnel's outer diameter. As a result, the total ring taper is 56 mm or ± 28 mm at the centerline of both types of rings.

The designed ring geometry is optimized to prevent crucifix joint formation during TBMs' tangent and curved drives, thereby reducing the risk of groundwater infiltration. Using a universal ring system offers several advantages, such as simplifying segment production through a single formwork set for each ring type, resulting in substantial cost savings. In presented configuration, as shown in Figure 5, ordinary segments have a parallelogram shape, while the key and reverse-key segments are trapezoidal. This rhomboidal segment system stands out as the most advanced when compared to other systems like hexagonal, rectangular, and trapezoidal systems. It offers several advantages, including the prevention of crucifix joints, improved sealing performance, continuous ring assembly from bottom to top, and compatibility with a dowel connection system.

Longitudinal and circumferential joints are designed as entirely flat joints. This design promotes efficient load transfer between segments and rings, enhancing joint watertightness. Furthermore, tapered longitudinal joints reduce early gasket friction during segment insertion in the ring assembly phase, making it easier to use fast connecting dowels in circumferential joints. This makes tapered longitudinal joints, hence rhomboidal segments, a preferred choice over rectangular ones.

Designed ring configuration also facilitates the ring assembly phase. As shown in Figure 4, the key segment's longitudinal joints are along the lines originating from a point 1500 mm directly below the tunnel center point.

This eccentricity facilitates the large key segment insertion during ring assembly.

Figure 4. Ring geometry.

The key draw distance is designed so that the minimum gap between the key ring and the reverse key ring is 30mm as shown in Figure 6.

Bolts are used as connection devices between pre-cast segments in longitudinal joints and dowels act as connectors of segments in circumferential joints. The insertion of the dowels is automatically performed by the TBM erector, which saves construction work and manpower during ring installation. Dowel type is modified Optimas SOF-FAST 110 with yield and ultimate pullout capacities of 110 and 160 kN, respectively (Figure 7). This type of dowel reduces the possibility of cracking caused due to joint

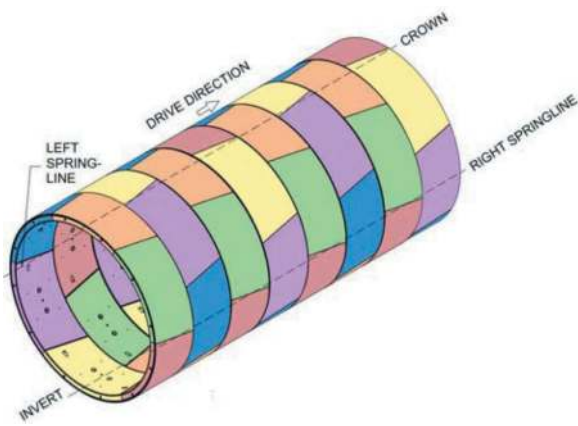

Figure 5. Successive rings on a tangent alignment.

Figure 6. Plan view of key draw.

misalignment by limiting the joint offsets and improves sealing performance of gaskets by limiting joint gaps.

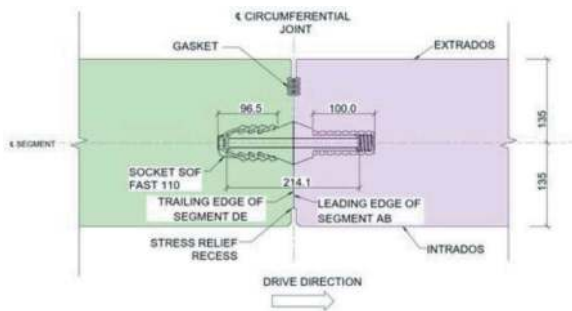

Figure 7. Dowels at circumferential joints.

The segment joints will be sealed using EPDM glued gasket. The gasket profile is Datwyler/Sealable M38596 type “Portland”. The sealing performance of the gasket is checked by obtaining the maximum groundwater pressure present along the entire alignment. The capacity of the gasket is checked by accounting for the relaxation factor for 100-year service life of tunnel and maximum potential gaps and offsets between segment gaskets as 5 mm and 10 mm, respectively. At these specified tolerances and considering a design gap of 1mm for the glued gasket groove construction tolerance, the tested water pressure resistance of the designed gasket profile is 15 bar, which

provides a safety factor of around 2.1 at the location of maximum groundwater pressure in the alignment.

The guidelines provided in ACI 533.5R-20, ACI 544.7R-16 and the ITA WG2 (2019) were followed for the structural design and analysis of precast concrete segments using the load and resistance factor design (LRFD) design method. Temporary and permanent load cases considered during the various stages of construction and at the final service stage are considered for design. For production and transient stages, segments are designed for formwork stripping (demolding), storage (stacking), transportation and handling load cases. Segment stacking is shown in Figure 8. For the construction stage, the considered load cases are TBM thrust forces, tail-skin and secondary grouting. The TBM thrust pad width is 900mm, and the thrust pad contact length with the segment along the thickness is 175 mm. TBM is designed using a 12-pad configuration (two pads per segment, as shown in Figure 9) which increases the gap between the pads and the longitudinal joints (which should be 200mm minimum). The theoretical eccentricity (also called mechanical eccentricity) is 35mm for a 270mm thick segment. We consider that we can correct 20mm thanks to the articulation, so it becomes 15mm. The construction tolerance is considered as +/- 30mm. While both linear elastic and nonlinear FEM simulations can be performed, the amount of stresses developed due to maximum/exceptional combinations of forces and eccentricities often exceeds tensile strength of FRC segments. It can be concluded that only nonlinear analyses can truly capture response of the FRC segments after cracking. Serviceability limit state (SLS) condition is the main concern as crack width opening dimension under jack forces may exceed the limits specified by project’s design criteria which is commonly taken between 0.25-0.30mm.

Figure 8. Segment stacking.

The next load cases to be analyzed are tail-skin and secondary grouting load cases. FE Analysis was performed on one segmental ring loaded under the governing grout pressure gradient anticipated in the alignment. This analysis produces axial and shear

Figure 9. Jack pads on a typical segment.

forces and bending moments which constitutes the structural demand. The governing load cases during the final service stage include earth pressure and groundwater load, and the longitudinal joint bursting. Two-dimensional finite element analyses were conducted for both load cases. The appropriate strength reduction factors and load combinations were applied for each case.

The precast tunnel segments are designed as fiber-reinforced concrete (FRC). Compared to conventionally reinforced concrete segments, FRC segments have superior crack control and offer cost savings hence the preferred solution for this project. The minimum compressive strength of the concrete at 28-day and at the time of stripping (demolding) was designed as 50 MPa and 12 MPa, respectively, to satisfy the demands of all governing load cases and to satisfy the durability requirements of the project. The design of the concrete mixture results in an optimized concrete performance that achieves a high early-age strength for stripping (demolding) and a high-performance concrete for long-term durability.

The type of fiber chosen for this mix design is cold-drawn wire ASTM A820 type I steel fiber. It has a strength of 2200 MPa, which is the highest strength for commercially available fibers in the market. Specified fibers are glued in clips, have double hooked ends, a minimum length of 60 mm, a maximum diameter of 0.75 mm, and an aspect ratio (length/diameter) of 80. The minimum specified content of steel fiber for reinforcing typical segments is 40 kg/m³. The limit of proportionality (LOP) and minimum specified residual flexural strengths at the stripping (demolding) age are $LOP = f_{R,1k} = 1.7$ MPa and $f_{R,3k} = 2.4$ MPa. The LOP and minimum specified residual flexural strengths at 28-day are $LOP = f_{R,1k} = 3.8$ MPa and $f_{R,3k} = 4.6$ MPa.

6 CROSS-PASSAGES

To satisfy NFPA 130 fire protection and life safety requirements, this project has three cross-passages between the two tunnels from Corktown Station to the Don Yard Portal as well as openings in the segments into an egress shaft at the Ordnance Street Emergency Egress Building between Exhibition Portal and King-Bathurst Station. Shear bicones are added in the circumferential joints of the rings at and around the opening areas into segments to take additional developed shear forces. Four SOF-SHEAR

375 bicones with shear capacity of 375 kN are placed on circumferential joints of segment, two around each dowel, which makes it 24 bicones per ring. As shown in Figure 10, six to eight bicones from cut rings will be removed in the opening areas, and remaining bicones take the shear force.

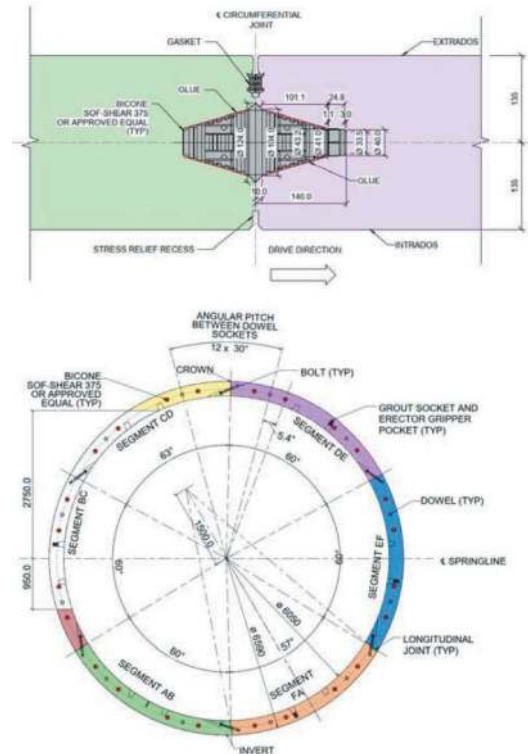

Figure 10. Bicone configuration at cross-passages.

7 GEOTECHNICAL INSTRUMENTATION

Since this project is being built in a densely populated area of Downtown Toronto, it is important to monitor the ground movements caused by underground construction to prevent any impact to the adjacent existing structures and make sure the initial

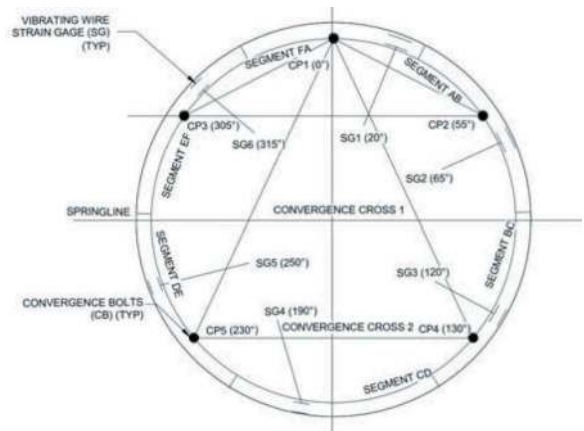

Figure 11. Instrumented Rings.
(SG: Strain Gauge, CP: Convergence Point)

and permanent supports perform as expected. The TBM segmental lining will be equipped with strain gauges (SGs) and convergence bolts as shown in Figure 11. Each instrumented ring will have six strain gages and five convergence bolts. The instruments will be installed all the critical locations.

In addition to these instrumented rings, the project will have surface monitoring program consisting of Multi-Point Borehole Extensometers (MPBXs), Ground Settlement Monitoring Points (GMPs), Manual Inclometers (INCs), Vibrating Wire Piezometers (VWPs) as well as structure, rail and utility monitoring points.

8 CONCLUSION

The 15.6-km Ontario Line South (OLS) project is a significant enhancement to the public transit system in the Greater Ontario providing faster and more reliable access to rapid transit within Ontario and reduces traffic congestion in the area. The site's geology comprises various layers, including granular fill, alluvial deposits, glacial till, and bedrock. Excavation for the Ontario Line South project will predominantly occur in the competent Type 17 rock of the Georgian Bay formation.

For the underground section, an excavation method using Earth Pressure Balance (EPB) was

selected based on optimal face stability, settlement control, and addressing geotechnical challenges, because of efficiency in excavating through rock discontinuities, potential buried valleys, and gas presence in the shale bedrock. The TBM tunnel from the Exhibition portal to Don Yard consists of two twin tunnels that have an inner diameter of 6.05 m and a ring thickness of 270 mm. With two types of rings, 1.2 m and 1.7 m in ring length, the entire alignment can be negotiated using universal segmental rings.

The optimized ring geometry and connection systems as well as gasket, fiber reinforcement and all other major characteristics of segmental rings are presented. It is expected that the segment production to begin in mid-2024 and tunnel construction starts between late 2024 and early 2025.

Design challenges in conventional tunnelling on the Sotra Link Project in Norway

Guido Barbieri*, Gianluca Bella, Edoardo Trivellato, Salvatore Agrillo & Matteo Giani
Pini Group SA, Lugano, Switzerland

ABSTRACT: In the perspective of easing the amount of traffic between Øygarden and Bergen along the existing Riksveg 555 (West Norway), the Sotra Link Project (SLP) will consist of 11 km of tunnels between Nye Kolltveit and Drotningstvik, 3 pedestrian/bicycle tunnels, 19 underpasses, 23 tunnel portals, 22 bridges and 24 kilometres of two-lane access roads. Concerning the underground works, the infrastructure will be established as a 4-lanes road and two parallel single-tube one direction tunnels. The present paper aims to introduce the general design approach for the mentioned main tunnels. The permanent rock support, realised with conventional tunnelling based on drill & blast, is evaluated through the NGI Q-system, that provides a useful recommendation to dimension the long-term lining. Afterwards, this paper focuses on representative tunnel sections where specific evaluations are required due to very low overburden conditions, undercrossing of existing infrastructures, extended fault zones and possible squeezing phenomena. These challenges are approached by detailed numerical analyses and overcome by adopting tunnelling solutions such as partial excavation phasing, specific tunnel face support and customized linings.

Keywords: Conventional Tunnelling, TBM, Numerical Modelling, Detailed Design, Rock Support

1 INTRODUCTION

The Sotra Link Project (SLP) is the largest and most complex road infrastructure project developed by the Government of Norway within its National Transport Plan 2018-2029. It represents one of Norway's priority infrastructure projects, including design, financing, realization and maintenance of several surface and underground works between the city of Bergen and the Sotra island in West Norway, along the existing Riksveg 555 (Rv.555). The whole project includes 9 km of highway and a suspension bridge (30 m wide/900 m long, including towers 144 m high) between the municipalities of Øygarden and Bergen. The road system includes 12.5 km of tunnels (Kolltveit, Straume, Knarrvika, Drotningstvik and ramp tunnels from/to the main Drotningstvik tunnels), 19 roads and pedestrian underpasses, 23 tunnel portals, 22 bridges and viaducts, and 14 km of pedestrian and bicycle paths. Moreover, BIM approach has been adopted for the Sotra Link Project, involving all phases of the design process that currently entered the Detail Design phase (Barbieri et al., 2024; Barbieri et al., 2023).

The current paper deals with geotechnical challenges and tunnelling experience gained during the design phase of some relevant underground

structures. Geotechnical complexities are related to the design of technical solutions for rock support of tunnels characterized by low overburden with loose shallow deposits and interferences with new and existing nearby structures or tunnels in expected fault zone with swelling potential. The detailed design overcomes these challenges by accurate finite element analyses, leading to a suitable dimensioning of customized linings, together with partial excavation phasing and specific tunnel face support. This paper deals with two relevant case studies with reference to Drotningstvik main tunnels.

Chapter 2 concerns the design of the North and South tunnel stretches close to Kiplevatnet Lake, where partial front reinforcement and surface grouting are a foreseen due to very low overburden and presence of existing and future viaducts. Another relevant case is exposed in chapter 3: it deals with a main tubes section located into an expected fault zone where a full front reinforcement and partial excavation phasing are specifically designed. For both cases, numerical analyses are exposed and main results are given.

The status of the works is exposed in chapter 4 and main conclusions are summarized in chapter 5.

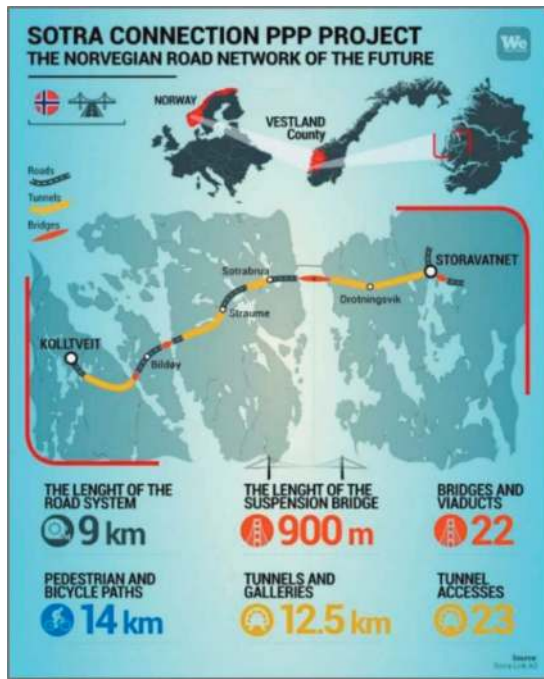

Figure 1. General overview of the SLP (Webuild Value Digital Magazine).

2 KIPLLEDALEN SECTION

The present chapter shows the challenges associated to the design of the permanent rock support of Drotningvik Tunnel in correspondence of the existing railway viaduct, part of the Rv.555, and Kiplevatnet lake. The complexities of the project are shown, and the design assumption are exposed together with the main results.

2.1 General overview

The Drotningvik Tunnel reference section (North tube and South tube) is 30 m long and it is located within an area interested by the presence of the Kiplevatnet lake. In the area, a hydraulic pipe collecting the discharge coming from Kiplevatnet lake is also found in correspondence of a section at the kilometric point 8+135 of the project chainage. The reference section

Figure 2. Kipledal section plan view.

comprehends an existing viaduct (Kipledal Viadukt I) and a future pedestrian bridge (Kipledal Viadukt II) to be built after the tunnel excavation.

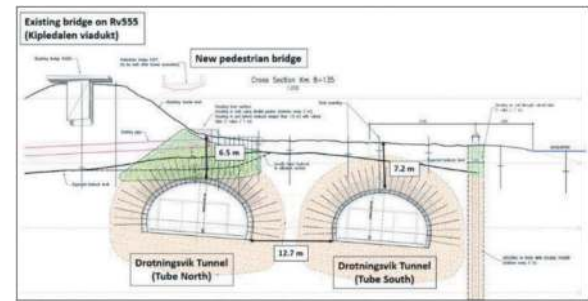

Figure 3. Kipledal cross section (km 8+135).

2.2 Main challenges and geotechnical characterization

The main challenges of the project consist of the low overburden conditions (approx. 6/7 m) together with the undercrossing of existing relevant infrastructure (Kipledal Viadukt I) and new one (Kipledal Viadukt II). Relevant core drillings allowed to define three main units: i) *rockfill* consisting of wet sandy soil with some gravel (0÷3.3 m depth), ii) *weathered bedrock* (3.3÷9.2 m depth), iii) *good rock mass* (>9.2 m depth). Starting from laboratory data (σ_{ci}) and a Q-value describing the rock mass quality (Using the Q-system, NGI, 2015), Mohr Coulomb properties are estimated by means of RocData v5.0 (Table 1).

Table 1. Geomechanical properties of the soil/rock units.

	Rockfill	Weathered bedrock	Good rock mass
γ (kN/m ³)	20	29	29
ϕ (°)	42	30	40
c' (kPa)	10	70	4500
E (MPa)	75	1500	6000
ν (-)	0.25	0.20	0.17
Ψ (°)	12	0	10
Q (-)	-	0,14	290

2.3 Numerical modelling

Bidimensional finite element (FE) analyses of transversal sections have been performed by means of RS2v.9.0 (RocScience Inc.), under plane strain conditions to estimate stresses and displacements on the concrete support during the excavation phases. Proper sizes were assigned to the model (170 m x 70 m) to avoid boundary effects, and soil/rock was discretized by 26'000 triangular meshes densified in the most relevant clusters. Boundary conditions consists in hinges along horizontal boundary and rollers along vertical boundaries. An elastic-perfectly plastic Mohr-Coulomb criterion was adopted as constitutive law. Acting on the safe side, rock bolts have not

been modelled, and largest excavation tunnel sections are considered. Shotcrete linings have been modelled as composite liner reproducing the excavation sequence. Two FE models have been considered:

- model n.1: ‘shallower’ interface rock/soil + existing bridge + new pedestrian bridge. This scenario represents a cross section close to km 8+126.
- model n.2: ‘deeper’ interface rock/soil + existing bridge. This scenario represents a cross section close to km 8+135.

The complexity of in-situ state of stress led to carry out some sensitivity analyses for two different cases (Table 2).

Table 2. Geomechanical scenario assumed for the FE models (i.p.=in plane; o.p.=out of plane).

Case	Rockfill	Weathered bedrock	Good rock mass
1	$k_0=0.33$ (i.p.)	$k_0=1.00$ (i.p.)	$k_0=1.00$ (i.p.)
	$k_0=0.33$ (o.p.)	$k_0=1.00$ (o.p.)	$k_0=1.00$ (o.p.)
2	$k_0=0.33$ (i.p.)	$k_0=0.50$ (i.p.)	$k_0=0.50$ (i.p.)
	$k_0=0.33$ (o.p.)	$k_0=0.50$ (o.p.)	$k_0=0.50$ (o.p.)

In “case 2” the *weathered bedrock* is assumed to be looser than in “case 1” because of the k_0 reduction from 1.0 to 0.5, both in plane and out of plane. For this reason, acting on the safe side, a higher deconfining ratio is assumed in “case 2” for an unsupported span equal to 3.0 m. The model steps and deconfining ratios λ assumed are summarized in Table 3.

Table 3. Finite element model steps.

Step	Description
1	Initialization with the load of the existing bridge
2	North tube: excavation of the tunnel face (case 1, case 2: $\lambda = 30\%$)
3	North tube: unsupported span = 3 m from the tunnel face (case 1: $\lambda = 60\%$, case 2: $\lambda = 80\%$)
4	North tube: excavation far from the tunnel face ($\lambda = 100\%$) and lining activation
5	South tube: excavation of the tunnel face (case 1, case 2: $\lambda = 30\%$)
6	South tube: unsupported span = 3 m from the tunnel face (case 1: $\lambda = 60\%$, case 2: $\lambda = 80\%$)
7	South tube: excavation far from the tunnel face ($\lambda = 100\%$) and lining activation
8	Activation of the loading due to the new pedestrian bridge (just for model n.1)
9	Seismic analysis

The FE model of the tunnel cross sections is given in the Figure 4 below for model n.1.

Figure 4. FE model, geometry loads and boundary conditions (km 8+126).

Ground improvements due to grouting are considered in the FE model for the North Tube at km 8+135 (weathered bedrock overburden 1.0m) for the model n.2, and an increase of the shear strength properties is assessed for both loosen backfill and weathered rock (Table 4).

Figure 5. Detail of the FE model with ground improvement above the North Tube, tunnel section km 8+135: treated backfill (green) and treated weathered bedrock (purple).

Concerning the loosen backfill, grouting effect was evaluated by an increment of unconfined compressive strength with an efficiency of 50%, with a consequent rising of effective cohesion.

On the safe side, friction angle value remained constant. Concerning the weathered bedrock, grouting effect was evaluated by an increase of RQD and joints’ roughness and alteration - Jr/Ja in Barton’s definition of Q value (Barton et al., 1974). Improved shear strength parameters assumed, in particular, that failure in the weathered rock could not necessarily occur on joints/or discontinuities, which may result cemented by grouting.

Seismic action and fire occurrence are also taken into account as Accidental Limit State conditions.

Table 4. Re-evaluation of geotechnical properties due to ground improvements.

Soil/rock properties	untreated		treated	
	Rockfill	Weathered bedrock	Rockfill	Weathered bedrock
φ (°)	42	30	42	67
c' (kPa)	10	70	70	100

The pseudo-static analysis is used to consider the seismic input, as last numerical step. According to the Norwegian Public Road Administration Handbook N400 and Eurocode EN 1992-1-2, the effects of fire are considered by properly decreasing the strength concrete properties and a liner section reduction.

2.4 Numerical results and rock support design

Numerical analysis showed that the case n.2 is the most critical for the design of the shotcrete linings both for Ultimate Limit State and Accidentally Limit State. Total displacement for the critical cross section at km 8+135, where ground improvement is foreseen above the North Tube, are approx. 1 cm on the lining, and less than 8 mm on the road and slope (Figure 6). These values are not considered critical.

Figure 6. Total displacement above the North Tube, tunnel section km 8+135, case n.2.

Ultimate limit state verifications designed both tunnel sections, while spiles and tunnel front supports are calculated by analytical approaches based on the limit equilibrium methods (Anagnostou and Kovari, 1994). Rock supports for the North and South tubes are summarized in Table 5 and 6, and Tables 7 and 8, respectively.

Table 5. North Tube. Rock support (part I).

North Tube (class V)		
Shotcrete	Steel mesh	Radial bolts
FRC B35 E1000, thickness=250mm (150mm 1 st layer; 100mm 2 nd layer) + 600mm unreinforced shotcrete for RRS or lattice girders	1 x K335 (8/8; 150/150)	Fully grouted rock bolting ϕ 25, L=4/5m, spacing transversal and longitudinal 1.5m

A longitudinal section of the North tube with the designed support is shown in Figure 7.

Eventually, the grouted schemes adopted for both tubes are represented in the figures below.

Table 6. North Tube. Rock support (part II).

North Tube (class V)		
Spiling	RRS or steel arches	Face support
Self-drilling hollow bolts* Titan 73/56, L=8m, transversal spacing=0.3m, longitudinal spacing=1.5m	RRS dimension D60/(6+4) Φ 20, long. Dist.=1.5m or equivalent lattice girders	FRC B35 E1000, thickness=100mm, Fiberglass bolts* Φ 25, L=12.0m, overlap=6.0m, spacing 1.20x1.20m

3 FAULT ZONE SECTION

The design of the second relevant section of Drotningvik Tunnel is described in this chapter: specific solutions issued from numerical modelling were required to overcome the advancement in critical geotechnical conditions. In particular, surveys from in-situ core drillings, together with surficial mapping of local geology, induced to consider a subvertical fault zone, with a longitudinal extent of weathered and highly fractured rock mass estimated at 20-30 m. This portion of the main tubes is located around 550 m western than Kiplevatnet area and it is to be excavated later – being the advancement direction from East to the West. In the following, numerical modelling is described and permanent lining solutions are presented.

3.1 General overview

The current designed support is expected for a maximal extension of 30 m. It is located between two junctions, connecting each main tube with the relative exit ramps. These two large sections are, in general, expected in good quality rock mass with reduced fracturing. On the contrary, the small valley/rift in between includes a zone with an extended peatbog – see indications in Figure 11. Core-drillings in this area show evidence of a significant core loss, highly fractured rock with infillings below the foreseen overburden of main tunnels, equal to 35 m. Figure 12 reports the retrieved rock cores from -40 to -50 m below the ground surface, at the kilometric point 7+590 of the project chainage.

Figure 11. Plan view of presumed fault zone section.

Figure 12. Retrieved core-drillings from Plan view of presumed fault zone section.

3.2 Main challenges and geotechnical characterization

The analysed tunnel portions are characterized by the absence of nearby structures and a regular terrain profile in the transversal section. Nonetheless, the extremely poor conditions estimated for the surrounding bedrock constitute the main challenge for tunnels advancement in this area. Q-system

defines a rock mass quality of class G, defined as *exceptionally poor*. Within these conditions, NGI's Handbook for geotechnical modelling based on the Q-system (Using the Q-system, NGI, 2015) attributes a Q value equal to 0.005: this class requires necessarily a special evaluation for excavation and lining design (e.g., by numerical modelling), overcoming the empirical indications of NGI's Rock Support Chart. With the Q-value defined above and laboratory data on undisturbed rock matrix (e.g., σ_{ci}), a Mohr-Coulomb failure criterion is estimated via RocData v5.0, for a tunnel case at 35 m of overburden, assuming the following geotechnical parameters (Table 9).

Table 9. Geomechanical properties of the rock mass.

Exceptionally poor rock mass – Class G	
γ (kN/m ³)	27
ϕ (°)	30*
c' (kPa)	100
E (MPa)	500
ν (-)	0.20
Ψ (°)	0
Q (-)	0.005

*Due to the high presence of joints, friction angle was taken equal to that of clayey infilled material, assuming preferential failure mechanisms along these discontinuities.

Together with the surrounding weak geotechnical conditions, the risk assessment conducted before the Detailed Design phase reports a high risk of swelling potential for clay minerals, if rock mass conditions show a favourable environment. Considering the actual fracturing, a swelling pressure acting permanently on the outer lining was taken into account and assumed equal to 500 kPa, according to available data of confined swelling tests on local amphibolitic gneiss.

Besides the particularly weak properties of the bedrock at this location, general design is further challenged by the enlargement of the South main tube section and the presence of the Northern ramp. Concerning the first point, the standard section foreseen in main tubes must be widened to an upper class of typological geometry (according to the reference Tunnelling guidance – *Håndbok N500 Vegtunneler*): this aspect requires a front opening which cannot be executed in full section. Numerical modelling had also to include the study of a suitable section division with proper safety measures for the first excavation. Concerning the second topic, the excavation and lining of the Northern ramp must be also included: it stretches from kilometric point 7+668 in the East-West direction and it crosses the potential fault zone northern to the North main tube – see Figure 11 with the identification of each tunnel.

3.3 Numerical modelling

A finite element (FE) model of the transversal section has been developed in PLAXIS 2D v.2023.1 (Bentley Systems Inc.), under plane strain conditions. According to the Tender Design phase, three typological tunnel geometries have been considered, respectively, for the South main tube (Eastbound), the North main tube (Westbound) and the Northern ramp, with different values of transversal span at the excavation perimeter, resumed in Table 10.

Table 10. Tunnel sections and front excavation design.

Designed tunnels	Max. longitudinal span [m]	Front opening
South main tube	18.80	Partialized
North main tube	13.50	Full section
Northern ramp	10.05	

A wide extension was attributed to the numerical model (400 m x 150 m) to prevent boundary effects. Boundary conditions were imposed preventing horizontal displacements along the vertical sides and vertical displacements at the lower model limit. Surrounding rock mass was discretized by 9'170 triangular 15-noded mesh elements and 76'100 nodes, properly densified around the excavations. An elastic-perfectly plastic Mohr-Coulomb criterion was assumed as constitutive law, with stiffness and shear strength parameters reported in Table 9. A gravity field stress is considered to define the in-situ stress state, assuming for this rock mass an initial earth pressure coefficient $k_0 = 1.5$ (e.g. Simonsen and Li, 2019). Besides acting on the safe side for the design of structures, this value is also considered more suitable for this higher overburden (35 m), compared to k_0 adopted for Kipledalén Section – see Table 2. As detailed in section 3.4, the initial k_0 value, together with the general poor rock quality and swelling potential in permanent condition led to include, for each section's opening, the excavation and support design of an invert, in order to prevent overloads at the sidewalls.

Table 11 resumes the model general phasing, while Table 12 and Table 13 include, respectively, the detailed excavation and advancement in full section and in partial section mode – with values of applied deconfining ratios.

In general, Table 12 and 13 both indicate that front advancement is foreseen at most 6 m ahead of the invert. Figure 13 shows FE model of the cross section. In the following, Figure 14 provides the details of partial openings for the South main tube.

3.4 Numerical results and rock support design

The FE model showed that invert yielded as crucial to verify Ultimate and Serviceability Limit states for each section: a proper design of its distance relatively to the front advancement was essential to

Table 11. Finite element model steps.

Step	Description
1	Initialization with a uniform superimposed dead load = 20 kPa (assuming worksite's engines).
2	North tube excavation and permanent support installation. See Table 12 for detailed design of opening in full section.
3	South tube excavation and permanent support installation. See Table 13 for detailed design of opening in partial section.
4	Norther ramp excavation and permanent support installation. See Table 12 for detailed design of opening in full section.
5	Uniform load activation = 500 kPa around outer lining simulating the swelling pressure in permanent conditions.

Table 12. Phasing in full section excavation.

Phase	Description
1	Front opening (except invert) + 1.5 m of unsupported length: $\lambda = 60\%$
2	Lining installation – see details in section 3.4
3	Repetition of Phase 1 reaching 4.5 m of supported excavation + 1.5 m of unsupported length: $\lambda = 80\%$
4	Invert opening for 4.5 m + 1.5 m: $\lambda = 80\%$
5	Invert lining – see design details in section 3.4: $\lambda = 100\%$

Table 13. Phasing in partial section excavation.

Phase	Description
1	Partial front opening + 1.5 m of unsupported length: $\lambda = 60\%$.
2	Lining installations: permanent on the outer perimeter and temporary on the inner wall to be demolished – see Figure 14a.
3	Repetition of phases 1+2 along the entire fault zone: $\lambda = 100\%$.
4	Full front opening (except invert) with 1.5 m of support + 1.5 m of unsupported length: $\lambda = 65\%$ within the excavated volume – see Figure 14b.
4	Invert opening with 1.5 m of support + 1.5 m of unsupported length: $\lambda = 65\%$ within the excavated volume – see Figure 14c.
5	Invert lining: $\lambda = 100\%$.

assure the short-term front stability – with the initial opening excluding systematically the invert volume. Meanwhile, the invert guarantees the long-term static verification of the entire retaining structure, reducing load concentrations at the sidewalls base.

Table 14 in the following resumes the maximal forces calculated in the lining, both for Ultimate and

Figure 13. Bidimensional FE model and geometry loads.

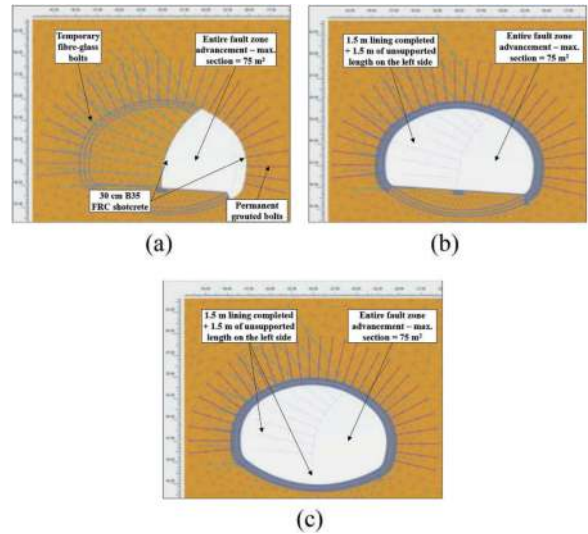

Figure 14. Partial excavation phasing for South main tube.

Serviceability Limit states, together with the efforts in concrete and steel rebars. No cracking was evaluated in any lining part. Numerical analysis confirms that South main tube results the most loaded section.

Table 14. Maximal forces and efforts in permanent lining.

In-lining acting forces	Limit States	
	Ultimate	Serviceability
Axial force, N (kN)	17'800	13'180
Bending moment, M (kN.m)	3'080	2'280
Shear force, V (kN)	950	705
Efforts in concrete and reinforcing bars (Serviceability Limit state)		
Concrete compression (MPa)	20.3	
Steel compression (MPa)	125	
Steel traction (MPa)	106	

Contour plot of total displacements after swelling pressure activation is shown in Figure 15:

Design modelling calculates relatively high displacements around tunnels, in particular occurring before lining installation, while the unsupported advancement of 1.5 m length occurs. Even if maximum displacements are equal to 43 and 78 mm,

Figure 15. Total displacement around tubes at kilometric point 7+590.

respectively in vault and invert of South main tube, relative lining displacements are estimated equal to 13 and 7 mm, thus respecting imposed limits on vertical deflexions (Tunnelling guidance – Håndbok N500 *Vegtunneler*). Nonetheless, total displacement values overmentioned should be taken into account during drill and blast operations at the advancement. Concerning surface settlements, a displacement of about 1 cm is calculated, which does not constitute any particular vulnerability due to the absence of nearby structures.

Table 15 and Table 16 resume the design for permanent rock support for the fault zone crossing. As done for Kipledal section, piles and front supports (i.e., fibre-reinforced shotcrete, fiberglass bolts) are dimensioned by analytical approaches based on the limit equilibrium methods (Anagnostou and Kovari, 1994).

Table 15. Fault zone rock support (part I).

Shotcrete	Steel mesh	Radial bolts
FRC B35 E1000, thickness=300mm (100mm 1 st layer; 100mm 2 nd layer; 100mm 3 rd layer) + 600mm unreinforced shotcrete for RRS or lattice girders	2 x K335 (8/8; 150/150)	Fully grouted rock bolting $\phi 25$, L=5m, spacing transversal and longitudinal 1.0m

A longitudinal section of the Fault zone lining solution, applied to the South main tube with divided section, is shown in Figure 16.

4 WORKSITES ADVANCEMENTS

The excavation of the Kolltveit tunnel started in July 2023 from West to East (Figure 17-a-b), and the completion of both North and South tubes is scheduled by April 2024. The Drotningstvik tunnel

Table 16. Fault zone rock support (part II).

Spiling	RRS or steel arches	Face support
Self-drilling bolts* $\phi 32$, L=6m, transversal spacing=0.2-0.3m, longitudinal spacing=1-2m	RRS** dimension D60/(7+5) $\Phi 28$, Base = 1.5 m laying on shotcrete. Dist.=0	FRC B35 E1000, thickness=100mm Fiberglass bolts* $\Phi 25$, L=20.0m, overlap=10.0m, spacing 0.70x0.70m

* temporary safety measures.

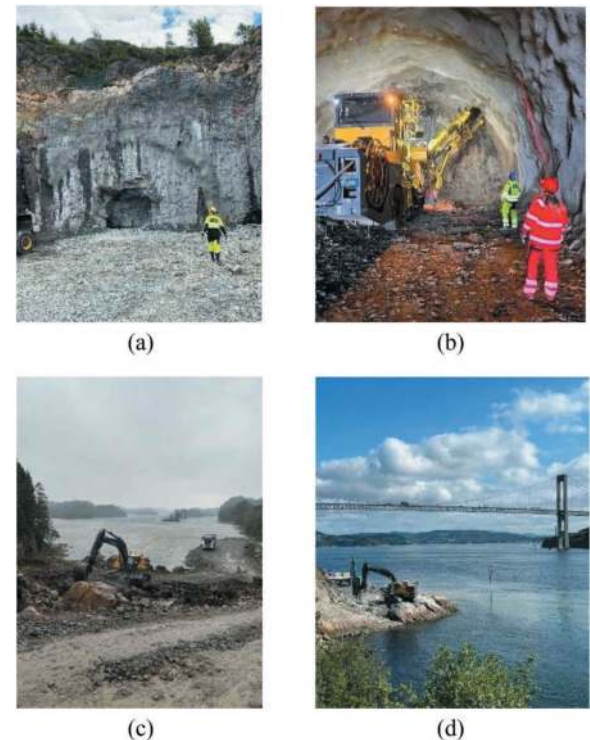

Figure 17. (a) View of Westbound West portal and (b) drill & blast excavation of the Kolltveit tunnel. (c) Filling works of the Storavatnet lake. (d) View from the Knarrvika side of the realization of the foundation of new Sotra bridge.

is currently under excavation, and it will be completed by August 2026, while the realization of the tunnel ramps started in 2024 in order to be completed by June 2026. Rocks excavated from the blasting of the Drotningvik tunnel portals have been partially used to fill the Storavatnet lake (Figure 17-c). In March 2023 works for the foundation of the new bridge on Knarrvika side started (Figure 17-d), while the completion of the suspended structure is foreseen by September 2026. The excavation of the Straume and Knarrvika tunnels is scheduled to start in 2024 to be completed by March 2026 and July 2025, respectively, including the access portals.

5 CONCLUSIONS

The main geotechnical challenges and the tunnelling experiences gained during the design phase of some relevant underground structures for the Sotra Link Project are presented in this paper. Numerical modelling was a key tool to simulate many excavation phases in heterogeneous rock-masses allowing the evaluation of the potential impact of the excavation works on nearby structures. A comprehensive monitoring system during the construction of all the surface and underground structures will allow to confirm the assumption made during the design phase and eventually permit optimizations, with a reduction in project costs. Currently, the modelling and delivery tasks are in line with the project scheduling. The PPP contract was awarded in September 2021 for a total value of about 2 billion €. The design phase of the whole project is expected to finish in 2024, and the infrastructure will be opened in 2027.

(I)-TM: I-System's tunnelling method – four years of application in most challenging ground in India

H. Bineshian*

Principal, Technical Director, Amberg Engineering AG, Australia

ABSTRACT: This paper is a brief technical note on (I)-TM; I-System's tunnelling method, a hybrid method that contains integrated classification and characterisation systems. This feature has made (I)-TM an all-in-one package for underground works from pre-design to post-construction phase. Due to having integrated I-System, it borrows the feature of being applicable for any medium under any condition. Classification and characterisation in pre-design using I-System assists in ground zoning along tunnel alignment, ground behaviour identification for each zone, diagnosis of associated ground hazards, determination of required support systems for each zone, structural dimensioning, and finally structural verification of design. In construction, employment of I-System enables designer to prescribe required measures and to optimise the design while post-excavation damage is assessed and required precautionary action prescribed. (I)-TM proposes suitable excavation technique with safe pull length, active support system configuration for optimised stability, efficient instrumentation technique for monitoring, intelligent prevention technique for avoiding and controlling hazards, and high-performance forecasting technique for prediction of ground ahead of tunnel face for a safe and optimised advance. This paper is a brief outcome of 4 years application of (I)-TM in design and construction of most challenging tunnels in India including T01 of USBRLP.

Keywords: (I)-Class, (I)-GC, (I)-TM, I-System, SRH, ViD

1 INTRODUCTION

A tunnelling method is an approach, which is used in the construction of underground structures. It should be applicable in both rock and soil under any challenging ground condition. A tunnelling method must be backed with a strong concept to assist in design procedure proceeded by construction that makes the tunnelling optimised in terms of cost, time, and safety for the desired life of structure. However, existing tunnelling methods are unclear in their approach and most of them remained as a hypothesis only; they are referred to as an excavation technique (ET) or as a supporting technique; though, they must shoulder a greater responsibility than that of being functioned. It has not been well defined how to employ existing tunnelling methods; besides, they failed to be trusted for application in all media and under all conditions due to their limitations. It is expected, a tunnelling "method" to provide a procedure for accomplishing construction of tunnels systematically but none of the existing tunnelling methods having this feature. Uncertainties in

definition of the tunnelling methods forms different understanding for designers, engineers, and geologists that causes misapplication. In some countries, tender documents of tunnelling projects are floated based on the name of some particular methods of tunnelling for execution while the definition of the method is not understood by the clients and it remained unclear for contractors. Some of the existing methods are based on valuable concepts but as they lack in a clear approach for application, they remain as theory. Contrary, some other methods having an approach in execution but their concept is not comprehensive enough to make them suitably applicable for all types of media in which the tunnels are placed; therefore, they make the tunnelling procedure costly and inefficient. (I)-TM (Bineshian, 2022a) is proposed as a practical tunnelling method to overcome the challenges involved with existing tunnelling methods' incomprehensible concept and incomplete approach. (I)-TM includes concept and approach that makes it applicable for tunnelling in any medium under any condition with an accurate evaluation and precise recommendations that can be

*Corresponding author: DrBineshian@outlook.com

applied from pre-design to post-construction phases. In full form, (I)-TM is I-System's (Bineshian, 2019, 2021b) Tunnelling Method that is fully based on I-System's (index of ground-structure) classification and characterisation. This paper aims to provide an outcome of employment of (I)-TM since its first introduction in 2019, including T01 of USBRLP (Mahi et al, 2022).

2 TUNNELLING

2.1 Tunnel Excavation Techniques

Excavation Techniques (ETs) in tunnelling are not same as tunnelling methods. ETs are employed in tunnelling methods as an important part and can be categorised into 4 main types; Manual, Mechanised Excavation (ME), Drill and Blast (DnB), and Open Cut (OC). Manual excavation includes partial-sequential digging (PSD) and/or partial-sequential excavation (PSE) using manual tools for small- to medium-scale openings respectively in multiple sequences without the use of explosives maintaining the stand-up time and maximum unsupported span in a safe range; e.g., pilot and enlargement, heading and benching (HnB), etc. ME includes medium- to large-scale excavation using machines (e.g., continuous-miner, excavator, hydraulic-hammer, roadheader, rotary drum cutter, shearer, TBM, etc.) without explosives. It is employed when the ground is poor and blasting is not advisable. It also can be employed when the ground is competent but excavation machineries result in better performance in excavation than blasting. DnB is the most common technique for small- to large-scale excavation of tunnels using parallel-, V-, or angle-cut. Only controlled or engineered blast should be employed in DnB for tunnels; uncontrolled blast in tunnelling is destructive, which deteriorates the rock mass and downgrades the ground class, damages the structure in vicinity, generates hazards, increases the cost, and affects the safety. OC is employed in tunnelling when overburden is shallow. It is used for semi-surface spaces executed from surface of ground. OC is applicable in semi-surface metro stations and shallow tunnels executed from surface. Sequential Excavation Method (SEM) is a "method of excavation" employed in tunnelling rather than a "tunnelling method", which can be used in either Manual, ME, and DnB.

2.2 Tunnelling methods

A tunnelling method is an approach having a concept for optimised design and a procedure for safe construction. They are categorised using two bases; the medium in which the tunnels are constructed in (including rock-, soil-, and underwater-tunnelling) and the concept that they are developed based on (including civil- and mining-tunnelling) (Bineshian, 2022a). Rock tunnelling is used for

construction of tunnels at any depth in rock mass that includes any concept-based tunnelling method. Employment of ETs depend on concept of method, site condition, and availability of skilled team, materials, equipment, and machinery. Main hazards involved with rock tunnelling generally include gravity-driven, time dependant, block fall, and rock-burst behaviour. Its concept is to utilise rock mass capacity under active load conditions by employment of active measures. Soil tunnelling is used for construction of tunnels in a granular and porous medium. Except DnB, all other ETs can be employed in soil tunnelling. Soil tunnelling like rock tunnelling can include any tunnelling methods. Main hazards in soil tunnelling include gravity-driven failure, slush flow, and settlement in large openings. Soil tunnelling concept is based on stabilisation of ground under passive load and consequently utilisation of passive measures; however, the design is quite inefficient if the arch pressure effect is neglected. Underwater tunnelling including but not limited to IMT (Immersed- tube Tunnel) is referred to as methods for tunnels on/under the bed of sea, river, ocean, lake, etc. that overburden is an individual column of water or water column + ground overburden. ET can be chosen in a similar way for rock and soil tunnelling. Hazards involved with rock and soil tunnelling are applicable for underwater tunnelling. Civil tunnelling is a group of tunnelling methods based on permanent life concept employed in civil works rather than mining. Civil tunnelling generally includes; Conventional, CnC, NATM, NMT, Pipe/box jacking, and SCL. Conventional tunnelling's concept is mainly based on an assumption of a passive stress state. A system of stiff support measures designed for the worst scenario of load is used to absorb the passive load; the same is applied along the entire length of the tunnel. DnB and/or ME is used as ET while in smaller cross sections or in challenging conditions, Manual excavation is applied. Typical sequences employed is; 1- heading excavation in a short pull, 2- placing rigid ribs, 3- lagging, 4- backfilling, 5- applying further measures at heading, 6- execution of drainage system at heading, 7- benching excavation, 8- installation of rib-legs, 9- invert excavation, and 10- ring closure. CnC tunnelling is usually used in soil in the urban areas. Load configuration in design of structure is the combination of live and passive loads from surface. Typical CnC sequences include construction of; 1- concrete diaphragm walls, 2- pin piles, 3- decking, 4- open cut excavation within the span of diaphragm walls, 5- traverse struts, 6- final concrete floor, 7- final concrete walls, 8- final internal structure fitting/s, 9- backfilling, and 10- surface restoration. NATM is used for deep conditions like mountain tunnels. It is based on maintaining the load-bearing capacity of ground and minimising support needs. Due to lack of any clear sequences or stages in NATM it is better to be called a "tunnelling concept" rather than a "tunnelling method". It is

crucial to understand the mechanical behaviour of ground before opening and monitoring after opening. Consequently, support measures are optimised based on mechanics of the ground, geomechanical hazards that may be encountered with, and pre- and post-excavation observation/s. The observation/s is based on sophisticated instrumentation and monitoring of displacement, deformation, strain, and stress. Moreover, regular face mapping, probing, and exploratory holes are conducted to obtain correct input data to classify and evaluate the ground and finally to identify the failure mechanism/s and associated geomechanical hazards. NMT is developed for hard rock while uses Q for classification and employs cross-hole seismic tomography for characterisation. It does not employ a new concept in tunnelling and actually it is similar to NATM for hard rock. The excavation method employed is DnB and ME. Like NATM, it is based on ground-support interaction evaluation. Unlike NATM, the application of monitoring or instrumentation techniques is only required in critical cases as it is developed for hard rock that may not need a monitoring system. Primary and final supports are fibre reinforced shotcrete (FRS) and fully grouted corrosion protected rock bolts; however, in poor to very poor grounds, it may be supplemented by pre-excavation grouting, crown spiling, and encased rib in shotcrete. Primary supports are part of final support system. It is not suitable to be employed for time-dependent behaviour such as squeezing, swelling, and heaving, as a thick layer of load-bearing ring of FRS or encased rib is rigid enough to stop controlled deflection, while load is accumulated behind the measures due to ground response that may cause sudden collapse. Pipe jacking or box jacking is based on installation of steel tubes with diameters usually between 1000 and 7000 mm. It is usually employed in soil or soft rock in the urban areas to prevent disturbing the surface traffic or considering other conditions/limitations. Key elements in pipe jacking include end shafts/pits, thrust walls, and pipe/box segments. In this technique pipes/boxes are pushed through the ground from the end shafts/pits. Thrust wall in the end shafts/pits is used to produce reaction forces during jacking. The main concept in this method is to maintain the virgin stresses untouched; thus, less deterioration is applied after jacking; therefore, induced stresses are not generated or the underground space is less disturbed. The ground material is removed using Manual or ME. SCL is described as NATM in Europe or SEM in North America. Shotcrete is the main support. Plain or reinforced cast-in-situ final lining may be used. Main sequences in SCL comprises; 1- SEM followed by immediate shotcreting, 2- drilling drainage holes, 3- instrumentation/monitoring, 4- invert closure (soft ground), and 5- further support measures (if required). SCL is classified into 3 categories; single shell lining (primary and final in one shell), double shell lining (primary + final), and composite shell lining (primary + waterproofing

membrane + final). Depending on thickness and stiffness of the lining, deformation of ground can be allowed to release the load behind the primary lining around the periphery of tunnel; however, by increasing stiffness of final lining, deformation can be controlled to prevent deflection and consequently to prevent failure caused by strain softening. Like NATM, SCL is not recommended in shallow conditions due to passive load and short stand-up time. It is not suitable for tunnelling in plastic medium due to occurrence of excessive deformation and loosening bond strength between particles of ground; the result is gravity-driven failure or slush flow in presence of water. Mining tunnelling is a group of underground methods developed for extraction of ore from ground. Mining tunnels mainly include access tunnels, adits, caverns, drifts/strikes, exploration tunnels, extraction tunnels, galleries, haulage tunnels, shafts, stopes, ventilation/wind tunnels, and winzes. Unlike civil tunnels, their life is considered to be short/temporary depending on volume and value of ore to be extracted and usually it is less than that of considered life for civil tunnels. It is influenced by concept of temporary use and lowering cost of tunnelling to improve margin of benefit out of extraction. Mining tunnelling employs temporary support; however, most of measures used in civil tunnels are invented in mining tunnelling method. ETs in mining are generally DnB, Manual, or ME. DnB in mining is not as costly as it is in civil tunnelling as less control is applied.

3 (I)-TM: I-SYSTEM'S TUNNELLING METHOD

3.1 *Design approach and design procedure*

A design approach in tunnelling contains four phases; empirical, theoretical, seismic, and observational that are dependent on ground classification and characterisation (Figure 1a). Design procedure defines tunnel design in seven stages as shown in Figure 1b. By completion of the design procedure, tunnel's design is complete and it is ready for implementation; however, a tunnelling method is required for construction, but the design outcome would be more accurate and appropriate if the design procedure started based on a tunnelling method. Tunnelling method should have a comprehensive concept and principal components to make the implementation of the design practicable in a safe and efficient manner in the medium in which the tunnel is designed for and under the condition/s that it is predicted to be faced with. In absence of a right tunnelling method, tunnelling procedure may differ from the design's output and perceptions that it was based on. This is happening in tunnelling works due to mismatch between the design and practice because of complex of challenges and varieties of surprises and difficulties involved with underground works. Instead,

a comprehensive tunnelling method can properly address them and tie its concept with the design procedure. It means that only having initial investigations and studies or predictions for mechanical properties of ground as input is not enough for a good for construction design in tunnelling while one of the important inputs prior to design is to have a comprehensive tunnelling method in mind that matches the design with its principal components. Thus, a tunnel design procedure in a healthy design approach is quite dependent on a tunnelling method's concept, which is comprehensive enough to direct the design as well as construction. The proposed design procedure (Bineshian, 2021a) explained here is fully dependent on I-System, which provides a detailed classification and characterisation for underground as well as surface and semi-surface structures. I-System's output for underground structures is a tunnelling method, which is called (I)-TM (Bineshian, 2022a).

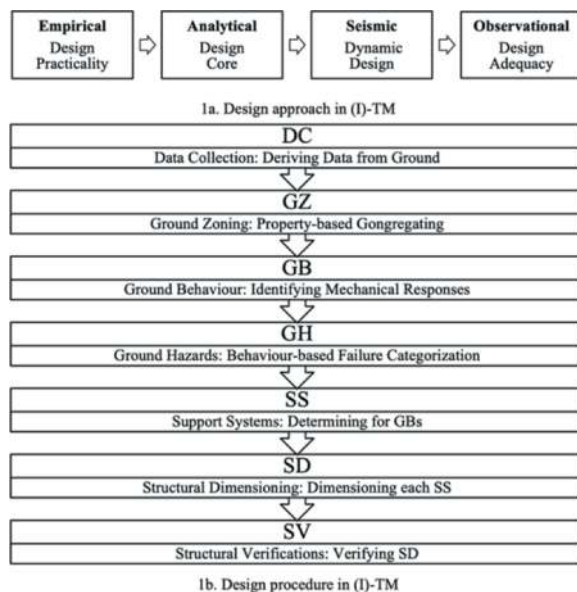

Figure 1. Design approach and design procedure in (I)-TM.

3.2 Application of (I)-TM

None of the existing tunnelling methods are comprehensive enough to be employed for all media and under all conditions. (I)-TM has been developed to address these issues and limitations. (I)-TM is applicable for rock and soil tunnelling, civil and mining tunnelling, and practicable under any challenging condition and ground behaviour including but not limited to time-dependent, squeezing, swelling, heaving, plastic, visco-elastoplastic, burst prone, gravity-driven, under water table, etc. from pre-design to post-construction phases (Figure 2). It assists in saving in cost by providing optimised practical design and does not neglect effect of primary measures

in final design. It is a hybrid tunnelling method, which combines I-System's classification and characterisation with construction method all together for a comprehensive range of applicability and ease of use in pre-design, design, construction, and post-construction phases.

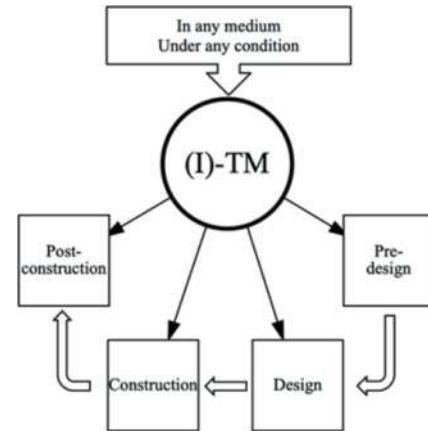

Figure 2. (I)-TM's application.

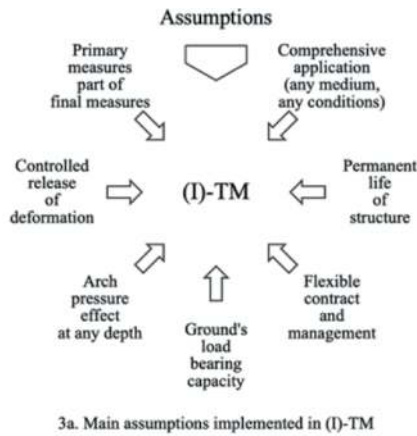

3.3 Concept of (I)-TM

The concept of (I)-TM includes a comprehensive range of components to facilitate with achievement of optimised design and construction of tunnels and underground spaces by means of engaging following ten important aspects (Figure 3 a and b):

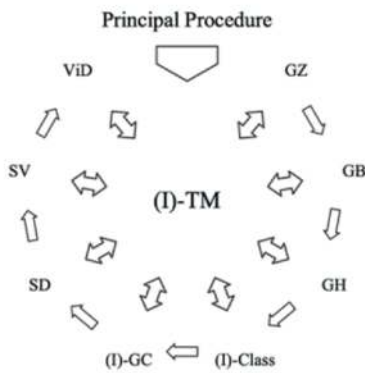

1. Comprehensiveness in application
2. Permanent life expectancy for tunnel structure
3. Flexibility of contract to ease construction management and variation of quantities
4. Utilisation of surrounding ground's load-bearing capacity
5. Assumption of arch pressure effect for any depth
6. Controlled release of deformation in plastic ground
7. Primary measures as part of final measures
8. Using I-System in design procedure
9. Employing I-System in construction
10. 10-Post-excavation damage assessment to minimise induced deterioration (e.g., ViD; Bineshian, 2021c)

A brief list of recommendations proposed by I-System in its (I)-Class outputs for underground spaces, which is employed in (I)-TM when ground is indexed (classified and characterised using I-System) is provided here:

- I. Active pre-/post-excavation support system (SS):
 - Pre-excavation measures including systematic horn-bolting, crown periphery spiling, forepoling, piperooting, pre-excavation grouting/injection, face bolting, etc. to control the stress state ahead of face, to utilise arching effect, and to

3a. Main assumptions implemented in (I)-TM

3b. Principles of method in design and construction procedure

Figure 3. Main concept in development of (I)-TM.

increase stand-up time for application of post-excavation measures.

- Post-excavation measures including systematic bolting, rigid-ribs, lattice-girder, FRS, drainage holes, SRH (Bineshian, 2020), etc. - rather than a passive system - to stabilise the opening.
 - Ring closure or invert closure to make a full load-bearing ring to improve the load-bearing capacity of surrounding ground when the ground is weak and requires further assistance at right time.
 - Mechanism of a thin elastic shell using application of a layer of FRS immediately after opening or as a post-advancement load-bearing shell that reduces the deflection of the underground space under loading when crown deflection should be prevented.
- II. Provision of suitable ET and advice on safe pull length by I-System that suits the assessed condition that is compatible with proposed support systems (SS) to obtain a safe and optimised advance at face. PSD and PSE technique/s are proposed to reduce deflection at crown or at walls and to maintain stand-up time when full-face or heading and benching (HnB) does not work efficiently due to scale effect or weak ground properties and existence of passive response of ground-structure.
- III. Use of efficient instrumentation technique (IT) for monitoring of ground-structure's mechanical

response to excavation-induced stresses and deformations/deflections and to provide required support measures in terms of type and dimensioning to modify requirement/s as per observations before and/or after excavation and application of measures in an optimised manner in a suitable period and right time based on diagnosed hazards (GH) and identified ground behaviour (GB).

- IV. Application of intelligent prevention technique (PT) to avoid geomechanical hazards, which is essentially predicted based on the ground behaviour by I-System.
- V. Exploitation of high-performance forecasting technique (FT) including geophysical systems (e.g., Electrical Resistivity Tomography, Multi-channel Analysis of Surface Waves, Seismic Refraction Tomography, Tunnel Seismic Prediction) and/or probing (e.g., drilling blind holes and logging) and/or coring systems (e.g., exploratory coring to log the encountered strata ahead of the tunnel face) to predict the geomechanical condition ahead of face to prevent surprise incidents and to get ready for challenges ahead.

Technical proposals and recommendations provided in I to V are included in (I)-Class's outputs when I-System is used for classification and characterisation of ground at face of tunnel or underground space. (I)-Class and (I)-GC are I-System's outputs for classification and characterisations respectively (Bineshian, 2021b). I-System is embedded in (I)-TM, which is employed also in pre-design, design, construction, and post-construction phases that forms the principles of (I)-TM. Observations and re-evaluations to optimise the ongoing work and revising the design is a regular practice in (I)-TM that should be repeatedly conducted till the work is completed (Section 3.4) to improve the efficiency and performance of tunnelling.

3.4 Utilisation diagram of (I)-TM

(I)-TM is an intelligent tunnelling method, which is employed from pre-design studies to end of construction and even after construction during the exploitation period for maintenance planning and resolutions for probable incidents. Its examined concept comprises a comprehensive design approach and an extensive range of practical solutions for a safe and optimised execution as an "all-in-one" package for tunnelling in any media and under any challenging condition. It is developed to be employed for tunnelling at any depth (shallow to deep), in any ground type (rock to soil), through any medium with various mechanism (continuum-, discontinuum-, or porous-mechanics), with any physical features (isotropic, anisotropic, homogenous, or heterogeneous), and under any condition and challenges (underwater, plastic, brittle, ductile, burst-prone, time-dependent, etc.). Tunnelling using (I)-TM is proved to be safe and optimised when I-System is applied and design is well-reviewed/revised as per observations, assessments,

and outputs of I-System during the construction phase. Derivation of the input data from ground (face of tunnel or underground space) is important and determinative due to its effect on accuracy of outputs of I-System; however, required data for I-System is confusion-free and easy to derive (Data Collection (DC) in the design procedure. (I)-TM's performance in design and practice is examined in tunnelling works in India. Utilisation flowchart of (I)-TM for design and construction phase is presented in Figure 4.

Utilisation of (I)-TM in construction is as followings:

1. Apply I-System for fresh face at tunnel to evaluate ground-structure condition (this is called indexing the face or classification and characterisation of the ground)
2. Advance at face and implement the recommendation/s of (I)-Class or use (I)-GC estimates for design revision
3. Repeat the steps 1 and 2 and advance at tunnel or underground space's face for one more pull.

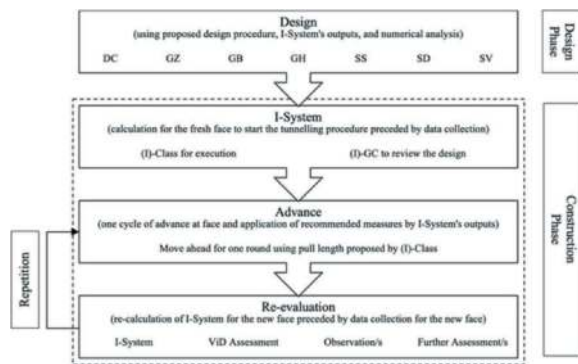

Figure 4. (I)-TM flowchart for design and construction phases.

3.5 I-System: Index of ground-structure

I-System as the first-ever classification that is applicable in both rock and soil medium, takes into consideration the most important features of ground-structure (Figure 5a) while it provides an accurate and precise prediction for ground behaviour for varieties of challenging conditions (Figure 5b). It has been verified against varieties of ground conditions to ensure that its outputs are credible (Bineshian, 2021b). It includes five key indices and two impact factors to enable appropriate modelling of ground-structure mechanical response to the full (Figure 6a) that is based on easily derivable main properties (key geomechanical, geostructural, geohydrological, geotechnical, geophysical, and geometrical features) and determinant seismic and excavation factors affecting the ground-structure response (Figure 6a). (I)-Class and (I)-GC are demonstrated in Figures 6b and 6c respectively. I-System Software is developed

as an engineering package for calculation of (I), classification of ground with (I)-Class, and characterisation of ground properties with (I)-GC. I-System Software also assists in (I)-TM with further utilities for configuring the systematic bolting, advising for the safe pull length in advancing at a face, measuring the GCD as ground conductivity designation (Bineshian, 2022b), identifying Squeezing, Swelling, and Heaving (SSH) ground from non-SSH ground (Bineshian, 2020), and assessing ViD (Bineshian, 2021c) as vibration-induced damage.

3.6 (I)-TM vs The existing tunnelling methods

A comparison of (I)-TM and the existing tunnelling methods based on their concept is presented in Table 1 as a quick reference (aspects 1 to 7 in Section 3.3 are considered as comparison criteria). Further comparison of (I)-TM and the existing tunnelling methods based on the principles in design and construction procedure is presented in Table 2 (aspects 8 to 10 in Section 3.3 are considered as comparison criteria). Tables 1 and 2 are shown after Section 6.

4 TUNNEL T01 – USBRLP – INDIA

Tunnel T01 with 3209 m length is a single tube tunnel and the most challenging segment of the USBRL Project of Indian Railways; a project of national importance and the largest project in the construction of a mountain railway since independence of India. Lithology along the alignment contains claystone, dolomite, limestone, mudstone, sandstone, shale, siltstone, scree, alluvium, and colluvium in a clayey and silty matrix and hosting mica family minerals including muscovite. T01 is crossing Reasi Thrust of Main Boundary Thrust of over critical thrust wedge of lower Himalayas; an active fault zone as one of the major Himalayan thrusts that is displaced above the Indian lithosphere (Mahi et al, 2022). From August 2016 till March 2022, T01 faced with 16 major failures with at least 46,000 m³ discharge of high pressure mix of debris and water (liquified ground) containing fully saturated crushed and sheared dolomite in a matrix of calcite, clay, and silt. This resulted in a huge loss of time (almost 67 months), resources, and machineries without any advance at faces. Due to this, Client decided to switch to (I)-TM from NATM and Conventional and to employ a design based on I-System instead of RMR and Q. Appropriate study in February 2022 revealed that the mechanical response of ground at both faces is visco-elasto plastic (VP) to fully plastic behaviour with almost zero stand-up time that requires pre-excavation measures to increase the stand-up time, a rigid response to absorb the passive load configuration, and a special ET to advance. The new design implemented from 2022/05/01 after 2012 days of unsuccessful tunnelling and accordingly safe and optimised advance at both faces resumed. 512 mm/day advance obtained and breakthrough achieved on 2023/12/20. In design procedure for T01, Ground Zoning (GZ) using I-System determined a single zone. Ground Hazards (GH) for associated GB is derived using I-System; then, by running I-System analysis required Support System (SS) is defined as a proper response to GB and a suitable control of the associated GH. (I)-GC as characterisation output provided the mechanical properties of ground used for Structural Dimensioning (SD) and Structural Verification (SV). Three principles of solution for T01 based on I-System and

(I)-TM includes; application of active pre-excavation measures (including perforated piperroofing and glass fibre face bolting injected by PU-2C), employment of passive rigid post-excavation system (including rigid ribs encased in a thick layer of FRS), and controlling the thrust ahead of the face using buttress at face of the tunnel. GCD (Bineshian, 2022b) is conducted before and after pre-excavation injection to measure ground conductivity and to assess solidification quality respectively as a criterion to judge against opening the face and commencing the advance after each round of piperroofing. Drainage holes are applied at back chainages of face whenever required to release hydrostatic pressure built behind the faces. PSD/PSE using ME in a system of HnB with short pull length of maximum 800 mm applied. Safe operation achieved by implementing the right method of prediction and the risk in advancement is minimised. The only way to achieve the acceptability of risk is to control them. To serve this purpose, Tunnel Seismic Prediction (TSP; Choudhary and Bineshian, 2022) is employed to forecast geological condition ahead of the faces at T01 as part of the prescribed solution for T01 as per I-System and (I)-TM. The result's accuracy is scrutinised during excavation and it is found that the matching between anticipated and actual encountered condition is almost 90%. Figure 7 Represents the geological profile of T01 as encountered condition. Figure 7 is placed after Section 6.

5 CONCLUSIONS

This is concluded that misdiagnosis of ground behaviour will lead to great loss in valuable time and resources in tunnelling specially in challenging ground and under hazardous condition. Moreover, it is proven that employment of expensive machineries and complicated set up in design will not help if they are inapplicable for the ground's mechanical configuration. Incidents and frequent failures and loss of time and resources in T01 are examples of incorrect diagnosis of mechanical behaviour, failure of inapplicable classifications, inapt tunnelling method, improper design, inappropriate method statement, and irrelevant machineries and equipment. Implementable design and its elements and applicable associated method statement, which is adopted from 2022/05/01 in T01 and its successful outcome is clear evidence that proves importance of correct understanding of mechanical behaviour using a pertinent classification and characterisation called I-System and appropriateness of (I)-TM as a comprehensive tunnelling method. A design, which is proved that the most challenging tunnel in India can be constructed using easily and locally available machineries, equipment, and materials if the mechanical behaviour of ground is well identified and suitable classification and tunnelling method is adopted.

Segment design for Australia’s largest diameter TBM tunnel

Shu Fan Chau*

Aurecon, Auckland, New Zealand

Harry Asche & David Oliveira

Aurecon, Brisbane, Australia

Justin Shepherd & Christian D’Hondt

Acciona, Sydney, Australia

ABSTRACT: The Western Harbour Tunnel is Sydney’s newest road tunnel project, and it includes twin three-lane tunnels driven under Sydney Harbour by TBM. The tunnel passes through a jointed and stress-relieved rock before encountering Pleistocene alluvial material under the Harbour. The analysis methods and some of the segment details for this tunnel, which will feature the world’s largest diameter steel fibre reinforced concrete (SFRC) segments, are described herein. At each cross-passage opening, the design philosophy is to use a combination of effective shear transfer structural elements to allow the safe tunnel lining opening with minimum construction inconvenience. The segment opening and the cross-passage design considerations are also described.

Keywords: TBM tunnel, cross passage, undersea, steel fibre reinforced concrete, lining segment, precast

1 INTRODUCTION

The Western Harbour Tunnel (WHT) is a new crossing under Sydney Harbour, linking Rozelle Interchange to the Warringah Freeway in Sydney, Australia. The twin 6.5 kilometre motorway tunnel will have three lanes in each direction and will create a western bypass of the Sydney CBD, taking pressure off the Sydney Harbour Bridge, The Sydney Harbour Tunnel, Anzac Bridge and Western Distributor corridors. The WHT is being delivered in two stages (Figure 1). Stage 2 will be delivered in partnership by Transport for NSW and ACCIONA, with the designer AECOM AURECON Joint Venture (JV). Stage 2 will use several roadheaders to excavate the northern section and two Tunnel Boring machines (TBMs) to construct the southern section.

The 1.5 kilometre long twin TBM tunnels are located between Birchgrove and Waverton and pass beneath Sydney Harbour. A short section of the TBM tunnel under the Harbour is within soft/ mixed ground conditions. There are 11 nos. mined cross passages between the two TBM tunnels. The tunnels have an ID of 14.15 metre and will be constructed by two 15.7 metre mixshield (slurry) machines, both advancing

from the assembly caverns at the south. Tunnel internal structures include a box culvert for facilitating tunnel construction logistics and subgrade backfill to the road level. Figure 2 shows the TBM tunnel and cross-passage layout plan, and Figure 3 shows the TBM tunnel cross-section.

The segmental lining design consists of precast Steel Fibre Reinforced Concrete (SFRC) segmental rings for most of the tunnel alignment, with short lengths of conventional steel bar reinforced precast

Figure 3. WHT TBM tunnel cross-section.

concrete segmental rings at cross passages only to cater to the lining opening effect. This paper focuses on the design philosophy and challenges in designing the SFRC segmental lining for this mega TBM, Australia’s largest diameter TBM tunnel project. Some segment details, including segment shapes and joints, are presented. The under-sea TBM tunnel stability, including flotation, face pressure and blowout, are also discussed. While this paper was being written, the cross-passage design was ongoing. However, the design considerations for the cross passage and segment openings are also described.

2 DEVELOPMENT OF SFRC LINING ON MEGA TBM TUNNELS – A BRIEF LITERATURE REVIEW

In the last 20 years, Steel Fibre Reinforced Concrete (SFRC) lining use has become increasingly popular in TBM tunnel projects, including small-size utility/water tunnels, medium-size metro tunnels, and large-diameter road tunnels. The key factors driving development of SFRC linings include:

- Design aspect: Including fibre reinforcement in the concrete mix results in a noticeable increase in the post-cracking tensile residual properties, allowing the removal of conventional bar reinforcement.

- Construction aspect: Fibre reinforcement facilitates a cost-effective lining segment production process, with reduced potential for damage, and reduces post-drilling clash risks.

Figure 4. TBM tunnel ID vs lining thickness (SFRC and mega TBM tunnel projects).

ITA (2016) has reported a list of TBM tunnel projects worldwide that adopt SFRC segmental lining design in combination (or not) with conventional rebar. The internal tunnel diameter and segmental lining thickness of these projects are graphically presented in Figure 4, together with some of the recent metro TBM projects with SFRC lining in Australia, New Zealand and Singapore. In the ITA data set, SFRC alone and hybrid use peters-out at just over 11m diameter and 13m diameter respectively.

However, the use of mega TBMs with a cut diameter of more than 14 metre rapidly increases. Up to 2023, more than 40 tunnelling projects worldwide have used a mega TBM. The segmental linings for most of these mega TBM tunnels have traditional steel rebar reinforcement (FHWA 2020). The mega TBM tunnels with SFRC lining recently completed or being constructed in Australia and New Zealand are also shown in Figure 4, with details summarised in Table 1.

According to Ireland et al. 2019 and Chau et al. 2020, Melbourne’s West Gate Tunnels (WGT) segmental lining is the largest diameter SFRC segmental lining without rebar ever completed (tunnel excavation and lining completed in mid-2023). There are many benefits associated with steel fibre reinforcement for large-diameter tunnels. Besides manufacturing cost benefits, reduced damage during construction has also been observed on the WGT project. Chau et al. 2020 also summarised the critical design philosophy for designing SFRC segments for mega TBM tunnels, including:

- Need for empirical and numerical analyses to PAS8810, a specific concrete segmental lining code. This approach overcame many design challenges and confirmed the SFRC segmental lining, including eliminating radial and circumferential joints steel reinforcement.
- Specification of material and segment testing to verify the design approach and assumptions.

Table 1. Recent ANZ Mega TBM Tunnels with SFRC Segments.

Project	Waterview Tunnels	West Gate Tunnels	North East Link	Western Harbour Tunnels
Location	Auckland, New Zealand	Melbourne, Australia	Melbourne, Australia	Sydney, Australia

3 GEOLOGICAL AND HYDROGEOLOGICAL CONDITIONS

A series of marine-based geotechnical investigations have been provided by Transport for NSW, including seismic survey data, boreholes and cone penetration tests (CPT) within the Harbour Crossing. A construction-phase targeted marine GI has also been undertaken. The geology along the alignment of the WHT TBM tunnels is shown in Figure 5.

Figure 5. Geological long section along TBM alignment.

TBM tunnels will be excavated mostly in Hawkesbury Sandstone, except for a short 180 metre section of soft ground (alluvial soil of Pleistocene age), where the tunnels cross a paleochannel under the harbour. This paleochannel has been progressively infilled with marine sediments. The boundaries for the harbour sediments show the Pleistocene units WH2.1, WH2.2, WH3.2, and WH4, filling the bulk of the paleochannel eroded into the bedrock. In the Hawkesbury Sandstone, due to stress relief in the eroded palaeovalley, geological features, including laminite beds, dykes, and thrust faults, have been identified from the existing and recently completed marine boreholes.

The face of the TBM is anticipated to encounter the following geology:

- Harbour Sediments, WH3.2: mostly firm to very stiff, clay and silty clay, interbedded with sandy fine soils.
- Harbour Sediments, WH4: Fluvial sandy silts and sands, interbedded with stiff to very stiff silt and clay layers.

- Hawkesbury Sandstone, ranging from massive to jointed and stress relieved,
- Dykes and thrust faults in the Hawkesbury Sandstone.

The groundwater head to tunnel crown ranges from 35m to 45m. Hawkesbury Sandstone is characterised as a dual porosity aquifer where groundwater potential is dominated by secondary alteration, such as joints, fractures, faults and bedding planes, whilst the intact Hawkesbury Sandstone is mainly “impermeable”.

Figure 6 illustrates the magnitude and variability of rock mass permeability along the tunnel alignment. Rock mass permeability is higher around the valley that forms the Harbour, where the rock has experienced stress relief and valley bulging. In these areas, existing open discontinuities and developed valley-side joints increase the defect aperture, potentially increasing groundwater flow.

Figure 6. Water packer test results along TBM alignment.

4 WHT SEGMENTAL LINING

The WHT tunnel is currently the largest diameter TBM tunnel project in Australia. The WHT segmental lining design follows a similar design philosophy

to WGT (Ireland et al. 2019, Chau et al. 2020) with project-specified considerations. It adopts SFRC-only segments for the tunnel alignment, except for RC segments at cross-passage opening locations. The WHT tunnel will be the world's largest diameter steel fibre reinforced concrete (SFRC) segment upon completion.

4.1 SFRC lining properties

The design compressive strength of the segment concrete is 65 MPa. The design characteristic residual flexural tensile strengths of the SFRC is f_{RI} of 4.0 MPa and f_{R4} of 4.0 MPa. The characteristic splitting strength is 6.0 MPa. All the design parameters for the SFRC are to be verified by testing. The steel fibre has been specified to be hook-ended with a minimum diameter of 0.75 millimetre, have an aspect ratio (l/d) of 40 to 80, and have a minimum tensile strength of 1800 MPa. However, experience has shown that a fibre tensile strength of 2200 MPa will likely be required and beneficial.

The specified design concrete compressive strength for Waterview Tunnels is 55 MPa (Chau et al. 2017), and for WGT is 50 MPa (Chau et al. 2020), although higher strengths have been achieved in practice for demolding time requirements. The specified design concrete compressive strength in WHT is higher than other recent mega TBM tunnel projects in the Australia – New Zealand region but generally consistent with what is actually used in the precast yard. The SFRC design properties and concrete mix design have been coordinated with the project segment precast team based on the same concrete mix design in another local TBM tunnel project, the Sydney Metro West – Central Tunnelling Package (SMW-CTP). The 28-days mean compressive strength and the splitting strength based on SMW-CTP production testing are 85 MPa (with a standard deviation of 4.29 MPa) and 9.8 MPa (with a standard deviation of 1.35 MPa), respectively. Considering a higher strength concrete mix design will be used for the project, higher design SFRC properties are therefore considered in the WHT tunnel segmental lining design.

4.2 Segment and ring configuration

The tunnel's internal diameter is 14.15 metre. The lining thickness is 500 millimetre, and the nominal length of a ring is 2400 millimetre. There are ten segments in a ring at an even 36-degree angle subtended by rhomboidal segments (8 nos.) and two trapezoidal segments, the key and the counter key. The radial joint angle for the rhomboidal segments is 5 degrees, and the radial joint angle for the key and adjacent segments is 10 degrees, with a key segment insert variant angle of 7.5 degrees to achieve a workable key draw distance. The segment ring is a universal taper ring with taper of 60mm (+/-30mm) so that the key can be built in all 20

possible locations. The schematic developed plan view of the ring arrangement is shown in Figure 7.

Figure 7. Schematic view of the developed intrados.

4.3 Rhomboidal segments

Rhomboidal segment arrangement has been widely used in metro-sized TBM tunnels. However, based on the available information, the segments of mega TBM tunnels are more commonly rectangular, including the WGT and Waterview tunnels. For WHT, the preferred ring configuration was to use rhomboidal segments together with circumferential joint dowels to improve the precision of the ring build and to lessen the potential for leakages through the lining joints under high water pressures. As far as the authors know, WHT is the second largest TBM tunnel with a rhomboidal segment ring arrangement, after the Santa Lucia Tunnel in Italy, despite the BART tunnel in San Jose, US, potentially using a mild joint angle of 2°. A detailed study has been undertaken to compare the rectangular and rhomboidal segment arrangements regarding ring stiffness and bursting stresses at circumferential joints.

4.3.1 Ring stiffness

Muir-Wood's equivalent ring stiffness due to the number of joints cannot explicitly account for the inclination of the joint. The approach proposed by Janssen (1983) (Figure 8) considers the joints as an equivalent concrete short column with a width and height equal to the effective width of the joint. Rotational stiffness expressions (M/q) are then developed for varying degrees of contact as the joint rotates. However, the maximum allowable moment across the joint is equivalent to the maximum axial force acting at the extreme fibre of the equivalent short-column concrete section ($N \cdot h_j - N h_j / 2$ in the theoretical model and shown as a plateau in the graph of Figure 8). For a slanted joint, the axial force acting perpendicular to the joint is anticipated to be slightly less than a flat joint, as there will be a component of this load acting parallel to the joint. As a result, the slanted joint will reduce the maximum moment and therefore, the equivalent rotational stiffness will be slightly reduced.

The above conclusion has been confirmed using two simple numerical models developed to compare the rhomboidal segments with the rectangular segments (Figure 9). Only a single ring (i.e. uncoupled) was modelled, as the aim is to compare the impact of the slanted joints without the effects of ring connectors (dowels or bolts). Considering that bending moments are a function (double derivative) of the deflections, the same conclusion applies to the flexural

performance. These results are consistent with the expectation discussed above, which, in turn, indicates a slight reduction in overall stiffness between the rhomboidal and rectangular segments for a single ring, i.e. when the effect of connectors is ignored.

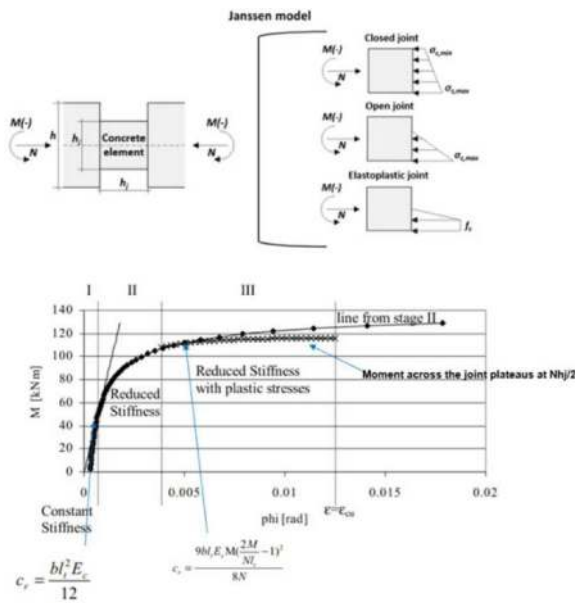

Figure 8. Janssen (1983) joint model.

Figure 9. Comparison of single ring (uncoupled) behaviour – rhomboidal vs rectangular.

4.3.2 Bursting stresses at circumferential joints

Circumferential joint bursting/splitting stress due to TBM thrust loads is a critical case for joint design, as the edge distance from the ram shoes on one side of the rhomboidal segment is less than that on the rectangular segment.

A non-linear model using the software Midas was adopted to analyse the relevant cases. The model has boundary restrictions at the trailing edge and considers a single segment only. However, its neighbouring segments' confining effects are included by compression-only springs. A non-linear analysis has been undertaken with elasto-plastic models that can represent the concrete material's compressive (crushing) and tensile (cracking and splitting) behaviour.

The principal compressive stress, principal tensile stress and cracking from both rectangular and rhomboidal segment models are shown in Figure 10.

Additional models have also been carried out using concrete specialist software called ATENA (Figure 11). Three segments have been included in the ATENA models, with all three loaded. These models allow for the contact of the longitudinal (radial) joints to be included more explicitly, capturing normal compressive and shear stresses (friction) that may develop.

The modelling by both Midas and ATENA indicates that both rhomboidal and rectangular segments are within acceptable limits for estimated cracking but with evidence that the rhomboidal configuration has a potentially greater risk of corner cracking and damage mostly due to the uneven stress distribution on the reacting circumferential joint. However, this risk is only marginally higher than the rectangular segments, and the benefits of the expected better ring-build outcomes of the rhomboidal segments outweigh the slight risk increase. A detailed discussion of ram load and circumferential joint performance is included in Section 4.4.

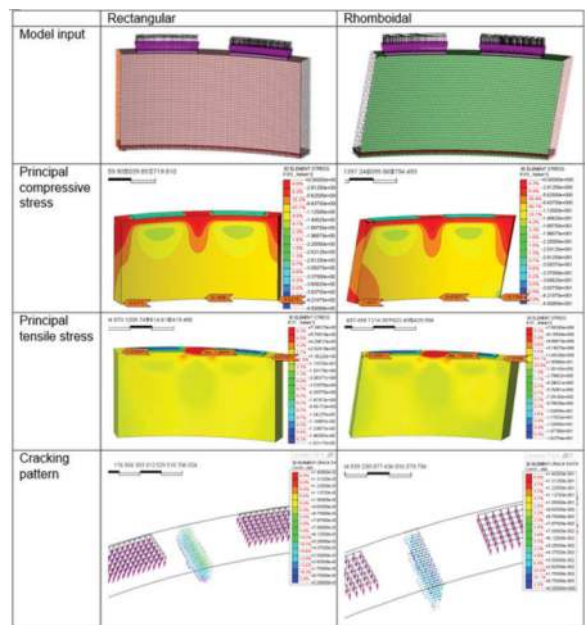

Figure 10. Modelling comparison between rectangular and rhomboidal segments (by Midas).

4.4 Segment joints

The WHT tunnel circumferential and radial joint design has eliminated the joint steel ladder/reinforcement requirement. Figure 12 shows the joint details.

4.4.1 Temporary ram load and circumferential joints

There will be 20 pairs of thrust cylinders (2 pairs per segment). The design considered a concrete pad of 1662 x 320 millimetre at the circumferential joint

Figure 11. 3D ATENA model results – rectangular (top) vs rhomboidal (bottom).

at the leading edge, and the ram shoe size of 1350 x 545 millimetre is advised by the construction team, giving a maximum working pressure magnitude of over 22 MPa (unfactored for a thrust of 194 MN) and 27 MPa (thrust of 233 MN) for an emergency case, i.e. full thrust. The ram shoe is oversized, so full contact with the bearing area is achieved via the concrete pad, irrespective of ring roll or eccentricity.

Figure 12. Circumferential joint and radial joint details.

The segment has been checked for bearing, bursting, and compressive loads as an equivalent short column. Adequate resistance to crushing and

splitting is demonstrated by the Guyon (1972) method; however, the section is highly utilised, indicating a risk of cracking should poor ring build occur. FEM non-linear analysis of the ram loading on the critical segment (S8, with ram shoe closest to segment edge) has been undertaken in Midas (Figure 13). The model considers the gasket groove, caulking groove details, ram shoe positioning tolerance, and ring roll. These models have been run for both the SLS cases to determine crack widths and the ULS cases to confirm structural capacity.

The FEM model, however, indicates a zone of plasticity that develops between the ram shoes as a result of the elastic deformation of the concrete under maximum design ram loading. The depth of the cracked zone is about 105mm. The maximum crack width is estimated at 0.05mm, with all micro cracks conservatively summed into one single crack. With the removal of the ram load, it is observed that more than 50 percent of the cracked elements observed during the ram loading stage are closed (as shown in green in Figure 13).

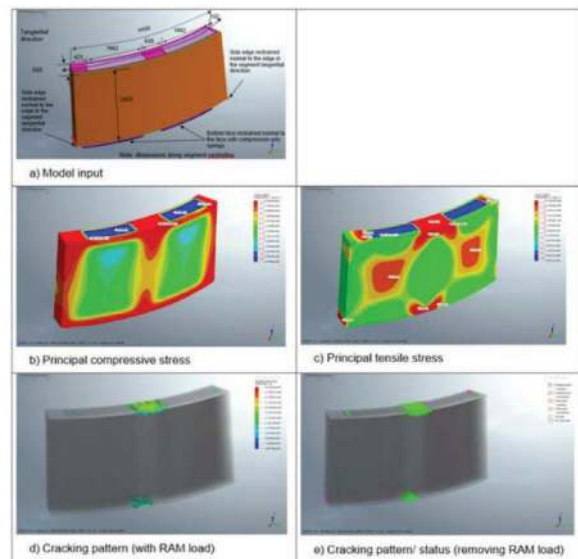

Figure 13. 3D Midas ram load and circumferential joint model.

The FEM analysis confirms that steel ladder reinforcement is not required for the circumferential joints for the 500 millimetre thick SFRC segment.

4.4.2 Radial joints

The lining is subject to bursting stresses from hoop loads on the radial joint and TBM ram forces on the circumferential joint. At ULS, numerical modelling was used to determine bursting stresses. Where SFRC is employed, the resistance is initially based on the tensile splitting strength of the concrete applied over the segment depth to resist the bursting force. The effects of joint rotation on the load distribution at the joints is considered for

the worst load-deflection combinations, including the effects of lipping. The analysis has been undertaken using Midas with elasto-plastic constitutive models used to represent the compressive and tensile behaviour of the concrete, similar to the circumferential joint model. The FEM model has also incorporated the guide rods and recesses. The general arrangement of the model and result is in Figure 14. The FEM models confirmed that the maximum tensile stress is lower than the first crack stress in all realistic cases. There are localised stresses near the bottom face where tensile stresses exceed the capacity however, these are not in the bursting zone and are due to the proximity to the boundary supports. This confirms no radial joint bar reinforcement is required.

Figure 14. 3D Midas radial joint model.

4.5 Segment handling and stacking

The segments are produced in a precast yard and transported to the tunnel construction site to build the tunnel ring. There is a series of handling, stacking and transportation processes, as summarised in Table 2.

The age, segment loading, and supporting conditions are different in each stage. A structural check on the SFRC segments has been undertaken to ensure no adverse effects on the segments occur during all stages. The minimum concrete strength for each handling and stacking case is then specified. The design has been coordinated with the construction team to facilitate segment production logistics and programme planning. This is achieved by determining the required minimum concrete strength to proceed to the next stage of handling/ stacking. The handling and stacking loads are based on the self-weight of the segments and their dynamic impacts - the maximum number of segments to be lifted and placed during the stacking process has been limited. As the handling and stacking are temporary load cases, load factors of 1.2 on segment self-weight and a dynamic factor equal to 2.0 are adopted. A 50 millimetre maximum tolerance for stacking spacer position is also considered. The planning and design of the precast facilities, including the segment production carousel, is currently being developed collaboratively. However, the design cases will be reviewed if the construction eventually requires a segment lifting arrangement different from the current design assumptions.

Table 2. Segment stacking and handling stages.

Step	Stage	Typical Schematic	Plant supporting segments	Min. concrete UCS (MPa)
1	Segment casting and initial curing		Segment mould	12
2	Demoulding		Vacuum pad (2/3 pads)	12
3	Lifting table extrados facing up		Lifting table	12
4	Turning of segment		Turning table	12
5	Lifting table intrados facing up		Lifting table	12
6	Initial stacking in buffer area (max. stack of 3 segments, with max. 1 segment per lift)		Grab	12
7	Transfer in group of 3 to external staging area		Conveyor	25
8	Transfer to storage yard by main portal crane - max. 2 segments per lift		Gantry crane & grab	25
9	Consolidate stacks to 6 segments - max. 2 segments per lift		Gantry crane & grab	25
10	Consolidate to 10 segments max (1 ring) - max. 2 segment per lift		Gantry crane & grab	25 (upper 4 segments) /50 (lower 6 segments)

12	Transport from tunnel site storage to TBM - max. stack of 2 segments		MSV	65

5 UNDERSEA TBM TUNNELS STABILITY

Generally, a bored (TBM) tunnel or an immersed tunnel (IMT) can be selected for a subaqueous road tunnel. Compared to the immersed tunnel, using a TBM excavating beneath the seabed does not require dredging and marine access. This difference made the TBM solution more favourable than the IMT option in the WHT Project, considering environmental concerns and constraints in the existing shipping fairways at Sydney Harbour.

A short section of the TBM tunnels is to be bored in soft/ mixed ground under Sydney Harbour. It is essential to understand the soil/ ground cover to achieve subaqueous tunnel stability in terms of structural integrity, tunnel flotation resistance and construction phase blowout prevention.

5.1 Tunnel flotation

The TBM tunnels have been checked against flotation. The soil cover shall always provide sufficient stabilising actions against the uplift force acting on the tunnel. This is particularly important for under harbour tunnels as the water level is always above the seabed (soil surface). The model and formulas adopted for the WHT flotation check are described in Lo et al. (2012). The flotation check also meets the following BS EN 1997-1:2004 requirement:

$$V_{dst,d} \leq V_{stb,d} + R_d \quad (1)$$

Where $V_{dst,d}$ = destabilising permanent and variable vertical actions

$V_{stb,d}$ = stabilising permanent vertical actions

R_d = any additional resistance to uplift

The partial factors for the flotation check are derived from PAS 8810:2016 Table 11 and 12 (Limit State UPL) and are listed in Table 3.

Due to the short-term effects, soil friction has been considered during the construction stage. In the operational stage, soil friction has been ignored, and a 2 metre seabed scouring/washout has been assumed.

Table 3. Flotation ULS partial factors.

Element		Partial factor
Actions	Self-Weight	0.9
	Water Pressure	1.0
	Weight density (soil density)	1.15
	Angle of shearing resistance	1.25
Ground Parameters (taken as the reciprocal of the specified value)	Effective cohesion	1.25
	Undrained shear strength	1.4
	Unconfined strength	1.0

5.2 Face pressure and blowout

The DAUB (2016) guide describes the mechanisms associated with face instability and provides a diagram of the allowable pressures at the tunnel crown to mitigate the risks, as shown in Figure 15. The ability to control pressure in a slurry TBM is known to be good, and the expected deviation of 20 kPa between the pressure set by the operator and the actual pressure (“Deviations” in Figure 15).

5.2.1 Lower face pressure limit

The lower face pressure limit is to prevent tunnel face cave-in failure. DAUB (2016) provides a formula (DAUB Equation 4) to estimate a minimal support force:

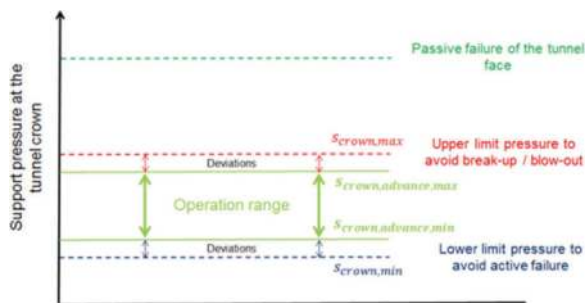

Figure 15. Allowable operational pressures at the crown (DAUB Figure 9).

$$S_{ci} = \eta_E E_{ci} + \eta_w W_{ci} \quad (2)$$

Where,

η_E safety factor for earth pressure force (=1.5) [-]

η_w safety factor for water pressure force (=1.05) [-]

S_{ci} required face pressure (circular tunnel face) [kPa]

E_{ci} face pressure due to earth pressure [kPa]

W_{ci} face pressure due to groundwater pressure [kPa]

For undrained behaviour, the stability number (N) proposed by Broms & Bennemark (1967) is used to estimate the face pressure at the tunnel axis. The critical stability number (N_{cr}) delivers the support pressure at collapse, and a safety factor of 1.5 shall be included in the calculation. The soil within a vertical opening is stable if the stability number is lower than 6.

$$N = \frac{\sigma_{v,axis} - S_{ci,axis}}{c_u} \quad (3)$$

Where,

N is stability number [$N_{cr}/1.5$];

$\sigma_{v,axis}$ is the vertical stress at tunnel axis [kPa]

$S_{ci,axis}$ is the face pressure at tunnel axis [kPa]

c_u is the undrained shear strength of soil [kPa]

For drained materials, the face pressure due to the earth pressure can be estimated based on the face stability study by Anagnostou & Kovari (1996), which is based on the force equilibrium approach for a sliding wedge at the TBM front face.

$$E_{ci} = F_0 \gamma' D - F_1 c' \quad (4)$$

where E_{ci} face pressure due to earth pressure [kPa]

F_0, F_1 dimensionless coefficient, read from nomograms in Figure 11

D tunnel diameter

c' soil cohesion

Figure 16. Nomograms for dimensionless coefficient F_0 and F_1 , from Anagnostou & Kovari (1996).

5.2.2 Upper face pressure limit and blowout

The upper face pressure limit is defined as a limiting pressure to avoid a break-up of the overburden or blowout of the support medium.

DAUB (2016) gives the upper support pressure limit to less than 90% of the total vertical stress at the tunnel crown (DAUB Equation 5), where this total vertical stress is the minimum, particularly using minimum water levels.

$$1 \leq \frac{0.9 \times \sigma_{v, \text{crown}, \text{min}}}{S_{\text{crown}, \text{max}}} \quad (5)$$

where

$\sigma_{v, \text{crown}, \text{min}}$ is Total vertical stress in the tunnel crown considering the minimal unit weight of the soil [kPa]

$S_{\text{crown}, \text{max}}$ is Maximal allowable pressure in the tunnel crown due to break-up safety/blow-up safety [kPa]

The above formula only considers the overburden stress and ignores the shear strength, which is conservative. Lo et al. (2012) provide an alternative method to estimate the limit pressure for a blowout using a limit equilibrium model (Figure 17). This limit equilibrium analysis can be carried out either drained or undrained, but the undrained analysis is more conservative. In this case, the loading conditions impose positive excess pore water pressures that reduce the shear strength of the soil. The analysis is performed with minimum water levels.

Figure 17. Factor of safety against blowout failure (Figure 7 in Lo et al. 2012).

Figure 18 shows the specific situation for WHT. The slurry pressure is applied to the cuboid of soil at the crown. Resistance to uplift includes the weight of the soil (saturated density) and the water pressure applied at the seabed, as well as frictional and cohesive

components applied to the four remaining along the cuboid of soil. An overall factor of safety of 1.2 against blowout failure shall be maintained. In WHT soft ground, the maximum face pressure is equal to:

$$S_{\text{crown}, \text{max}} \leq \frac{D \cdot b \cdot (\gamma \cdot h_s + \gamma_w \cdot h_w) + 2 \cdot (D + b) \cdot h_{3.2} \cdot c_{3.2}}{1.2 \cdot D \cdot b} \quad (6)$$

where

$S_{\text{crown}, \text{max}}$ is the maximal allowable pressure in the tunnel crown due to break-up safety/blowout safety [kPa]

D is TBM tunnel [15.7 m]

b is the length of slurry pressure – Adopted 13.5 m

$c_{3.2}$ is undrained shear strength of WH3.2 [80 kPa]

Figure 18. Lo et Al. 2012 model for WHT.

5.2.3 Numerical analysis of face pressure

To verify the minimum and maximum face pressure in the mixed/ soft ground under Sydney Harbour, a PLAXIS 3D analysis has been undertaken. The model simulates the excavation of 2.4 m and simultaneously applies face pressure and shield pressure (on the front shield length) and installation of 2.4 m lining at the rear of the TBM shield. The “safety” calculation type (i.e. phi/c’ reduction) has been completed in PLAXIS to obtain the factor of safety (FoS) to check the stability of the face pressure model. Under the minimum face pressure of 400 kPa at the crown and maximum face pressure of 530 kPa at the crown, the FoS are 1.25 and 1.21, respectively. Figure 19 shows the analysis results on the ground plastic points and ground movement shading from the maximum face pressure model. A sensitivity model is also run to evaluate the ultimate blowout failure pressure, which is 580 kPa (about 2 bars above hydrostatic pressure) at the crown and with a factor of safety of 1.072.

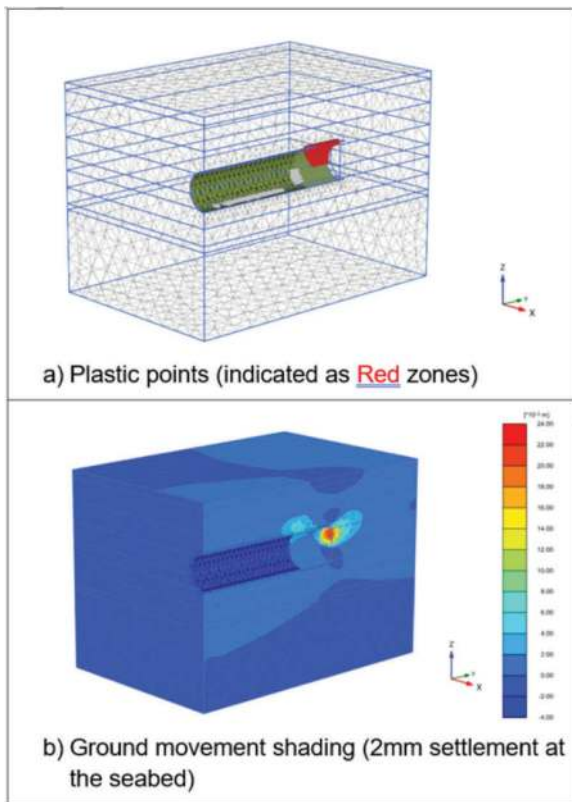

Figure 19. 3D face pressure model results (max. face pressure).

6 CROSS PASSAGES AND SEGMENT OPENING

The TBM section has eleven cross passages with a typical spacing of 120m (Figure 5). However, the separation between cross passages XP27 and XP29 is 260m. No cross passage is in the soft ground location, and all cross passages have been laid out to ensure they will be in competent rock. The soft ground cross passage has been eliminated to reduce the significant construction risks of tunnel opening and cross-passage excavation through the soft ground under the Harbour. Assessment has also demonstrated that the operational, fire, and life safety requirements are still met with the greater separation between XP27 and XP29.

Cross passages in road tunnels are for emergency pedestrian movement from the incident tunnel to the non-incident tunnel. The spaceproofing of the cross passages provides the following elements:

- Civil/ Structural: segment opening and collar, emergency egress, comms pit, wall elements, fire-rated doors, internal structures, and drainage.
- MEP (Mechanical, Electrical and Plumbing): Deluge main, Deluge manifold, electrical equipment room (EER), mechanical ventilation equipment, ITS, and lighting.

Cross passages have two different profiles: those with EER and those without EER. The cross-

passage's cross-sectional area is similar to a typical metro-size mainline tunnel. The cross passages between the TBM tunnels are in competent rock. They will be excavated by impact hammers with rock bolts and shotcrete as primary support and cast in-situ fibre-reinforced concrete secondary lining. Probing and grouting processes are required for groundwater inflow control before segment lining opening and cross-passage excavation. The cross-passage excavation support and lining are under design development.

Mega TBM tunnel linings are normally associated with significant axial hoop forces. The high lining hoop forces from the opening segment rings must be transferred through high-capacity shear structural elements to the adjacent non-opening segment rings or external structures during segment opening. This is typically accomplished using heavy and large steel structures (such as steel segments, straight and arched beams, jacked props, etc.). Measures are also required to limit the segmental lining deformation due to the larger collar excavation area at the segment extrados compared to the smaller segment opening size. Harding and Treweek (2016) have summarised and discussed the major solution types of segment opening support and their load path mechanism and key features. Chau et al. (2023) further elaborates upon the segment opening support systems to include the WGT solution, which adopts a combination of shear bi-cones and shear key as the segment opening support system for the high shear force transfer and using non-opening RC segment rings for supporting jacks. Such a support system allows the segment opening with minimum construction inconvenience. Bi-cones are a proprietary product evenly distributed around the circumferential joint. Shear keys used in West Gate Tunnels comprise a seamless steel pipe installed in a post-cored hole from segment intrados through/across the circumferential joint and encapsulated within high-strength grout. The design of the segment opening support for WHT is still under development. However, it may adopt similar principles as WGT from Chau et al. (2023), with additional project specific constructability inputs and coordination to improve construction planning and efficiency and reduce construction safety risk.

7 CONCLUSIONS

Steel fibre-reinforced concrete segments have been widely used in tunnelling projects. Typically, as a minimum, steel ladders or reinforcement are required at radial and circumferential joints to resist the high bursting stresses in segmental lining design.

The Western Harbour Tunnel (WHT) project in Sydney is Australia's largest diameter TBM tunnel project, currently under design and construction. The WHT TBM tunnels pass through jointed and stress-relieved rock and a section of soft ground under

Sydney Harbour, with a 35 metre to 45 metre water head above the tunnel crown. The segment design has used different empirical and numerical analyses to overcome many design challenges and confirmed the SFRC lining design for the tunnel alignment. This makes the WHT the world's largest TBM tunnel (15.15 metre tunnel OD) using SFRC segmental lining without radial and circumferential joints steel ladder/ reinforcement. The WHT project further develops steel fibre segmental tunnel lining design for mega TBM tunnels, which results in a cost-effective, durable and sustainable segmental lining design.

Review of key technologies for design of Dalian Bay Undersea Tunnel

Zhengjie Chen*, Hong Chen & Ming Lu

Shanghai Tunnel Engineering & Rail Transit Design and Research Institute, Shanghai, China

ABSTRACT: The Dalian Bay Undersea Tunnel is the first immersed tunnel in the cold ocean of northern China. The immersed section is 3035 meters long, divided into 18 elements. This paper provides a detailed exposition of key technologies for design, such as the concrete structure durability technology of the immersed tunnel in the cold marine environment of northern China, the fully flexible segmental element scheme, the closure joint constructed by segment jacking method, and the restoration scheme for immersed elements passing beneath the breakwater, which will offer reference and inspiration for the future design and technological application of immersed tunnels in China.

Keywords: Immersed tunnel, Closure joint, Breakwater, Durability

1 PREFACE

The Dalian Bay Undersea Tunnel is located in Dalian City, Liaoning Province, China (Figure 1). It passes beneath the Dalian Bay, connecting the Zhongshan District on the south bank and the Ganjingzi District on the north bank, and effectively breaks the traffic bottleneck caused by the ‘C’-shaped spatial structure of Dalian city. It is part of the urban rapid road that runs through Dalian city from north to south, connecting the eastern core area and the Jinpu New Area, thus holds significant importance in alleviating traffic congestion, promoting the integration of both banks, and establishing the Dalian coastal economic zone. This project is the first large-scale cross-sea tunnel project implemented in the PPP mode in China, and it is also the first immersed tunnel in the cold ocean of northern China.

In view of the characteristics and requirements of this project, a series of key technology research have been completed, such as the concrete structure durability technology for the immersed tunnel in the cold marine environment of northern China, the fully flexible segmental element scheme, the jacking segment method for the construction of closure joint, and the restoration scheme for immersed elements passing beneath the breakwater and so on, laying a solid foundation for the tunnel opening to traffic on May 1, 2023.

2 PROJECT SCHEME

As shown in Figure 2, the Dalian Bay Undersea Tunnel project begins at the Planned Road 20 in

Figure 1. Project location.

Suoyuwan on the north bank of Dalian Bay, extends southward beneath the Dalian Bay waters, the Ganjingzi western channel, and the northern breakwater of Dalian Harbor, and ultimately reaches the land at the dock basin between the Berth 3 and Berth 4 of Dalian Harbor on the south bank. From there, it continues eastward along Ganglong West Road to Renmin Road. The total length of the main line of the project is about 5098.227m (K0+208 ~ K5+306.227).

Figure 2. Project layout plan.

*Corresponding author: chen.zhengjie@stedi.com.cn

Figure 3. Visual representation of the tunnel.

Based on the urban rapid road standard, the main line of the tunnel has six lanes in bi-direction with a design speed of 60km/h (Figure 3). The tunnel is constructed by the immersed tube method. Vehicles carrying flammable, explosive, toxic chemicals, and other hazardous materials are prohibited from passing through the tunnel. The design life of the tunnel is 100 years.

The main line of the tunnel has a smooth plane line, with a total of 2 horizontal curves, where a R-1050m horizontal curve is set in the immersed section, and a R-320m reverse horizontal curve is set in the cut and cover section on the south bank.

The longitudinal section of the main line of the tunnel is roughly in the shape of a “W” (Figure 4), with a maximum longitudinal slope of 4%.

Figure 4. Longitudinal section (unit: m).

The total length of the tunnel section is 4857m, including an immersed section of 3035m (consisting of one 135m long straight element, twelve 180m long straight elements, and five 148m long curved elements), a north-bank cut and cover section of 380m, a south-bank cut and cover section of 1192m, a north-bank open section of 50m, and a south-bank open section of 200m. The immersed section adopts gravel bed foundation with a thickness of 1.3m. The bottom of immersed elements from K0+785 to K2+100 is directly on the bedrock (highly weathered and moderately weathered dolomite). The bottom of immersed elements from K2+100 to K2+840 is on the cohesive soil (Local treatment is carried out by using block stones for replacement), and the bottom of immersed elements from K2+840 to K3+820 is directly on the bedrock (highly weathered and moderately weathered slate).

According to the process requirements for immersed tunnel construction, two dry docks are set up on the north bank to serve as prefabrication sites for immersed elements during the construction phase.

A total of four equipment areas are built along the entire tunnel line, one on the north bank and three on the south bank.

A total of two ventilation equipment rooms are set up along the entire tunnel line, which are respectively arranged in the north bank equipment area and the south bank equipment area. Two tall exhaust towers and a set of short air shafts are arranged on the ground.

A management center is arranged for the tunnel on the north bank.

3 KEY TECHNOLOGIES FOR DESIGN

3.1 Concrete structure durability technology for the immersed tunnel in the cold marine environment of northern China

The environmental category of this tunnel is both marine chloride environment and freeze-thaw environment. Therefore, the impact on concrete brought by the above two environmental categories must be considered for the technical performance requirements of concrete.

- 1) According to the “Standard for Design of Concrete Structure Durability” (GB/T 50476—2008), the environmental categories and action levels of this project are confirmed as I-B, III-C, III-E, II-E, and V-D. The waterproofing and durability design indexes for concrete structures are shown in Table 1.
- 2) For this project, the frost resistance index is selected as the concrete frost resistance indicator, and it is proposed that the concrete frost resistance index DF shall reach 80%. Furthermore, considering the project construction schedule and the requirements of winter construction, it is also proposed for this project that the critical strength of concrete frost damage shall not be less than 70% of the design strength.
- 3) As another important component of the durability of the concrete structure, the specific requirements for the minimum thickness of concrete cover are put forward. Taking the immersed section as an example, for water-facing surfaces of the top slab, bottom slab, and sidewall, the thickness shall be 70mm; for the non-water-facing surfaces, the thickness shall be 50mm; and for either side of the middle wall, the thickness shall be 50mm. For the special range where sidewalls of the north-bank cut and cover section are in the splash area, the minimum thickness of the concrete cover shall be increased to 120mm, and the stainless steel reinforced mesh that does not come into contact with the regular steel reinforced cage is set up in the cover.

Table 1. Waterproofing and Durability Design Indexes for Tunnel Concrete.

Project site		Immersed section, shore section
Site environment		The outer side is in contact with seawater-containing soil, while the inner side is exposed to the marine atmospheric environment.
Concrete strength class		$\geq C45$ (28 days of age) $\geq C50$ (56 days of age)
Concrete impermeability level		P8~P12
Control of cementitious materials	Type of cementitious materials	PO, PI, or PII cement with low heat of hydration + high-quality fly ash (\geq Grade II fly ash) + superfine slag powder ($\geq S95$) and other ultra-fine mineral admixtures
	Consumption of cementitious materials (kg/m^3)	380~480
w/b		≤ 0.34
Concrete chloride diffusion coefficient (m^2/s) (detected by the RCM method)		$\leq 6.5 \times 10^{-12}$ (28 days of age) $\leq 4.5 \times 10^{-12}$ (56 days of age)
Depth of rapid carbonization (cm)		≤ 2
Alkali content (kg/m^3)		≤ 3
Chloride ion content (%)		≤ 0.08
Sulfur trioxide content (%)		≤ 4
Air content in concrete (%)		≤ 7

On the other hand, for the concrete structures in the splash area or the water level fluctuation area, its exterior surface is coated with a solvent-free epoxy anticorrosive coating, combined with an aliphatic polyurethane coating, serving together as a special durability measure. The solvent-free epoxy anticorrosive coating has a thickness of $600\mu\text{m}$ and is characterized by its ability to be applied in dry, humid, and underwater environments at room temperature. In humid and underwater environments, it can cure within 24 hours and provide a good overlapping transition with the polyurea waterproof coating on the top slab of cut and cover tunnel. The applicable aliphatic polyurethane coating has a thickness of $80\mu\text{m}$. Its excellent resistance to UV aging and salt mist makes it suitable as a surface protection coating for the marine concrete structure with an outdoor service life of ≥ 15 years. Additionally, this coating also exhibits outstanding recoatability, facilitating future maintenance, repairs, and recoating of the coating.

3.2 Fully flexible segmental element scheme

1) Cross section of the element

As shown in Figure 5, the cross section of the element is designed to have 2 tubes and 1 gallery. The outer dimensions of the element are 33.4m (width) \times 9.7m (height), with a clear height of 6.90m for the traffic tubes and a clear width of 12.65m for a single tube. Both the top and bottom slabs of the element have a thickness of 1.4m , the middle wall has a thickness of 0.6m , and the side-wall has a thickness of 1.25m .

Considering factors such as concrete weight, steel content of the structure, water density, construction loads, and element fabrication errors, the freeboard

height of the element after outfitting is calculated to be within the range of 100mm to 200mm .

Figure 5. Element cross section (unit: mm).

2) Element selection scheme

This project adopts a fully flexible segmental element scheme, which is the first of its kind in China. The feature of full flexible segmental element is mainly reflected in the structures of an element joint (between two elements) and a segment joint (between two segments of a single element), which enables effective reduction in longitudinal forces on the element structure, and allows for better adaptation to uneven foundation settlement.

Currently, the maximum length for a segmental element can reach 180m . Compared to the shorter monolithic element, it not only reduces the number of elements and the times of immersion, but also correspondingly decreases construction risks. In this project, the 180-meter-long standard straight element is divided into 8 segments; the 135-meter-long straight element is divided into 6 segments; and the 148-meter-long curved element is divided into 7 segments.

In this project, a total of 19 flexible element joints are set. Each element joint mainly consists of the

end steel shell, vertical steel shear keys (VSK1~2 in Figure 6), horizontal reinforced concrete shear keys(HSK1~2 in Figure 6), GINA gasket, OMEGA seal, fireproof structure and so on.

Figure 6. Schematic diagram of a flexible element joint.

In this project, a total of 119 flexible segment joints are set. Each segment joint consists of the OMEGA seal and its embedded part, shear bar, temporary pre-stressed pipe, middle-buried waterstop, sand blocking device, fireproof structure and so on, as shown in Figures 7-8.

Figure 7. Typical cross-section arrangement of a segment joint.

Figure 8. Longitudinal section of top slab at the segment joint.

The segment joint can transmit compression, but not tension. Furthermore, the segment joint can transmit vertical and horizontal shear forces through the special shear bar distributed on the top slab, bottom slab, side wall and middle wall. According to longitudinal force calculation results of the immersed elements structure and bearing capacity test results of the special shear bar, 124 sets of special shear bars are installed at part of the segment joints and 68 sets of special shear bars are installed at the other segment joints.

Before the element is floated, it needs to be tensioned using temporary pre-stressed cables to connect longitudinally segments within the element as a whole. And it shall also be ensured that during construction processes like floating and sinking, the compressive stress at each segment joint is not less than the minimum compressive stress required. The pre-stressed pipes are symmetrically arranged along the element centerline, with 24 pre-stressed pipes arranged on the top slab and 22 pre-stressed pipes arranged on the bottom slab (including 2 reserved pipes respectively).

Vacuum grouting is carried out in the pre-stressed pipe after the temporary pre-stressed cable is tensioned. The pre-stressed anchor heads at both ends of the element are equipped with sealing covers capable of withstanding 0.4MPa water pressure.

After the element is sunk into position for a period of time, the temporary pre-stressed cable at the segment joint is cut to release the pre-stressing force, so that the segment joint becomes a flexible joint that can adapt to certain deformation. The principle of cutting temporary pre-stressed cables is to cut all temporary pre-stressed cables of an element at a batch. Before cutting, it shall be ensured that the backfill coverage, and at least the first layer of ballast concrete, have been completed, and the settlement is also stabilizing (with a change rate not exceeding 0.5mm/day).

Monitoring data indicates that the change in settlement before and after the cutting of temporary pre-stressed cables is not greater than 1mm.

3.3 Closure joint constructed by segment jacking method

In this project, diverging and converging ramps are set within the south-bank dock basin, with a gradual change in the cross section. The boundary mileage between the immersed section and the cut and cover section on the south bank is set at K3+820, located at the northern end of the dock basin. The north-south length of the dock basin is about 660m. After the temporary cofferdam is set up at the northern end of the dock basin, the concrete can be cast-in-place at the cut and cover section in it, as shown in Figure 9.

According to the construction schedule, immersed elements are sunk one after another from north to south. So as to meet the requirement of the construction period, the closure joint is arranged accordingly at the south bank side. The bottom elevations of the

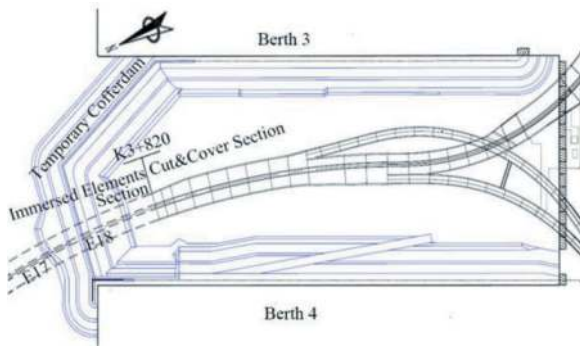

Figure 9. South-bank dock basin tunnel layout plan.

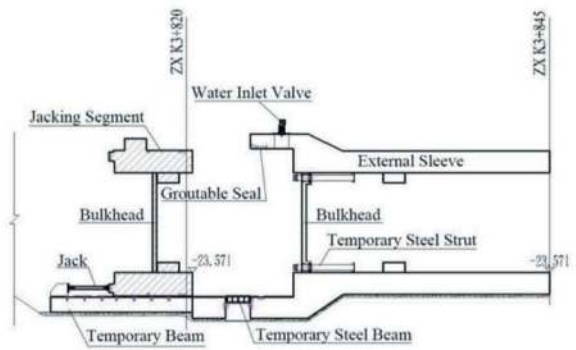

southernmost three elements (E18 to E16) gradually deepen from south to north, with elevations ranging from -25.7 to -27.1m.

The closure joint constructed by segment jacking method is a new type of closure joint. The joint is located at the junction of the immersed section and the cut and cover section. This closure joint structure primarily consists of an external sleeve, jacking segment, waterstop structure, pushing device, locking structure, and post-cast strip structure (Figure 10). During construction, under dry working conditions, the external sleeve structure connected to the cut and cover section is poured first, and then the jacking segment structure is constructed a certain distance away from the external sleeve. Next, push the jacking segment into the external sleeve and install the water stop structure, then fill the site with water. Once the final element is sunk to position, the jacking segment is pushed out using the reserved pushing device for initial compressive connection. Subsequently, the water inside the element joint compartment is discharged, achieving hydraulic compressive connection. After then, install the locking structure. Close the water inlet valve of the jacking segment and discharge water. Pour reinforced concrete at the post-cast strip between the jacking segment and the external sleeve, conduct backfill coverage, and grouting for the foundation of the jacking segment. Finally, remove the bulkhead to complete the closure joint.

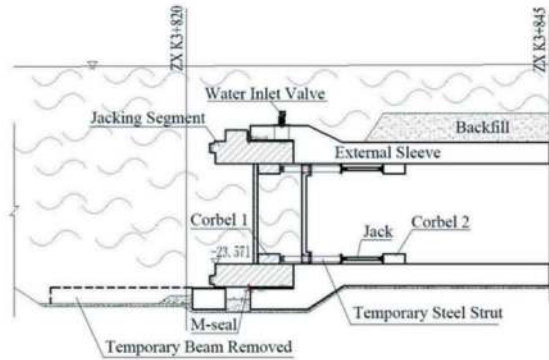

By comparison, this project adopts the closure joint constructed by segment jacking method, considering simpler structure fabrication, the main work completed in a dry working environment and minimal underwater works, which assures construction quality, a shorter construction period, limited affection by water depth, and lower construction costs.

In this project, the main components of the closure joint constructed by segment jacking method are as follows:

- 1) The external sleeve is a cast-in-place reinforced concrete structure. It has a maximum width of 36.23m, a height of 12.70m, and an initial engagement length with the jacking segment of about 2.95m. The lateral internal gap between the external sleeve and the jacking segment is

(a) Casting jacking segment

(b) Jacking segment in position

(c) Hydraulic compressive connection of closure joint and locking the jacking segment

(d) Water discharge and post-pouring concrete (after locked)

Figure 10. Diagram of construction sequence for segment jacking method (unit: m).

- designed with a spacing of 100mm in the engagement range. A reinforced concrete bulkhead is set up in the external sleeve.
- The jacking segment is a reinforced concrete structure with two tubes and one gallery, having a width of 34.03m, a height of 10.05m, a length of 5.75m, and a bottom elevation of the bottom slab is -25.171m (the top elevation -23.571m). A reinforced concrete bulkhead is set up in the jacking segment. The end face of the jacking segment that connects the immersed element is equipped with the end steel shell, embedded part of vertical steel shear keys, and embedded part of horizontal concrete shear keys etc. A sliding plate structure consisting of mirror-finished stainless steel plate and polytetrafluoroethylene plate is set up at the bottom of the jacking segment, with a sliding friction coefficient of about 0.1. The jacking segment is pushed out in the water for a distance of about 1.5m.
 - The structure adopts two waterstops (Figure 11): M-seal and groutable seal. Waterstops are arranged along the outside of the jacking segment, with one ring each, forming a dual-sealed ring. The circumference of each exceeds 87m. With the design water pressure, the M-seal meets the watertightness requirement when stretching out by $1.5\text{m} \pm 0.1\text{m}$; the groutable seal, when grouted (with water), expands to seal the gap between the jacking segment and the external sleeve, thus meeting the water-tightness requirement.

Figure 11. Diagram of the longitudinal section of two waterstops after the jacking segment is pushed out.

- The pushing device consists of 4 pushing jacks behind the bulkhead of the external sleeve, along with the temporary steel strut and reinforced corbel 1 and corbel 2, as shown in Figure 12. If necessary, the pushing device can also use the steel corbel for pulling back.

Figure 12. Pushing device structure.

- The locking structure uses 24 temporary steel struts combined with later-installed steel struts. Each individual steel strut can withstand an axial force of 550t.
- The post-cast strip uses self-compacting compensating shrinkage concrete with a layered pouring process.

Considering that the jacking segment method is being applied for the first time in China, the pushing process test and the waterstop watertightness test were done on small-sized models before design. This provided reliable calculation parameters and optimization suggestions for the design and construction of the closure joint.

The measurement data after breakthrough survey indicates that the axial horizontal deviation of the jacking segment is no more than 3mm, and the elevation deviation is no more than 2mm; the relative horizontal deviation from the end of element E18 is about 17mm, and the relative elevation deviation is 38mm, both of which meet the requirements.

3.4 Restoration scheme for immersed elements passing beneath the breakwater

In this project, the immersed section passes beneath the northern breakwater of Dalian Harbor, with an angle of about 57° between the tunnel axis and the breakwater axis. This breakwater was originally constructed between 1908 and 1918, featuring a gravity-type cubic structure with a top width of 6m and a breakwater top elevation of 3.64m. Before the sinking of immersed elements, it is necessary to dismantle about 420 meters of the northern breakwater of Dalian Harbor to carry out the underwater foundation trench construction for the immersed elements. This breakwater will be restored after the immersed elements are sunk to position.

A special breakwater of about 64.6m in length is restored on the top of the immersed tunnel. It adopts a lightweight caisson structure form. By widening the bottom width of the breakwater and adding side loads to it, this mitigates the partial load under wave action, decreases the stress on the breakwater foundation, and solves issues related to excessive localized stress and uneven settlement of immersed elements. Compared to the high foundation gravity-type cubic structure, this scheme is featured with less cost, faster construction speed, and a smaller offshore footprint. The lightweight caisson structure has been verified through ocean physical model tests, confirming that the stress on it meets the requirement.

Specifically, a bed of 10 to 100kg riprap is first laid on the immersed tunnel, with a top elevation of -12.0m. The lightweight caissons are situated on the riprap bed, with four caissons arranged in total, as shown in Figure 13. The dimensions of a single lightweight caisson are about 16.0m x 25.5m x 14.7m (length x width x height), with internal compartments arranged in a 4x3 layout. Overhanging plates with an

overhanging width of 2.0m are set up for the bottom slabs on the south and north sides. The caisson breast wall is a reinforced concrete structure, with a top elevation of 3.64m.

To ensure uniform force distribution across the cross-section of the immersed element, the outer edge lines of stacked loads on the north and south sides of the lightweight caisson are perpendicular to the tunnel axis. The stacked load is composed of 10-100kg block stones with a minimum width of about 12m, a top elevation of -8.0m and a side slope of 1:2. At the north side (facing the ocean), 400~500kg block stones are used for protection, while at the south side (facing the dock basin), 100~200kg block stones are used for protection.

On the other hand, block stone replacement is applied to the cohesive soil foundation of the immersed elements within the breakwater area, with a replacement thickness ranging from 2.0m to 6.0m based on the longitudinal structural calculations.

Following the implementation of the above plan, the cumulative settlement of the element E12 ranges from -33.9mm to -19.8mm, all of which fall within the allowable range of design.

4 CONCLUSIONS

The Dalian Bay Undersea Tunnel is another milestone success in the development of immersed tunnels in China. In response to the construction

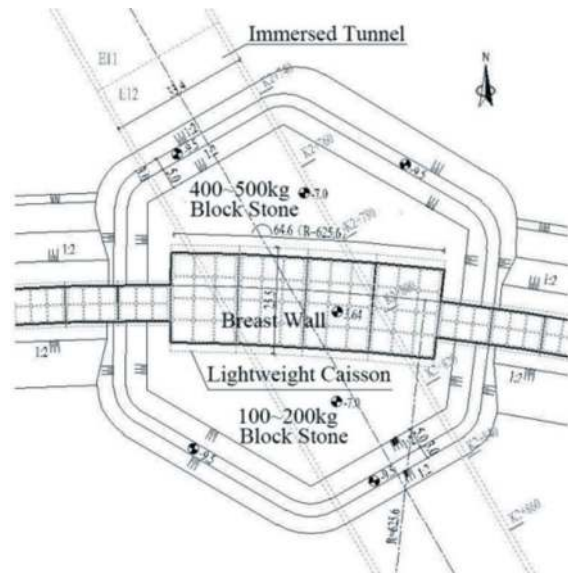

Figure 13. Breakwater restoration plan (unit: m).

conditions and requirements of the Dalian Bay Undersea Tunnel, this paper elaborates on a series of key technical research achievements completed by the design team. These key technologies have not only laid a solid foundation for its smooth opening to public traffic but also provided more references and insights for the design and technical application of immersed tunnels in China.

Design of tunnel brace and retaining structure on East Artificial Island of Shenzhen-Zhongshan Link

Hong Chen, Chun Ning He*, Xiao Dong Lai & Long Yu

Shanghai Tunnel Engineering & Rail Transit Design and Research Institute, Shang Hai, China

ABSTRACT: For the Shenzhen-Zhongshan Link, the East Artificial Island is built in the estuary on the Shenzhen side, and the tunnel excavation is carried out in the soil layer that is backfilled and preloaded on the island. Considering that the original marine silt layer in the estuary is widely and unevenly distributed, thick, with low strength and high compressibility, the tunnel brace and retaining structure and respective measures are proposed. The tunnel passes between the pier 53 and pier 54 of the existing Guangzhou-Shenzhen Coastal Expressway, where the tunnel excavation is about 46m wide and 15.5m deep. The outer edge of the retaining structure is only about 1.0m from the nearest point of the pier. Through analysis and comparison, the design schemes and measures are proposed such as interlocked steel pipe piles with bored pile driven inside, rotary jet piles between pipe piles as water stop, bracing servo systems with appropriate ground improvement. These measures were finally successfully implemented to minimize the risk of pier deformation during the tunnel excavation. The monitoring data showed that the deformation of the pier of the Guangzhou-Shenzhen Coastal Expressway caused by the excavation works was below the horizontal displacement limit of 5mm required by the transportation and management authority.

Keywords: Complex ground conditions, marine silt layer, interlocked steel pipe piles, bracing servo system, ground improvement

1 PREFACE

Located in the core of Guangdong-Hong Kong-Macao Greater Bay Area, the Shenzhen-Zhongshan Link directly connects the Shenzhen Special Economic Zone and Zhongshan City. As a sea crossing project integrating “tunnel, artificial island, bridge and underground interchange”, the project connects with the Jihe Expressway in the east, passes through the south side of Shenzhen Airport and the Pearl River estuary, and finally reaches the Zhongshan Xinlong Interchange in the west, where it connects with Zhongkai Expressway. The project has total length of 24km with eight lanes in both directions. The project is designed according to expressway standards with a design speed of 100km/h.

According to the function and traffic organization of the project, the east artificial island is constructed in the estuary on the Shenzhen side. The main tunnel on the island connects to the Coastal Expressway Phase II in the east and to the cofferdam tunnel in the west. The design mileage of the main tunnel is between K5+695 and K6+550. The total length of the tunnel is 855m, of which the open section is 395m long and the cut and cover section is 460m long. See Figure 1.

2 DIFFICULTIES IN THE CONSTRUCTION OF THE TUNNEL ON EAST ARTIFICIAL ISLAND

2.1 *Complicated geological conditions*

The engineering site is at Pearl River estuary, where the geological condition is complex and changeable. The soil layer distribution is extremely uneven. The soil layers in the site include silt, clay, mucky clay, residual soil, completely weathered granite, and strongly weathered granite from top to bottom.

The silt is widely distributed, which belongs to marine sedimentary and is characterized by high water content, large pore ratio, low shear strength, high sensitivity, high compressibility, local under-consolidation, and poor permeability. Even after the construction and preloading of the East Artificial Island, the parameters of the silt layer are still relatively poor with internal friction Angle as 9.4° and soil cohesive strength as 6.5kPa, and the layer is distributed in the range of the excavation depth to 12m below the excavation bottom with thickness about 1.8-8m, having a relatively deep depth.

Therefore based on the detailed survey and the supplementary survey data, it is necessary to select the brace and retaining structure reasonably with

*Corresponding author: he.chunning@stedi.com.cn

Figure 1. Tunnel on East artificial Island.

regard to the characteristics of silt layer such as uneven distribution, layer thickness and depth. And according to the results of excavation stability check calculation, the type and length of the retaining structure are determined, and appropriate ground improvement measures are proposed to ensure the excavation safety.

2.2 Constraints of the existing Guangzhou-Shenzhen coastal expressway

The Guangzhou Shenzhen Coastal Expressway is a north-south artery in the Pearl River Delta. It is constructed according to highway standards, with eight lanes in both directions with design speed 100km/h. The expressway was completed and opened to traffic in December 2013. See Figure 2.

Figure 2. Existing Guangzhou-Shenzhen coastal expressway.

The main tunnel on the East Artificial Island runs under the Guangzhou-Shenzhen Coastal Expressway, and passes between the pier 53 and pier 54. The structural width of the main tunnel is about 46m, the excavation depth is about 15.5m, and the outer edge of the retaining structure is only about 1.0m from the nearest pier. Considering the complex geological conditions and working conditions of island construction and backfilling on the original marine silt layer at the tunnel site, it is necessary to carefully design the retaining structure and make a reasonable construction organization so as to minimize the potential deformation risks of the bridge

piers during the construction. The horizontal displacement limit of the piers during excavation must be less than 5mm required by the transportation and management authority.

See Figures 3 and 4 for photos of the construction phases of the East Artificial Island and the tunnel.

Figure 3. Bird's-eye view of construction of the East Artificial Island and tunnel excavation.

Figure 4. Excavation passing through Guangzhou-Shenzhen Coastal Expressway.

3 DESIGN OF TUNNEL BRACE AND RETAINING STRUCTURE ON EAST ARTIFICIAL ISLAND

3.1 Overall construction process for tunnel on the island

The locations of the tunnel on East Artificial Island, the cofferdam tunnel and the Coastal Expressway are shown in Figure 5.

To avoid the mutual interference by the construction of the East Artificial Island and the temporary cofferdam, the eastern end of temporary cofferdam is located approximately 130m from the Coastal Expressway.

Figure 5. Schematic diagram of overall construction process of the tunnel on the Eastern Artificial Island and cofferdam tunnel.

The overall construction of the East Artificial Island progresses from the east side of the Coastal Expressway to the west side. The tunnel on the island is also constructed in sections with the formation of the island. The backfill thickness for the construction of the island is 8m. To avoid the impact of the backfilling loading on the safety of the operation of the Coastal Expressway, the tunnel on the island is divided into two sections at the mileage of K6+171.5m, a distance of approximately 161.5m to the east of the Coastal Expressway.

So the tunnel on the island and the cofferdam tunnel are roughly constructed in three phases. The cofferdam is constructed first. The eastern section of the tunnel on the island is commenced when the island is roughly completed. The western section of the tunnel begins to construct after the completion of the cofferdam tunnel and the eastern section of the tunnel.

3.2 Design standard and principles

- (1) The safety level of the excavation shall be determined based on the surrounding environmental conditions, excavation depth, and the function of brace and retaining structure.

The tunnel on East Artificial Island consists of 39 structure sections (CE1-CE39) from east to west. The excavation safety level and deformation control standards for each structural section are detailed in Table 1.

- (2) The reasonable brace and retaining system shall be designed according to the excavation safety level, depth and engineering geological conditions.
- (3) Calculations shall be conducted on the strength, deformation, stability and impermeability of the brace and retaining structure.
- (4) When determining the depth of the retaining structure, calculations shall be carried out on anti-sliding, anti-overturning, overall stability, anti-uplift and anti-piping stability. For the weak soil areas, vertical bearing capacity, deformation, and stability calculations shall also be checked, and reasonable measures shall be taken for the ground improvement.

3.3 Design of the brace and retaining structure of the tunnel on the island

For the retaining structure of the tunnel, depending on the depth of excavation, there are six types: slope excavation, single row steel sheet pile, double row steel sheet pile, bored pile + mixing pile water curtain + rotary jet grouting pile between the bored pile, interlocked steel pipe pile with bored pile driven inside + rotary jet pile between pipe piles, and diaphragm wall. Concrete and steel pipe braces are arranged according to different depths. See Figure 6.

Table 1. Control standards for excavation deformation.

Section (safety level)	Maximum horizontal displacement on top of retaining structure	Maximum horizontal displacement of retaining structure	Maximum ground settlement
CE4-CE 11 (L1)	min(1%H, 80mm)	min(1% H,80mm)	0.25%H
CE12-CE23 (L2)	min(0.4%H, 50mm)	0.3%H	0.25%H
CE24-CE29 (L2)	min(0.4%H, 50mm)	0.3%H	0.25%H
CE30 (L1)	min(0.2%H, 30mm)	0.3%H	0.25%H
CE31-CE32 (L1)	min(0.2%H, 30mm)	0.18%H	0.15%H
CE33-CE39	min(0.2%H, 30mm)	0.3%H	0.25%H

Note: H presents the depth of excavation.

Considering the poor quality of bored piles and rotary jet grouting pile construction in the backfilling of sand layer, silt, and sandy soil of island, long casing is adopted to drive through the silt layer to ensure the quality of the pile. A row of mixing pile is set at the outer side of the bored piles to cut off the water, and the rotary jet grouting pile is set between the bored piles to stop the possible seepage between the bored piles and the mixing pile to ensure the water stopping effect. See Figure 7.

To control the deformation of the retaining structure and to minimize uneven settlement during the long-term operation, the weak soil at the bottom of the excavation is reinforced with skirts and strips.

The calculation of the retaining structure simulates the whole construction process according to the principle of load increment method. The finite element method of elastic foundation rod system is adopted to simulate the actual construction process of excavation, bracing, and dismantling, and the structural analysis is carried out according to the principle of "deformation first, brace later". According to the calculations, both the maximum horizontal displacements and all the stability calculations meet the requirements of the code.

4 DESIGN NODE OF TUNNEL PASSING THROUGH GUANGZHOU-SHENZHEN COASTAL EXPRESSWAY

4.1 Brace and retaining structure design scheme

In combination with the analysis of the impact of the backfilling of the East Artificial Island and the tunnel excavation on Guangzhou-Shenzhen Coastal

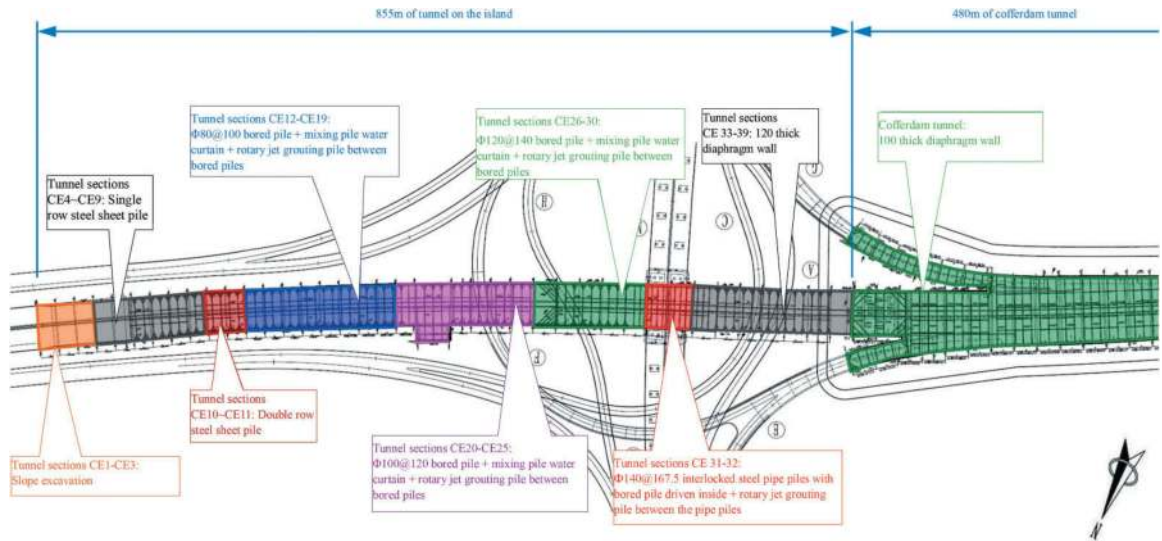

Figure 6. Layout of tunnel retaining structure on the island (dimension unit of retaining structure indicated in the figure: cm).

Figure 7. Schematic diagram of bored pile, mixing pile water curtain, and rotary jet grouting pile.

Expressway, the design scheme of the retaining structure and the construction organization design are optimized to minimize the potential deformation risks of the bridge piers. The tunnel retaining structure is designed as combined together with the protection structure of the Coastal Expressway in the construction of the East Artificial Island. The specific design is as the followings:

- (1) The $\Phi 140$ cm interlocked buckle steel pipe piles are set at the pier side every 167.5cm. The pile length is 27.1-30.1m. The bored piles are driven inside the steel pipe piles to increase the stiffness of the retaining structure. The rotary jet grouting piles are set on the outer side for water stop between the pipe piles.
- (2) There are four braces, e.g., one concrete brace + three steel pipe braces. All of the steel pipe braces are provided with the servo system. The brace servo system is an intelligent horizontal displacement control system, composed of hardware equipment and software programs. It is suitable for projects with strict control requirements for deformation of retaining structure during excavation. The system can realize 24h real-time

monitoring, low voltage automatic servo and high voltage automatic alarm, providing comprehensive and multiple safety guarantees for the excavation. The excavation profile passing through Guangzhou-Shenzhen Coastal Expressway refers to Figure 8.

- (3) Considering the complex geological conditions and working conditions of backfilling the island on the original estuary silt layer, in combination with supplementary survey data, skirt + strip rotary jet grouting pile is used to improve the area from the top of the silt layer to the bottom of the excavation about 12m. The skirt width is 5m, the strip width is 5m, and the spacing is 5m. The improvement range extends appropriately along the tunnel to both sides of the bridge. See Figure 9.
- (4) As the second steel pipe brace is basically located at the center of the bridge pier abutment, the soil between the interlocked steel pipe pile and abutment is reinforced with rotary jet grouting piles, so as that the second steel pipe brace and the reinforced soil may be formed as a lateral constraint for the abutment.
- (5) To ensure effective control of the displacement, settlement, and inclination of the piers of Guangzhou-Shenzhen Coastal Expressway during the artificial island backfilling and excavation, safety evaluation of the operation status of the existing bridge is conducted before construction. And based upon the evaluation, the special construction scheme is formulated to ensure the safety of the bridge. The construction monitoring runs through the whole construction process, which provides timely the monitoring information. And measures shall be taken timely to control the displacement of bridge piles and to ensure the safe operation of the Coastal Expressway.

Figure 8. Cross section of brace and retaining structure of the tunnel passing through Coastal Expressway.

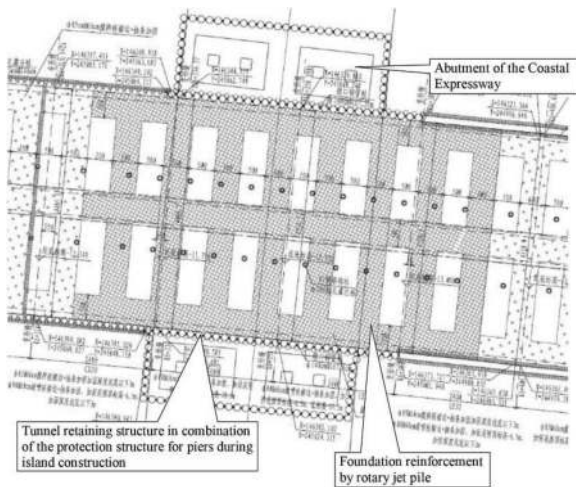

Figure 9. Layout of excavation reinforcement at the location of tunnel passing through Coastal Expressway.

4.2 Calculation and analysis

In addition to the calculation and analysis by the finite element method of elastic foundation rod system, 3D finite element model is also used to study the impact of island construction and tunnel excavation on the existing Guangzhou-Shenzhen Coastal Expressway. Considering the linear elasticity of the material, the soil and abutment are simulated with solid units, the retaining structure of excavation is simulated with plate elements, and the pile and brace structure are simulated with beam elements. The calculation model and working conditions refer to Table 2 for in detail, and the calculation results refer to Figures 10-13.

The calculation shows that: Impacts of construction of the East Artificial Island and excavation of tunnel on the pile foundation of Coastal Expressway are as follows: Horizontal additional displacement $4.32\text{mm} < 5\text{mm}$ (towards the side of the excavation), and vertical additional displacement $-0.685\text{mm} < 5\text{mm}$ (settlement), showing a relatively small impact. After applying the additional bending moments, shear forces, and axial forces, the calculation of pile foundation of Coastal Expressway still meets the design requirements both in ultimate limit state and serviceability limit state.

The 2D finite element model is also used for parallel check analysis. In the analysis, the soil is modelled with soil hardening model, the brace structure is simulated with anchor elements, and other structures are simulated with beam elements, considering the linear elasticity of the material. The working conditions calculation is the same as the 3D model. The calculation results refer to Table 3.

According to the calculation results, the impacts from the east artificial island construction and the tunnel excavation on the pile foundation of Coastal Expressway are as follows: Horizontal additional displacement $3.88\text{mm} < 5\text{mm}$ (towards the side of the excavation), and vertical additional displacement $-0.937\text{mm} < 5\text{mm}$ (settlement), showing a little impact.

4.3 Comparative analysis of monitoring data

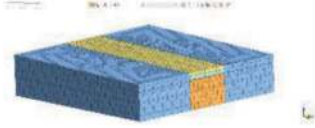

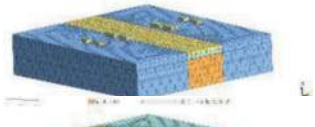

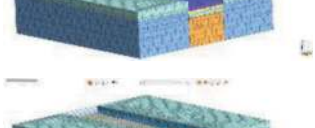

4.3.1 Brace axis force

The envelope values of each brace obtained by the finite element method of elastic foundation rod system are as follows: The axis force of the first concrete brace is 2796kN, the axial force of the second steel pipe brace is 2535kN, the axis force of the third steel pipe brace is 2264kN, and the axis force of the fourth steel pipe brace is 944kN.

The measured axis forces of each brace during the excavation measured are shown in Figure 14:

- (1) The axis force of the first brace gradually increases with the excavation. After the second steel pipe brace is installed, the axis force decreases, and then gradually increases with the next excavation. After the third steel pipe brace is installed, the axis force of the first brace tends to be stable.
- (2) Upon the application of bracing servo system, the steel pipe brace axis force is timely adjusted based on monitoring data, and the axis force of each steel pipe brace becomes relatively stable.
- (3) The brace axis forces monitored on site are not beyond the design envelope values, which are approximately 70-85% of the design envelope values.
- (4) According to the axis force change curve, it can be seen that the steel pipe brace failed to be installed in time due to the rainstorm weather during the construction, which is particularly obvious in the first brace axis force curve. The on-site excavation and brace installation must follow in queen, and brace shall be done with the excavation progress.
- (5) Some steel pipe braces may experience looseness in the pre-applied axis force during the excavation. In this situation, the load must be strictly applied in levels according to the excavation conditions and be adjusted at any time according to the axis force monitoring curve.

Table 2. List of working conditions analysed by 3D finite element models.

Working condition	Calculation model	Descriptions of working conditions
Working condition 1		With pile foundation and abutment provided, calculate initial ground stress, and clear the displacement
Working condition 2		Island backfilling, preloading, and consolidation for 90 days
Working condition 3		Loading/unloading
Working condition 4		Construction of retaining structure and foundation reinforcement
Working condition 5-1		Excavation is carried out step by step from top to bottom with the erection of corresponding brace
Working condition 5-2		
Working condition 5-3		
Working condition 5-4		
Working condition 6		Cast the bottom slab and remove the fourth brace

Figure 10. Diagram of overall deformation (mm).

Table 3. List of main analysed working conditions of 2D finite element models.

	Calculation model	Descriptions of working conditions
Working condition 2		 $U_v \max = -1.82 \text{mm}$, $U_h \max = -2.86 \text{mm}$
Working condition 3		 $U_v \max = 0.3 \text{mm}$, $U_h \max = 0.671 \text{mm}$
Working condition 6		 $U_v \max = -0.788 \text{mm}$, $U_h \max = 3.78 \text{mm}$

Figure 14. Brace axis force monitoring curve.

4.3.2 Horizontal displacements of soils

According to the monitoring data of the horizontal displacement as the monitoring sections of ZQT62, 64, and 65, see Figures 15-18, it can find that:

- (1) When excavating to the bottom of the second steel pipe brace, at a depth of about 4.5m, the horizontal displacement of each sections within depth of 15m is basically between the calculated values of the soil structure model and the load structure model; while below 15m the horizontal displacement is close to the calculated curve of the soil structure model.
- (2) When excavating to the bottom of the third steel pipe brace, at a depth of about 8.5m, the

horizontal displacement of each sections within the depth of 13m is basically between the values calculated by the soil structure model and the load structure method; while below 13m, the displacement is relatively consistent with the calculated curve of the soil structure model.

- (3) When excavating to the bottom of the fourth steel pipe brace, at a depth of about 12m, the horizontal displacement of each sections within the depth of 18m is more consistent with the soil structure model; while below 18m, the displacement is between the calculated values of the soil structure model and the load structure model.
- (4) When excavating to the bottom of the fourth steel pipe brace, at a depth of about 15.5m, the horizontal displacement of each sections within the depth of 18m is more consistent with the soil structure model; while below 18m, the displacement is between the calculated values of the soil structure model and the load structure model.

The soil layer in the excavation is relatively complex, with a thickness of 3.3~6.3m of silt layer. The spatial differences in soil layer distribution, the different soil layer parameters selected for the two calculation methods, and possible deviations in soil layer parameters result in slight deviation between the calculated values and measured values.

Figure 15. Horizontal displacement when excavating to the bottom of second brace.

Figure 17. Horizontal displacement when excavating to the bottom of fourth brace.

Figure 16. Horizontal displacement when excavating to the bottom of third brace.

Figure 18. Horizontal displacement when excavating to the bottom of the excavation.

4.3.3 Horizontal displacement of piers

The horizontal displacement monitoring curves of pier 53 and pier 54 of Coastal Expressway (see Figure 19) shows that before the tunnel excavation, the horizontal displacement of the piers caused by island backfilling and preloading is about 1.4-2.6mm towards the outside of the excavation, and the horizontal deformation is relatively stable before the

excavation. With the tunnel excavation, especially after excavating to the second brace, the horizontal displacement curve of the piers change significantly and begin to gradually deform towards the excavation. When excavating to the bottom, the horizontal displacement of the piers is about 0.4~3.4mm, which meet the horizontal displacement limit of 5mm required by the transportation management authority.

Figure 19. Horizontal displacement time curves of piers 53 and 54.

5 CONCLUSION

This paper presents the design scheme for tunnel excavation after island backfilling and preloading on the existing marine silt layer, focusing on the brace and retaining scheme for the tunnel passing through the Coastal Expressway. Based on the analysis of on-site monitoring data, the stress and deformation characteristics of the excavation are obtained. The successful construction of the tunnel excavation passing through Coastal Expressway, not only ensures normal operation of the Coastal Expressway, but also provides reference for similar projects in the future.

For the tunnel passing through the Coastal Expressway, the following conclusions are obtained:

- (1) The retaining structure in combination with the protection structure of the Coastal Expressway

during the island construction and the bored piles driven into the interlocked steel pipe pile greatly improve the rigidity of the retaining structure, and the displacement of the retaining structure is controlled effectively.

- (2) With the favourable conditions of the second steel brace located at the center of the pier abutment, the soil between the interlocked steel tube pile and the abutment is reinforced with rotary jet grouting piles, which can effectively form lateral constraints on the abutment and minimize the horizontal displacement of the abutment and pile foundation.
- (3) The steel bracing servo system automatically compensates for the brace axis force and actively regulates the brace axis force, effectively controlling the displacement of the retaining structure.
- (4) According to the calculation results of the load structure model and the soil structure model, as well as the comparative analysis of monitored data, the horizontal deformation of the excavation is basically between the calculated values of two models.
- (5) In the design of the brace and retaining structure, the effects of the excavation method and sequence on the displacement and stress conditions of the brace and retaining system shall be considered. During construction, the dynamic engineering monitoring and timely analysis of the monitoring results shall be carried out, and the data shall be collected to provide a basis for scientific research and structural design.

Sustainability of Shihmen reservoir by desilting tunnel in Taiwan

Chen-En Chiang, Pao-Sheng Kuo, Hsien-Tsung Chiang & Yan-Jhih Lin*

Geotechnical Engineering Department, SINOTECH Engineering Consultants Ltd., Chinese Taipei

ABSTRACT: Earthquake and typhoon are two major natural hazards in Taiwan. Earthquake-triggered landslide in mountainous areas accompany with torrential rainfall supply large amount of sediment to river basin and cause sediment accumulation of reservoir. Considering strategies can be used to reduce sediment delivery or prevent sediment deposition, hydraulic desilting has proven to be the most effective and economical method. Shihmen Reservoir is the main water conservation facility in northern Taiwan and the catchment area is 763.4 km². After 60 years of operation, the storage volume reduced from 3.09×10⁸ m³ to 2.09×10⁸ m³ because of sever siltation. To solve the problem, Water Resources Agency (WRA) decided to construct a desilting tunnel which is bypass Shihmen dam in 2017. The tunnel is completed in February 2023 and operated while typhoon Haikui attacking Taiwan. About 2×10⁵ m³ silt was discharged by this event and it consider a great success to achieve the objective for the project.

Keywords: Shihmen Reservoir, Sediment, Desilting tunnel

1 INTRODUCTION

1.1 Project background

Shihmen Reservoir is the main water conservation facility in northern part of Taiwan with the function of irrigation, electric power generation, water supply, flood prevention and tourism. Shihmen dam impounds the water from Dahan River with the watershed area of 763.4 km² (Figure 1). Due to the extreme hydrological events happened frequently, large amount of sediment is flushed into the reservoir. According to the annual sedimentation survey, the average of 3.42×10⁶ m³ silt move into the reservoir every year. The

Figure 1. Location and watershed area of Shihmen Reservoir.

capacity of the water conservation decreases from 3.09×10⁸ m³ to 2.05×10⁸ m³(in 2023),which means only 66% of its original storage volume is remained.

Considering the strategies used to reduce sediment delivery or prevent sediment deposition, hydraulic desilting has been proven to be the most effective and economical method. Therefore, Water Resources Agency (WRA) planned to build a desilting tunnel for the Shihmen Reservoir. The basic design has been completed in 2017 and D&B contract is started in November 2017 with USD \$120 million of contract price. The construction has completed in February 2023.

1.2 Objectives

Two major objectives arise from the desilting tunnel. (1)To enhance the desilting capability and decrease sediment of the reservoir; (2)To enhance the flood-discharging capability to ensure the safety while extreme hydrological events happened.

The desilting tunnel, which is a bypass tunnel of the reservoir, is expected to discharge 6.4×10⁵ m³ silt per year. Furthermore, the desilting tunnel is designed to provide another 600 m³/s flood-discharging capability for Shihmen reservoir as well. The comparisons of sediment discharge and flood prevention capacity before and after the desilting tunnel is completed shown as Table 1.

*Corresponding author: fcjooyclin@mail.sinotech.com.tw

Table 1. Capacities with/without the desilting tunnel.

Item	Without desilting tunnel	With desilting tunnel
Sediment discharge capacity [10 ³ m ³ /yr]	2,070	2,710
Flood prevention capacity [m ³ /s]	14,100	14,700

2 STRATEGIES AGAINST SEDIMENTATION

In general, three different strategies are considered for reservoir sediment management: (1) Reduce sediment delivery (watershed management); (2) Prevent sediment deposition (route sediments through or around storage); (3) Increase or recover volume (removal of deposited sediments)

Figure 2 shows a variety of sediment management techniques proposed by Kondolf et al. (2014) including the three strategies. A combination of several measures from these categories is necessary to maintain reservoir capacity and achieve reservoir sustainability. In overall, hydraulic desilting is the most effective and economical method to release sediment out of reservoir.

To solve the problem of severe siltation at Shihmen Reservoir, WRA proposed an integrated desilting strategies as shown in Figure 3. By the combination of mechanical removal, dredging, and hydraulic discharge, the sediment discharge amount is up to 2.07×10^6 m³/yr.

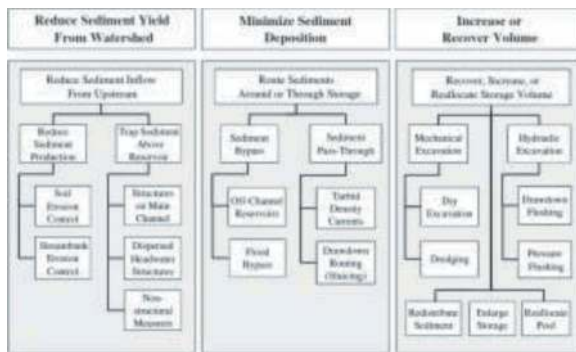

Figure 2. Diagram of sediment management options for reservoir sustainability (Kondolf et al.2014).

It should be especially noted for the hydraulic desilting passway, which is reconstructed from existing penstock in 2012 and works as a bottom outlet for the dam with a discharge capacity of 300 m³/s, has been desilt 3.1 million m³ of sediment during the typhoon period in 2013-2016. After the installation of this hydraulic desilting passway, the ratio of desilting during a typhoon event could reaches to about 30% in average in Shihmen Reservoir (Table 2).

After Amuping desilting tunnel and Dawanping sluicing tunnel are completed, the average of total sediment discharge amount will raise to 3.42×10^6 m³ and equal to the annual income.

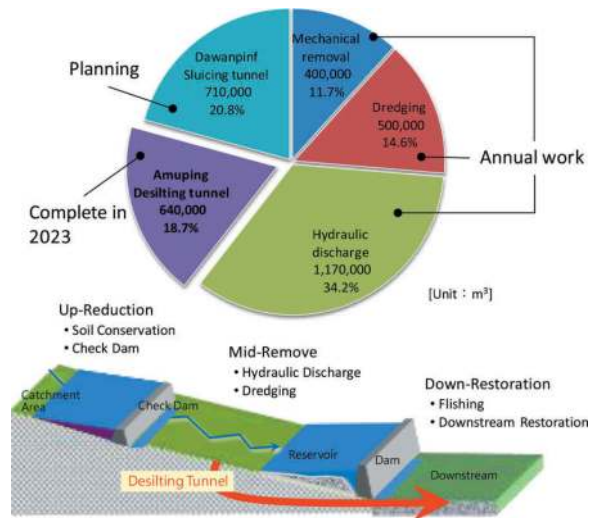

Figure 3. Integrated desilting strategies for Shihmen Reservoir.

Table 2. Comparison before and after the hydraulic desilting passway completed.

	Year	Typhoon	Ratio of desilting
Without desilting passway	2008	Fung-wong	12.9%
		Sinlaku	26.5%
		Jangmei	17.9%
	2009	Morakot	14.3%
	2010	Fanapi	3.0%
With desilting passway	2011	Saola	15.0%
		2013	Soulik
	2015	Trami	37.2%
		Soudelor	36.7%
	2016	Djuan	37.4%
		Megi	21.1%

3 DESIGN CONCEPTS OF DESILTING TUNNEL

3.1 Layout of desilting tunnel

According to annual silt survey started from 1963, the shihmen reservoir has been silted by several typhoon events (Figure 4). Therefore, to solve the problem of sedimentation at midstream and upstream as well, the intake of desilting tunnel are arranged at Amuping area where is midstream of the reservoir and 7 km far from the dam.

The desilting tunnel consists of intake structure, adit, desilting tunnel, sifting facilities, outlet structure, and deposition pool. The general layout is shown in Figure 5. The intake structure is 80 m long and situated at Amuping area. The length of the desilting tunnel is about 3,702 m with a varied slope from 10% to 2.863%. The typical cross section of the desilting tunnel is overturn-D type with 8 m in width and 7 m in height as Figure 6. Some information and scales about the tunnel are listed in Table 3. A 306 m long adit is connected to desilting tunnel at

Figure 4. Profile of annual silt survey with tunnel intake location.

millage of 0k+309 serves as the access route during construction period and also works as the maintenance route after completion. The cross section of the adit is as same as main tunnel.

Figure 5. General layout of dedilting tunnel at shihmen reservoir.

In addition, some criteria need to be followed while designing. (1) The design flood-discharging capability for tunnel is $600 \text{ m}^3/\text{s}$ and the maximum discharge is $700 \text{ m}^3/\text{s}$.

(2) Ensure the required freeboard in the tunnel and the safety of operation while desilting operate (The freeboard remains 25% with $600 \text{ m}^3/\text{s}$ and 15% with $700 \text{ m}^3/\text{s}$). (3) To avoid the flow chock happening, the shape of intake is designed as streamline shape. The width at the entrance of tunnel is 14.2 m. The designed plan of intake structure is shown in Figure 7. (4) The design storage of deposition pool is $2 \times 10^5 \text{ m}^3$

For tunneling, the process of excavation is by drill and blasting which is based on NATM(New Austrian Tunneling Method) method. Measuring is the first step and then drill and buried the bomb, blasting and remove the rock, then use the support material such as Lattice Girder, shotcrete and rock bolt to stabilize the cutting face. Repeat the cycle until the tunnel go

Figure 6. Typical cross section of the desilting tunnel.

through and then construct the concrete lining. The process of excavation shown in Figure 8. Considering the flow velocity is up to 20m/s in tunnel, the invert is design as flat and increase thickness and strength of concrete lining.

Figure 7. Plan view of intake structure.

For control and operation needed, there are three tainter gates designed in front of intake structure with $W \times H = 6.5\text{m} \times 5.3\text{m}$. The gates are closed in normal time to against reservoir water and are opened simultaneously while discharge. Also three tainter gates are arranged in the end of deposition pool with $W \times H = 18.0\text{m} \times 11.3\text{m}$ and might be the widest tainter gate in Taiwan. The gates are also closed in normal period to contain the silt and opened before desilting process.

Table 3. Information and scales of desilting tunnel.

Figure 8. Process of excavation by NATM.

3.2 Multifunction of desilting tunnel

The desilting tunnel works as a transportation channel in which four steel pipes are installed and the sediment dredged by the upstream dredging boats is transported via the pipes at usual time. Then the sediment will be screened by sifting facilities at the exit of the tunnel and be separated into coarse sand, fine sand and silt respectively. The percentage of coarse sand and fine sand is expected over 50%.

The coarse sand and fine sand are valuable and can be used as the mixing materials for concrete. On the other hand, the rest of silt will be stored in the deposition pool and be discharged to the downstream during typhoon or heavy rainfall period.

Furthermore, the desilting tunnel can be used as an access road which provides the trucks pass by during drought period. The mechanical machines can dig directly on the river bed at intake area. The multifunction of the desilting tunnel is shown in Figure 9.

3.3 Reused by sifting facilities

According to the efficiency concern, three vibrating screen, three sand washers and three sand separators are designed to install, along with the area about 6,000 m² including the storage area. The sediment is separated by the facilities and can be divided into 4 parts:

- Gravel or wood, which retained above No.4 (4.76 mm) sieve.
- Coarse sand, which passing the No.4 and retained on the No.18 (1.00mm) sieve.
- Fine sand, which passing the No.18 and retained on the No.200 (0.074mm) sieve.
- Silt, which passing the No.200 sieve and store in the deposition pool.

The process and layout of the sifting facilities are shown as Figure 10. The vibratory screen with No.4 sieve screened out gravel and wood first. The rest is transported to sand washers and sand separators, then be separated into coarse sand and fine sand. The coarse and fine sand can be sold and

reused as construction or concrete material. The by the shifting facilities, we can enhance the amount of desilting and solve the problem of silt elimination as well.

Figure 9. Multifunction of the desilting tunnel.

Figure 10. The arrangement of sifting facilities.

4 PLANNING OF OPERATION

In 2012, WRA reconstructed the penstock of the existing power plant as a hydraulic desilting passway for Shihmen Reservoir and operate during typhoon period. After the desilting tunnel is completed in 2023, this tunnel will be the first priority to drain with 600 m³/s and flush the siltation in deposition pool during the typhoon period. As the inflow increasing, the spillway and drainage tunnel will be operated to the purpose of flood-discharge. The desilting penstock will be operated then and discharge high density currents with 300 m³/s at the bottom of the reservoir. The flood-discharge and desilting plan is shown as Figure 11. In addition, to ensure the water-supplying, Zhongzhuang Reservoir, which is located downstream of Shihment dam and was completed in 2017, can provide 6 days of water for New Taipei City while desilting tunnel operating.

For the operation of intake tainer gates, the opening will be limited and contolled base on the designe flood-discharging capability(600cms).

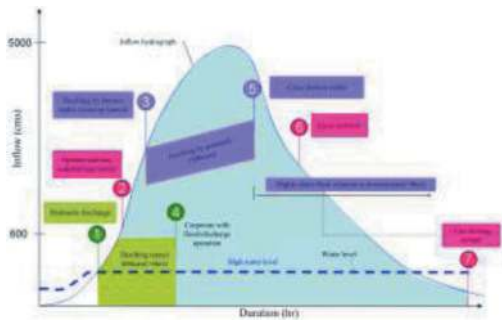

Figure 11. Operation planning of the desilting tunnel.

Figure 12. The operation for the intake tainter gate.

(1) Intake structure and cofferdam (2022.6)

(2) Concrete lining for the desilting tunnel (2021.6)

(3) Outlet and deposition pool structure

Figure 13. Photos for the construction period.

According to the analysis, the gates can be full open with discharge amount reaches 600cms while the storage elevation of 242.0m for Shihmen reservoir. Then the gates should be closing down with the storage level is raising up, for this operation is totally contrary to normally concepts. The operation for the intake tainter gates is shown in Figure 12.

5 CONCLUSION

Extreme hydrology events have occurred frequently, large amount of sediment is flushed into the Shihmen Reservoir. The capacity of the water conservation decreases from $3.09 \times 10^8 \text{ m}^3$ to $2.09 \times 10^8 \text{ m}^3$ (in 2023) in the past 60 years, which is 66% of its designed storage volume. It is predicted that heavy rainfall and landslide may cause reservoir to lose capacity more severely and may even cut-off water supply.

In order to sustain the life and ensure the safety of Shihmen Reservoir, WRA has completed many measures such as soil erosion control of the upstream areas, digging, dredging, flushing and sluicing. Considering all of the remediation measures, hydraulic desilting proves to be the most economical and rapid method.

Taking effectiveness and economical efficiency into account, a desilting tunnel is planned to construct and is expected to enhance the desilting and flood-discharging capability. The purpose is to deal with $6.4 \times 10^5 \text{ m}^3$ silt per year and provide $600 \text{ m}^3/\text{s}$ flood-discharging capability. After 5 years of construction (some photos are taken while construction period shown in Figure 13), the tunnel was completed in February 2023 and looking forward to operate in the future.

ABSTRACT: Old Wu-shan-ling divert water tunnel is located on the right bank of Zengwen river in Tainan city. The divert water tunnel is an important hydraulic facility connected the Tsengwen river to Guantian river for the water resources of Wushantou reservoir and Chianan irrigation system. It is operated more than 80 years. For the aging lining problem of this old tunnel and long-term consideration for stable water supply, it is necessary to build up a new Wu-shan-ling tunnel. The new Wu-shan-ling tunnel is 3,422m in length. The cross section of the tunnel is 5.4m in width. The geology of the tunnel is the alluvium, Yenshuikeng Shale, Tangenshan Sandstone and several fault zones. It is reported that there were several hazards including gas explosions, leaks, and water inrush disasters during construction period of the old tunnel. Therefore, this project was at the risk of gas burst during the construction. Through the advanced countermeasure for encountering heavy gas influx, the new tunnel was completed and is operated. There was no casualties or incidents due to gas influx during construction time. This paper will take this tunnel as an example to illustrate the advanced countermeasure including risk assessment of encountering gas, gas investigation, gas concentration management threshold value and precautions and strategies against gas hazard.

Keywords: Divert water tunnel, Gas influx, Strategies against gas hazard

1 INTRODUCTION

The new Wu-shan-ling divert water tunnel is approximately 3,422 m long and 5.4 m width with the horseshoe shape profile, which is designed to hold the flow rate of 56 m³/s. As shown in Figure 1, through the new intake and divert water tunnel, the tunnel starts from the east weir construction in the Tsengwen River, where is around 80 m to the downstream side of the existing Wu-shan-ling divert water tunnel east intake weir to the west output located in the upstream side of the Wushantou Reservoir, Jiangziliao nearby, which is about 150 m to the southwest of the existing Wu-shan-ling divert water tunnel exit.

Figure 1. Site location of this project.

2 TOPOGRAPHY AND GEOLOGY

The strike of the mountain range and the drainage pattern in the district is mainly along the southwest

direction. Connecting the watershed of the Tsengwen River on the east to the watershed of the Wushantou Reservoir on the west, the planned tunnel was bored through the branch in the south of the Alishan

*Corresponding author: kschou@ceci.com.tw

mountain range. The level of the district is between 400 to 700 m with the Western stratigraphic region on the east and the hill zone on the west.

Strikes of strata in the concerned area are also primarily along the southwest direction. From the east to the west end of the tunnel, strata are recent Alluvium, Yenshuikeng Shale, Tangenshan sandstone, Liuchunghsi Formation and Kanhsialiao Formation (Figure 2). Among these strata, except for the Tangenshan sandstone is composed of thick dense sandstone, others mainly consist of shale or mudstone.

Figure 2. Project geological profile.

3 RISK ASSESSMENT OF ENCOUNTERING TOXIC/ INFLAMMABLE GAS IN THE TUNNEL

The survey record indicated that encountered strata may contain explosive gas and it is very likely to be exposed in the toxic gas while tunnelling. Figure 3 demonstrates the assessment on the risk of encountering the toxic gas along the tunnel, which is approached by considering the explode history record of the excavation in the stratum, the type of the tectonics activity and drilling reports in the design stage. It can be found that there is risk to be endangered by the gas all along the underground alignment, the section 1k+170~1k+260 and 1k+870~2k+350 are even in the high risk region.

Figure 3. Risk assessment of the special geological condition may encounter.

4 GAS INVESTIGATION

In order to investigate high gas leak potential strata, including Liuchunghsi Formation anticline, Lunhou fault zone and Tangenshan sandstone, sets of the in-situ test in the borehole and lab test were conducted to evaluate the methane concentration and the

potential leak gas amount. The test includes resistivity logging measurement, borehole imaging, mud logging and measurement while drilling (MWD) technique. With the result of recording the level of gas brought up in the mud and the composition analysis in the laboratory, the relationship between potential concentration of leak gas, amount, strata attitude and fracture features can be established and the geological model and the feature of potential gas leak strata can be evaluated. The photograph of in-situ tests is shown in Figure 4. Figure 5 is the demonstration of the possible methane concentration evaluation during the excavation of east tunnel section in Tangenshan sandstone.

Figure 4. Photographs of the resistivity logging measurement, borehole imaging.

5 PRECAUTIONS AND STRATEGIES AGAINST TOXIC GAS HAZARD

According to the construction experience of the existing Wu-shan-ling divert water tunnel in 1920s and the investigation outcome in each stages, it can be foreseen that during the excavation of the tunnel, the hazard of inflammable gas might be quite high. Therefore, it is necessary to devise precautions and strategies against toxic gas hazard in the design stage. Based on measures against the inflammable gas in the past, primary principles can be summarized as: (1) Enhance the ventilation, (2) Monitor diligently, (3) Shorten the round length, (4) Decrease the explosion/vibration, (5) Strengthen the support and (6) Protect immediately. Once the above measures cannot reduce the inflammable gas concentration, auxiliary methods must be applied to prevent from the enlargement of dangers. Besides the aforementioned principles, implementation of the safety regulations and equipment, the control of fire and escape plan while encountering the inflammable gas are even vital to ensure the security of property and life safety. Figure 6 illustrates the primary principles against inflammable gas.

Figure 5. Evaluation of possible methane concentration during the excavation of east section tunnel in Tangenshan sandstone.

Figure 7. Location of the automatic gas detector.

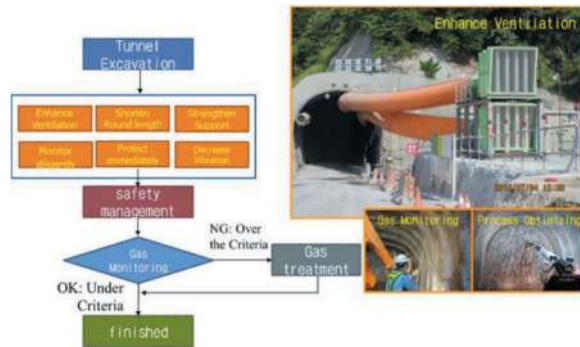

Figure 6. Principle against inflammable gas.

Figure 8. Site photographs: (a) fixed gas detector, (b) portable gas detector and (c) gas measurement.

- (1) Enhance The Ventilation: Based on the relative experience, enhancing the ventilation is the most effective way to remove the toxic gas. Sufficient air amount and velocity can dilute the inflammable gas into the safe range and remove it, which ensures the workplace safety and property security. The new Wu-shan-ling divert water tunnel is approximately 3,422 m long with the workface in two ends, therefore the maximum construction length of each end has to be less than 2,000 m. The independent ventilation system is installed for each side with the control system and ventilation ducting to send in the fresh air and remove the dust and polluted air.
- (2) Monitor diligently: Fixed gas detectors (Figure 7) are installed in every 250 m along the tunnel with all cables connected to the automatic record monitor and warning system outside the tunnel. The automatic warning system sends the alarm and light, once the detected gas concentration reaches the toxic gas concentration warning threshold value (5,000 ppm, 0.5% or LEL=10%). Furthermore, the toxic gas detection should be implemented with the portable gas detector with particular emphasis on workfaces, safety shoulders, U-turn lane and locations where the toxic gas might accumulate when drilling the blasthole and before and after the blast. Figure 7 shows the photograph of fixed, portable gas detector and the measurement. The record of the toxic gas measurement is displayed in Figure 8.

- (3) Shorten the round length: Based on the estimated amount of the inflammable gas leak, the length of the daily excavation round is found to possess a positive correlation to the leak amount. Therefore, it is suggested to keep the round length less than 1 m whenever the excavation may encounter with the toxic gas in the front (gas concentration less than 2,500 ppm, 0.25% or LEL=5%) and decrease the volume of excavation mass and the gas leak with the immediate installation of the support after the excavation according to the experience and geological condition in the site.
- (4) Decrease the explosion/vibration: For the concern of safety, it is necessary to install precisely the required blasthole length, distance and apply the design amount of explosives as the construction plan.
- (5) Strengthen the support: The amount of the inflammable gas soars as the result of the increase in the porosity of the surrounding rock plastic zone after the excavation of tunnels. By means of reinforcing the support for suppressing the large tunnel deformation, the surrounding rock plastic zone and the amount of inflammable gas leak can be reduced. Therefore, installing the forepoling or the pipe roof depending on the rock condition to stabilize the excavation face and reduce the excessive tunnel deformation can be feasible in the high inflammable gas hazard section.
- (6) Protect immediately: Spraying the shotcrete right after the excavation of each advancement step to seal the surrounding uncover rock not only prevent the rock from falling, weathering and deformation but block the path of gas leak. In addition, reducing the usage of rock bolts in

common sections except for the portal, over-excavated section and the geological fracture zone with ensuring the security and functionality of the tunnel can efficiently block the path for inflammable gas intrusion.

- (7) Auxiliary methods: If the toxic gas amount keeps exceeding the safe range, auxiliary methods such as the air-tight shotcrete, auxiliary blowing machine, compensation grouting and spray type air-tight layer can be conducted to restrain the toxic gas leak. To reduce the risk of encountering the inflammable gas leak, the air shaft can be set in the high gas leak potential section.

6 INFLAMMABLE GAS TUNNEL SAFETY MANAGEMENT

The inflammable gas tunnel safety management includes the management of fire, personnel, gas concentration detection and emergency plan, which is designed to secure the operator with periodical monitoring the operation environment and taking counter-measures and procedures according to the measured gas concentration. Table 1 demonstrates the regulation of personnel safety management. The

frequency and location of the gas measurement are shown in Figure 9.

Figure 9. Frequency and location of the gas measurement.

Auxiliary methods that can be applied in the situation, which the indistinct decrease of the inflammable gas concentration after the additional ventilation, are introduced as follow. For the gas constantly leak from the workface, the compensation grouting should be considered if necessary. If the measured gas concentration exceeds the range, the source, path and the reason of the inflammable gas should be found out through additional measurements. For the case of the gas accumulation due to the limitation of the space, the auxiliary blow machine can be installed. Preventive air-tight methods such as the air-tight shotcrete, compensation grouting in excavated sections and spray type air-tight

Figure 13. Completed photos.

layer can be conducted for the case of inflammable gas leaks from the excavated sections. The contractors should decide the feasible method and apply it after the agreement from the responsible entities in accordance with the site condition. Table 2 lists the gas concentration management threshold value and its actions. The illustration of the air shaft used in this project is shown in Figure 10. Figure 11 is the record of the gas concentration measurement during the each advancement step.

7 CONCLUSIONS

Construction had encountered the gas leak multiple times, some of which even reached the warning and action threshold value. With the prudence and conscientiousness of all crews, the tunnel construction was completed in 23 May 2018. The photograph of the completion ceremony is shown in Figure 12. The completion date is 2020/6/20 and the completed photos are shown in Figure 13. The construction safety can be severely affected if the rock porosity increases due to the tunnel excavation disturbance and the massive toxic gas leaks with high concentration to reach the range of explosion. With the thorough ventilation, fire and personnel management and

fixed/portable gas detector, the new Wu-shan-ling divert water tunnel construction effectively reduced the risk of the toxic gas blow up.

ABSTRACT: The “Américo Vespucio Oriente” Concession (AVO 1) is part of ambitious program, promoted by the Chilean Ministry of Public Works, to close this Ring Road to highway standard in Santiago de Chile. The project integrates this 8,278 m highway with three lanes in each direction, of which 7,678 m are underground, in a dense urban area of the city.

The underground works combines 3 main construction methods: SEM and NATM tunnel: La Pirámide and Mapocho Branch (2,100 + 415 m). Cut & Cover tunnel: 2,891 m in a pile trench with two subway platform levels. “Hybrid” tunnel: 2,687 m between Apoquindo and Tobalaba.

The construction works began in November 2017 and its completion was done in July 2022, with a final budget of 900 MUSD. Based on the set of conditioning factors, a highly innovative hybrid tunnel section solution was designed to fit the tunnel layout under an existing boulevard, as well as each of the seven existing connections with exit/enter branches.

The hybrid tunnel enables two roads overlapped with three lanes each. Level -1 platform is resolved by means of a NATM tunnel, while Level -2 has been constructed as a conventional trench-type structure using 1.00x1.00 m handmade piles with different spacings and a minimum embedment of 3.5 m, which are braced at their head by a post-tensioned slab between both levels. The gap between piles is reinforced by means of a lining wall. The hybrid tunnel has crossed below two existing underground parkings as well as under metro line 1. For that purpose, an improvement using jet-grouting from the deepest parking level was done. The paper describes the main design facts as well as the experiences during its construction.

Keywords: Urban tunnel, Soil tunnel, Innovation, Large tunnel

1 INTRODUCTION

The “Américo Vespucio Oriente Concession, Section Av. El Salto-Príncipe de Gales”, known with the acronym AVO 1, is part of the ambitious public-private partnership program promoted by the Chilean Government, through its Ministry of Public Works, to close the Américo Vespucio Ring Road, surrounding the city of Santiago with a highway standard. Figure 1 shows a general plan of the AVO 1 project.

The project addresses the challenge of integrating in an urban dense area a subway highway with three lanes in each direction over a length of 8,278 m, of

which 7,678 m run through tunnels. Considering the construction method used the following three sections can be distinguished:

- Conventional NATM & SEM tunnel: 2,100 m under San Cristóbal hill, known as La Pirámide Tunnel, that includes 415 m of Mapocho Branch Tunnel. These are two conventional tunnels of 3 and 2 lanes in the branch, with a bifurcation cavern. The La Pirámide tunnels also crosses under the Mapocho River and it has its exit afterwards, in the area known as “Punto Limpio” in Vitacura. Before, just besides the river’s defense walls, there is a ventilation shaft (ϕ15 m and 32.5 m depth).

*Corresponding author: jmgalera@systra.com

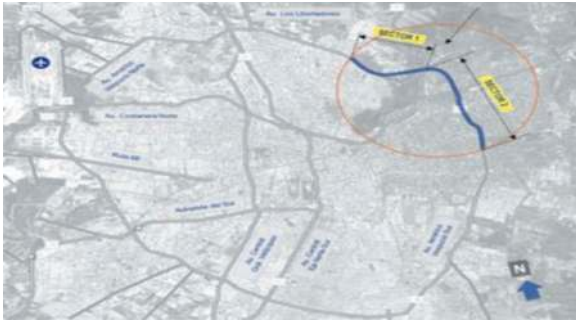

Figure 1. Location and general layout of AVO1 concession in Santiago de Chile.

- Cut & Cover tunnel: 2,891 m of cut & cover tunnel in a pile trench with two subway platform levels located along the pre-existing central boulevard park of Americo Vespuccio Avenue. In this section there are seven inbound and outbound branches. At the main one, located in the junction with Kennedy Avenue, there are five mined branches that were constructed using NATM method (Branches 1C, 5, 5A, A and A1).
- "Hybrid" tunnel: 2,687 m of the Hybrid Tunnel, configured in an innovative solution also under the central boulevard park of the avenue, in which the level -1 of the tunnel (North traffic direction) has been constructed using NATM & SEM method, while the level -2 below, has been excavated using a pile diaphragm wall. In this section there are two exit branches and five entrance branches, built using NATM method.

Figure 2 shows a detailed scheme of these three construction typologies used for the construction of AVO1.

The construction works began in November 2017 and its completion was done in July 2022, with a final budget of 900 MUSD.

Figure 2. Construction typologies used for the constructions of AVO1.

2 DESCRIPTION OF THE HYBRID TUNNEL

The Cut & Cover section, under the central boulevard park of Americo Vespuccio Avenue, should have cross under two underground existing parkings as well as under the Santiago Metro Line 1 located between

these two parkings, at Apoquindo Avenue. This stretch approximately 400 m length was initially designed using a mined German construction method, but after having initiated the construction works, it was decided to continue using mined methods till the end of the concession towards the South.

Based on the existing conditioning factors, a highly innovative hybrid tunnel section solution was designed to fit the tunnel layout under the existing boulevard, including the junctions with seven exit/enter branches.

The hybrid tunnel enables two roads overlapped of three traffic lanes each. The Level -1 platform, that houses northbound traffic, is resolved by means of a NATM/SEM tunnel, while Level -2, that houses southbound traffic, has been constructed as a conventional trench-type structure using 1.00x1.00 m handmade piles with different spacings and a minimum embedment of 3.5 m, which are braced at their head by a post-tensioned slab between both levels. The gap between piles is reinforced by means of a lining wall. As it has been described previously, the hybrid tunnel crosses under two underground parkings as well as under metro line 1. In this area a ground improvement using jet-grouting from the deepest parking level, was done.

Figure 3 shows the hybrid tunnel concept, while Figure 4 shows its dimensions. At it can be appreciated the tunnel is 13.20 m of inner width and 5.0 m clearance, at both traffic level. In the junction sections the inner width, at Level -1, has reached 22.6 m.

3 GEOLOGY, HYDROGEOLOGY AND GEOTECHNICS

Santiago de Chile is located on a plain area known as the "Santiago basin" belonging to the Chilean Intermediate Depression. This depression is limited to the N by the Chacabuco Mountain Range, the Andes to the East, the Paine narrows to the South and the Coastal Mountain Range towards the West. Within the basin there are several pre-Andean reliefs, including the Cerro San Cristóbal Hill, where the La Pirámide Tunnel is located, in which the rock substratum outcrops.

Figure 3. The "hybrid" tunnel concept.

Figure 4. Cross section of the hybrid tunnel.

These reliefs are constituted by stratified volcanic and continental rocks from the Abanico Formation (Upper Cretaceous to Oligocene) as well as intrusive rocks from the Miocene.

The Santiago basin is filled with recent alluvial materials known as the Maipo system, in the South city, and the Mapocho system, towards the North.

Figure 5. Contact between the 2nd deposit and the 1st deposit units of the Mapocho River alluvial gravels.

The Cut & Cover and “Hybrid” Tunnel sections are located in the Mapocho River Gravel Unit. This unit has traditionally been divided into two formations: the “2nd deposit”, the most recent one, and the “1st deposit”, the oldest and therefore deepest unit. In the Figure 5 the contact between both units is shown at the tunnel excavation face.

While the Level -1 of the tunnel has been entirely excavated in the more recent and shallower “2nd deposit” gravels, the excavation of the Level -2 was done partially also in the lower “1st deposit” gravels. In the exit/entrance branches also some anthropic fills were encountered.

From the hydrogeological point of view the “Hybrid” tunnel is located in the Aquifer Unit UH2 (Mapocho Alto Upper System) that is a free surface aquifer, that includes both stratigraphical units, and that in this area has a thickness ranging 20 and 40 m, with a permeability is on the order of $1E-5$ m/s. The water table is located just below the tunnel lower slab.

Figure 6 shows a geological longitudinal cross section of the tunnel, in which the “2nd deposit” has been represented in light green, while the “1st deposit” is shown in dark green.

From the geotechnical point of view, the main difference between both stratigraphical levels is the greater plasticity of the final fraction in the case of the “1st deposit”, which is older one.

Table 1 shows the main geotechnical data of all the units involved in the tunnel construction.

Chile is one of the countries with the highest seismicity due to its geotectonic context in a subduction zone. For the quantification of seismic actions, standards NCh 433-Of-96 and NCh 2475 have been considered, as well as the Highway Manual, Volume 3 (Directorate of Roads, Ministry of Public Works).

The Maximum Ground Acceleration obtained is $A_0 = 0.3$ g. and a Seismic Design Deangulation has been considered for the underground works of $\theta_s = 3.5 \times 10^{-4}$ for the cut & cover and hybrid section.

4 CONSTRUCTION METHOD

The “hybrid” tunnel combines two different construction methods at each construction section.

Figure 6. Geological cross section of the hybrid tunnel (“2nd deposit” in light green and “1st deposit” in dark green).

Table 1. Geotechnical parameters of the ground.

Unit	Stress Ratio K_0	Density kN/m^3	Def. Modulus MPa	Cohesion kPa	Friction Angle $^\circ$
Anthropic Fills	0,5	17,0	20	10	33
2 ^a Deposit	0,65	22,5	100 ($Z \leq 5$ m)	25	45
1 ^a Deposit	0,65	22,5	42 x Z0.55 ($5 < Z < 17$ m) 55 x Z0.53 ($Z \geq 17$ m)	35	48

While the upper level, Level -1 platform, is excavated using NATM/SEM method, the lower level, Level -2, has been constructed as a conventional trench-type structure.

In the case of the Level -1, depending on the tunnel inner width, that has ranged between 13.2 and 22.6 m in one of the existing junctions, full face NATM method or SEM (two and three excavation phases) were used. In all the cases a systematic elephant foot was used.

For the Level -2, the trench-type section consists in the construction of 1.0x1.0 m handmade squared piles, spaced 5.0 m, with a minimum embedment of 3.5 m. These piles are braced at their head by a post-tensioned slab located between both levels. The gap between piles is reinforced by means of a final lining wall and a lower non-strut slab completes the section. Figure 7 illustrates the construction sequence.

Figure 7. Hybrid tunnel construction sequence.

The support and lining applied at Level -1 the following:

- a) Support (Primary lining), composed by:
 - 5 cm shotcrete SH-30 seal reinforced with 4-5 kg/m³ of synthetic macrostructural fibres
 - HEB-160 steel sets with elephant foot spaced one meter
 - 25 cm of 25 cm SH-30 shotcrete with the same number of fibres as before.

If those cases in which due to the width larger than 13.2 m, two or three excavation phases were used,

the temporary supports between excavation phases have been

- 20 cm of SH-30 shotcrete with the same amount of fibres
 - HEB-160 metal frames each meter
- b) H-30 concrete slab 80 cm thick
 - c) Lining (Final lining), composed by 30 cm of H-30 shotcrete reinforced with 1.5 kg/m³ of fire-resistant polypropylene fibres

The support and lining used for the Level 2, was the following:

- 1x1 m square piles embedded in the ground 3.5 m, spaced 5 m. The amount of steel reinforcement is 145 kg/m³
- The piles are capped at the head by the intermediate concrete slab
- The level -2 platform is configured with a rigid concrete pavement (H-30) with a thickness of 45 cm
- Lining wall between piles composed by wire mesh and 10 cm of H-30 shotcrete reinforced with 1.5 kg/m³ of fire-resistant polypropylene fibres

In the Figure 8 the constructive sequence of the hybrid tunnel is shown. It must be considered that do not correspond to the same given section, but they are really representative of each construction phase.

Figure 8. Typical constructive sequence of the hybrid tunnel section.

In the first image the excavation of the top-heading (Level -1) is shown. As it can be observed in this case three asymmetrical excavation phases can be observed, while the second image, show the demolition of two temporary support diaphragms using three symmetrical excavation phases. The third image shows several hand excavated piles close to the elephant foot at the floor of the Level -1, while in the fourth one, the construction of the intermediate slab is shown.

Finally, images fifth and sixth, show respectively the Level -1 once the final lining is completed and the

aspect of Level – 2, excavated between piles diaphragm walls and with the final lining wall between piles.

Due to the reduced height at both sides of the Level – 1 tunnel, one of the most peculiar aspects of these solution has been the necessity to used hand excavated piles with a squared shape of 1.0 m, as is illustrated in the Figure 9.

Figure 9. Aspect of a final hand excavated squared pile and a moment of its construction.

A real important aspect of the construction method has been the determination and definition of the safety distances between excavation phases, in those cases in which Level-1 has been constructed using more than one excavation phases.

Figure 10, taken for the stress-strain analysis of a given section, show the gap established between the three excavation phases, that was defined with a minimum distance of 15 m between them; and the minimum distance in which it was allowed to start the demolition of the temporary support diaphragms, established in 25 m.

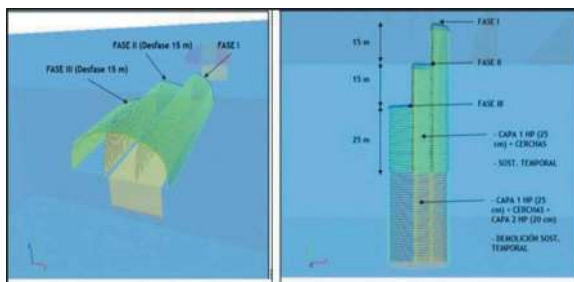

Figure 10. Minimum excavation gaps between excavation phases of Level 1 and the demolition of the temporary support diaphragm.

5 EXAMPLE OF THE DESIGN OF A SUPPORT AND LINING SECTION

The design of the Hybrid Tunnel has been carried out in accordance with Chilean regulations and using AASHTO for structural design.

Tridimensional numerical models have been developed for each section of the tunnel, simulating the different phases of excavation and support of the tunnel, the execution of the lining and the intermediate structural slab, for Level -1. Afterwards, the

execution of the piles, and the excavation of the Level -2, allowing the obtention of the following variables to be quantified:

- Induced settlements and deformations on the surface
- Requests induced in support and coating
- Stresses in the piles and dimensioning of the sections

The calculation tool used was FLAC 3D, while for the structural dimension of all the structures, FAGUS7, CEDRUS7 and our own software were used.

Following an example of the design process used for one of the complex sections is shown. In this case the Level -1 has four traffic lanes so the excavation width of the top heading is 20.4 m. Figure 11 shows, at the left image, the aspect of the model developed, while at the right image the stratigraphy in the transversal section is illustrated. As it can be seen at the surface there is a layer in red, 1.45 m thick, that corresponds to the anthropic fills, the 2nd deposit is represented in green, with a total thickness of 14.2 m, and finally, in blue this unit corresponds to the 1st deposit of the Mapocho alluvial gravels.

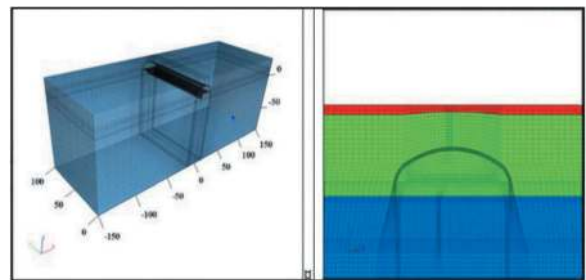

Figure 11. General aspect of the 3D numerical model, and distribution of the stratigraphical units.

Figure 12 shows the detail of the model in a transversal cross section, in which as can be observed, all the elements, except de shotcrete seal, have been considered:

- First shotcrete layer (SH-30) of 25 cm and HEB-160 steel arch spaced 1 m
- Second shotcrete layer (SH-30) of 20 cm
- Final lining of 30 cm of H-30
- Temporary support composed by 20 cm SH-30 and HEB-160 spaced 1 m
- Intermediate structural slab 80 cm thick of H-30

At the same manner, Figure 13 shows all the structural elements that have been included at Level -2. In particular:

- Piles 1x1 m spaced 5 m, with a total length of 8.6 m
- Lower slab composed by 45 cm of concrete H-30

Figure 12. Detail of all structural elements included in the 3D numerical model at Level 1.

Figure 13. Detail of all the structural elements included in the 3D numerical model at Level 2.

For this analyzed section, the following results for the ground were obtained:

- The maximum deformation at the section with a value of 94 mm in the final excavation phase
- The maximum semi-convergence at the top heading is 6 mm at the right tunnel wall (Level -1), which reaches a maximum of 10 mm between the piles of level -2
- The ground plasification can be considered to be moderate

For this analyzed section, the following results for the ground were obtained:

- The maximum deformation at the section with a value of 94 mm in the final excavation phase
- The maximum semi-convergence at the top heading is 6 mm at the right tunnel wall (Level -1), which reaches a maximum of 10 mm between the piles of level -2
- The ground plasification can be considered to be moderate
- The maximum subsidence at the surface is 80 mm

Figure 14 illustrate these four results.

Concerning the solicitations to the structural elements, the following result were obtained:

- The maximum compressions in the shotcrete are 9.4 MPa (FS>2.7)

- In the steel sets, the maximum axial force obtained is 59.7 t and the maximum bending moment is 0.8 t.m, both in the final phase.
- In temporary support, the maximum axial force is 44.1 t and the maximum bending moment is 1.92 t.m.
- The maximum stresses in the piles are 83.4 t and 81 t of bending moment and shear stress, respectively.

Figures 15, 16 and 17 shows graphically these results at the support elements.

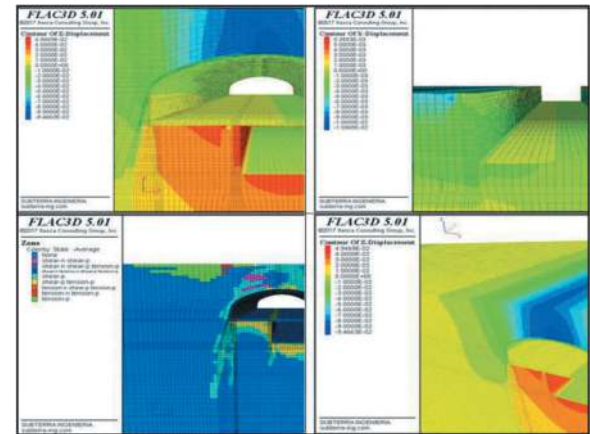

Figure 14. Results of the model including deformations (upper row) yielded elements and subsidence (lower row).

Figure 16. Bending moment at the HEB 160 steel arches.

Figure 17. Shear stresses at the piles.

6 THE UNDERPASS OF THE APOQUINDO NORTH PARKING

Following the underpass below the Nort Apoquindo car-parking is described, as the most challenge part of the project, just at the boundary between the Cut & Cover stretch and the starting of the “Hybrid” tunnel.

As can be seen at Figure 18, after the Cut & Cover, with no colour at the left, it was necessary to make a 22.6 m wide cavern at the level -1 to incorporate on of the entrance branches, coming from Los Militares Street (Los Militares N) at the surface. The normal 3-lane tunnel has been shadowed in a different brown colour.

Figure 18. Layout of the entrance branch Los Militares.

At the end of this 4-lane section, Figure 19 shows the bifurcation with the entrance branch of Los Militares N branch.while Figure 20 shows the bifurcation cavern.

Figure 19. Hybrid tunnel portal at the ending of the cut & cover tunnel.

Figure 20. Bifurcation cavern of Los Militares N entrance branch.

The minimum distance between the foundation of the Level -3 of the existing Nort Parking of Apoquindo and the vault of the tunnel is 3.5 m.

For this reason, a Jet-grouting treatment from level -3 of the parking was designed, while the excavation of the Level -1 of the hybrid tunnel was decided to do it using SEM (Sequential Excavation Method) with two lateral side-drifts and central gallery, with excavation round lengths of 1.0 and keeping a minimum distance between them of 10 m.

Figure 21 shows two sections, the first one right on the abscissa where both tunnels are individualized, while the second corresponds to the final cavern section, just before the mentioned bifurcation.

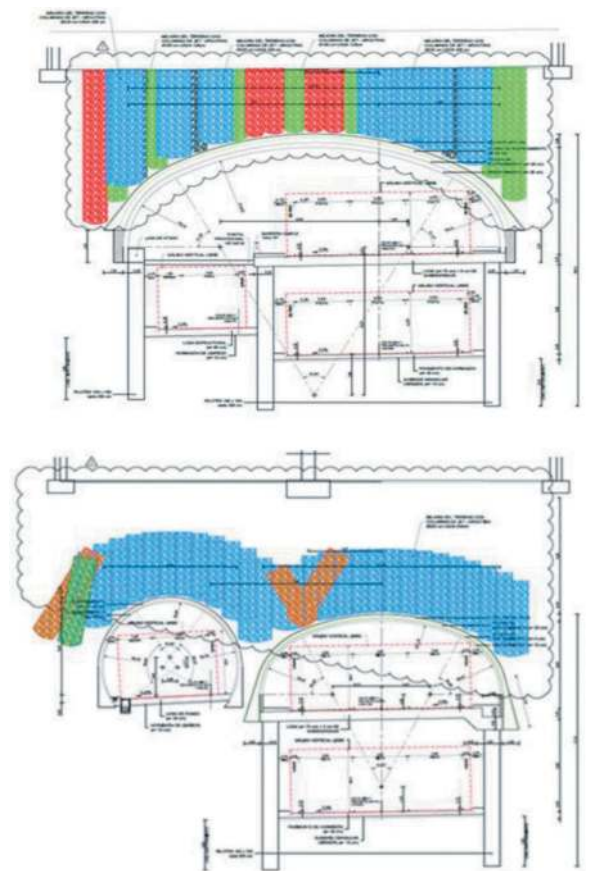

Figure 21. Cross section fo the bifurcation cavern Los Militares N, just under the north apoquindo parking.

This figure also shows the jet grouting carried out prior to the excavation of the tunnel from the deepest level of the existing parking.

During the existence of close structure located just above the tunnel (between 3.5 and 8.0 m) a strict control of deformations was done, including:

- in the tunnel (convergences and vault topographical levelling)
- in the parking, topographical levelling
- on the surface, topographical levelling

The maximum deformation induced in the North parking lot at its -3 level has not exceeded 27 mm.

Figure 22 shows the deformation measured at the abscissa Dm 5+725,4 (control line 16) and the abscissa Dm 5+696,9 (control line 22).

Figure 22. Deformation measure at the Level 3 of the north apoquindo parking.

Figure 22 corresponds to the date of the excavation of the top heading, 2 to the date of the finalization of the excavation, and 3 to the demotion of the temporary support diaphragms.

As it can be observed, the deformation was always moderate and without causing any damage to the existing parking.

7 CONCLUSIONS

The “Américo Vespucio Oriente” Concession (AVO 1) is an ambitious program to improve the mobility conditions in the city of Santiago de Chile, using the underground space and freeing up space on the urban surface for other uses, in a dense urban

area of the city. The construction works started in November 2017 and where finished in July 2022.

The project supposes 7,7 km of tunnel, but considering the length of the exit and entrance branches, the total tunnel length is almost 10 km. For its construction three different tunnel construction methods have been used, SEM and NATM, Cut & Cover, and what has been called the “Hybrid” tunnel.

The hybrid tunnel enables two roads overlapped with three lanes each. Level -1 platform is resolved by means of a NATM tunnel, while Level -2 has been constructed as a conventional trench-type structure.

This innovative construction method has made possible to preserve all the existing park located at the central boulevard of the avenue, decreasing the environmental impact of the project.

The effect of the movement joint on the seismic response of the cross-passage intersection in segmental tunnel lining

Gabriele Giordano*, Diego L'Amante & Giorgio Fantauzzi
SYSTRA France, Paris, France

ABSTRACT: Cross-passages intersections in segmental tunnel lining are critical components in underground tunnels that need a specific design, particularly when they are subjected to the earthquake effects. During seismic events, these intersections are subjected to significant dynamic loading, which can potentially lead to structural damage and compromise the overall integrity of the tunnel. This is particularly true for tunnels located in highly seismic zones., such as the Asian section of the Ring of Fire.

This paper presents the case of a specific structural movement joint between the cross-passage and the main tunnel collar designed to mitigate the seismic effects on the tunnel. The seismic joint allows relative displacement between the collar and the secondary lining of the cross passage. This significantly reduces the seismic induced stresses in the segmental lining in the proximity of the opening.

The movement joint is designed as a disconnection between the secondary lining of the cross-passage and the collar. The gap between these two structures is stuffed with rubber sheets, the waterproofing of the joint is assured by means of a steel-edged rubber waterproof strip. This paper presents the simplified 3D FEM analysis carried out, concerning this joint and the consequences in terms of the seismic induced stresses in the segmental lining at the proximity of the opening.

The use of such a movement joint can be seen as a valid mitigation measure, and it can significantly enhance the seismic resilience of the tunnel structure, improving safety and durability.

Keywords: TBM, Tunnel openings, Earthquake, 3DFEM Analysis

1 INTRODUCTION

The intersections of cross-passages and segmental tunnel linings are critical components in underground tunnels that need to be specifically designed to withstand seismic events. During earthquakes, these intersections are subjected to significant dynamic loading, which can cause structural damage and compromise the overall integrity of the tunnel. For such reason, the movement joint can be considered as a valid solution to allow displacements between the main tunnel collar and the cross-passage section by reducing the risk of significant cracking on the main tunnel segmental lining at the proximity of the opening during the seismic event.

The aim of this paper is to study the impact of the use of the movement joint on the internal forces of the segmental lining at the proximity of the cross-passage opening. A simplified FEM analysis is carried out in order to set out in a pragmatic way the use of such kind of joint between the collar and the cross-passage in a seismic analysis. Two different FEM models are built, and the results compared. One with a fixed connection between the collar and the cross-passage section and a second one with the movement joint.

2 STRUCTURAL DETAIL OF THE MOVEMENT JOINT

Unlike the main tunnel, the lining of the cross-passage is continuous, except that the secondary lining is disconnected from the main tunnel collar by a structural joint. Details are shown in the figure below.

In this case, the gap between the secondary lining and the portal is filled with nitrile cork rubber sheets, and it is barred by steel-edged rubber strip and waterproof strip. Moreover, the steel reinforcement of the connection portal is not connected with the secondary lining steel reinforcement of the cross-passage. The steel reinforcement of the connection collar is illustrated in the figure hereafter.

The movement joint represents a real structural disconnection between the connection collar and the cross-passage section. Therefore, in the FEM modelling, the movement joint works only in compression and not in traction. All FEM modelling hypothesis are introduced in the following paragraph.

*Corresponding author: ggiordano@systra.com

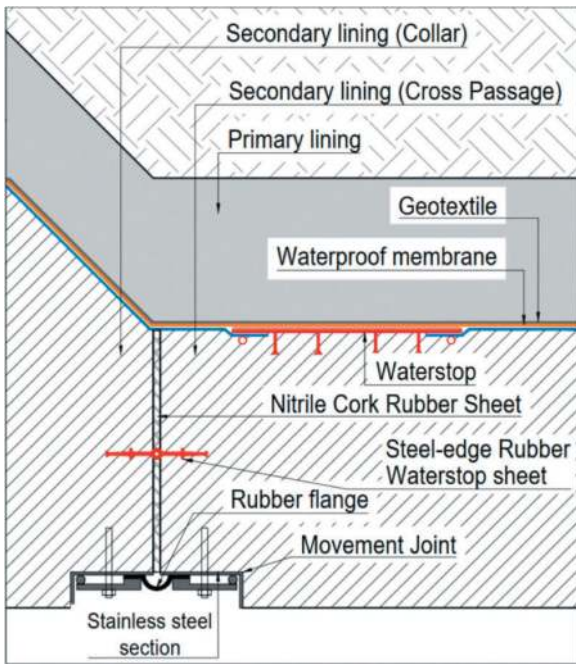

Figure 1. Movement joint details.

Figure 2. Example of a connection collar steel reinforcement with the movement joint at the intersection between the main tunnel and the cross passage.

3 FEM MODELLING

The structural analyses are calculated using SOFISTIK finite element structural code. The software fits all the engineering application fields, ranging from 2D Slab design to 3D building and bridge design and tunnel design. The software provides the possibility of design according to Eurocodes and many other design codes, plus interactive post-processing and 64-bit solver.

The 3D model used in this analysis is shown in the figure hereafter. Please note that the tunnel rings numbering scheme is depicted in the figure hereafter.

Figure 3. Sofistik model and tunnel rings numbering.

The actual cross-passage (CP) construction staging can be resumed as follow:

- Excavation and segmental lining installation of the two TBM tunnels.
- Ground improvements at the CP location.
- Installation of the steel frame in the TBM tunnel.
- Cutting and opening of the segmental lining.
- CP Excavation and temporary support installation.
- CP Final lining installation.

3.1 The main tunnel

The tunnel is modelled by a sequence of C40/50 reinforced concrete plate elements representing continuous rings 1.6m long. The ring thickness is 30cm equivalent to the segmental lining thickness. A total of 8 rings are used in the analysis.

The cutting line of the segmental lining corresponds to extrados of the cross-passage (about 3.4m wide and 4.3m high). In total, 4 rings of the main tunnel are affected by the cut. A focus on the opening is illustrated in the figure hereafter.

Figure 4. Cross-passage opening in the sofistik model.

3.1.1 Contact surface between rings and dowels

The concrete-concrete contact between the rings is modelled in the 3D FE model and will only transfer normal horizontal forces. Joints are modelled so that no tensile normal forces can be transferred (compression only).

The contact surface is considered on the whole contour of the ring with a thickness of 190 mm (the effective width of the joints).

Additionally, 18 dowels (3 per segment) are regularly spaced on the main tunnel contour.

The stiffness of a dowel is calculated from the elastic limit of the element, corresponding to 160 kN of shear force for a limit displacement of 30 mm, i.e.:

$$k = (160 \text{ kN}) / (30 \text{ mm}) = 5333 \text{ kN/m} \quad (1)$$

3.1.2 Main tunnel support stiffness

The soil-structure interaction is modelled by the use of springs. The used spring stiffness in the hyperstatic reaction method in Sofistik at the Main tunnel segmental is calculated by Galerkin's formula:

$$k_R = E/R(1 + \nu) \quad (2)$$

$$k_T = 1/3k_R \quad (3)$$

Where k_R is the radial stiffness (kPa/m), k_T is the tangent stiffness (kPa/m), R is the curvature radius of the tunnel (m), E is the ground Young modulus (kPa) and ν is the Ground Poisson ratio (-).

3.2 The main tunnel collar

The cast in place connection beam is modelled by beam elements. Moreover, in a simplifying and conservative way from the structural point of view the upper beam is modelled as a straight plate with a width of 1.2m instead of a U-shape geometry. The collar is fixed to the main tunnel segmental lining. Please refer to the Figure 2 and the figure hereafter.

Figure 5. The collar in the sofistik model.

The collar support stiffness representing the contact with the surrounding ground is modelled as for the main tunnel by the use of springs. In this case the stiffness of the springs is calculated according to Vesic 1961.

3.2.1 Movement joint

As introduced in paragraph §2, the movement joint is modelled by the use of springs at the surface contact of the collar with the cross-passage. These springs can only work under compression loads and don't react to traction forces. The spring working law aim is to represent the effect of the structural disconnection between the main tunnel collar and the cross-passage. This aspect is clearly illustrated in Figure 2 in which a steel reinforcement of the collar is totally disconnected from the cross-passage one.

3.2.2 Fixed joint

The fixed joint is also modelled by the use of springs at the surface contact of the collar with the cross-passage. In this case springs can work both in compression and traction. This working law represents a "classic" junction solution between the collar and the cross-passage section in which the steel reinforcement can be considered as continuous between these two elements. A typical case of fixed joint is illustrated in the figure hereafter.

Figure 6. Example of fixed joint between the collar and the Cross Passage Section.

3.3 The metallic temporary structure

The metallic temporary structure used in the model is shown in Figure 3. This structure is composed by two horizontal beams with a square hollow section 400x400mm and two vertical columns which have the same shape but a reduced section i.e. 200x200mm. This structure plays a key role during the phase of the main tunnel opening. Its main role is to support the stresses of the main tunnel segments interested by the opening during the temporary phase of the opening, before the concrete collar is constructed and acquire its full strength. The Sofistik modelling allows to design this structure and to optimize its position.

3.4 The model loads

The tunnel loading is modelled in Sofistik by a combination of static loads described hereafter.

3.4.1 The geostatic loads

The earth and water pressure applied on the Sofistik model are calibrated with the results issued from a geotechnical FEM analysis calculated in the same section using the software Plaxis 2D. This calibration allows to obtain similar axial force and bending moment in the segmental lining studied with the two different softwares.

3.4.2 The seismic load

The seismic calculation approach presented hereafter is based on an internationally recognized method which performs the seismic analyses according to ITA/AITES guidelines for the design of Segmental tunnel linings 2019 and to ITA/AITES Seismic design and analysis of underground structures, 2001. According to this method, the seismic response of a tunnel is dominated by the surrounding ground response and not by the inertial properties of the tunnel structure itself, as "for most underground structures, the inertia of the surrounding soil is large relative to the inertia of the structure".

Therefore, the underground seismic design is based on the free-field deformation of the ground and its interaction with the structure, in contrast to the design of the surface structures. Further studies (for example using 3D full dynamic modelling) should be carried out to better investigate the negligibility (or not) of inertial effects in function of the dimensions and thickness of the structure.

The applied methodology foresees the application of a distortion to the ground to deform the underground structures and obtain the stresses acting in the lining in case of a seismic event.

The starting point of the study is the site-specific design acceleration at surface, $a_{\max,S}$. For the specific case, a value of 0.9 g has been considered.

In order to consider the depth of the tunnels, the ITA/AITES Seismic design and analysis of underground structures, 2001 defines the peak acceleration at the tunnel depth ($a_{z,\max}$): the procedure consists in the determination of a reduction coefficient C for the peak acceleration on the surface depending on the tunnel depth as shown in the equation here below:

$$a_{z,\max} = C a_{\max,S} \quad (4)$$

Where, $a_{z,\max}$ is the peak acceleration at the tunnel depth (m/s^2), C is a reduction coefficient (-) and $a_{\max,S}$ is the site-specific design acceleration at surface.

The value of $a_{z,\max}$ is used to determine the γ_{\max} (maximum shear deformation in free-field condition) from the peak ground velocity V_s which is a function of the earthquake magnitude and distance from the seismic source, as shown in following equations:

$$\gamma_{\max} = V_s / C_s \quad (5)$$

$$V_s = k a_{z,\max} \quad (6)$$

Where, γ_{\max} is the maximum shear deformation in free-field condition (-), V_s is the peak ground velocity (m/s), C_s is the apparent propagation velocity (km/s) and k is the ratio of peak ground velocity to peak ground acceleration.

The main input parameters used in the calculation illustrated in this paper are resumed in the following table.

Table 1. Input for the seismic analysis.

Tunnel overburden (m)	15
Type of surrounding ground	Soft Rock
Moment magnitude (M_w)	8.5
Source to site distance (km)	< 20
Gravity acceleration (m/s^2)	9.81
$a_{\max,S}$ (g)	0.9
C	0.9
$a_{z,\max}$ (g)	0.796
k (cm/s/g)	127
V_s (m/s)	1.01
C_s (km/s)	0.775
γ_{\max} (-)	0.0013

A FEM modelling is carried out with the aforementioned parameters and the seismic induced stresses in the segmental lining are analysed.

Subsequently, the simulation of the earthquake effects in Sofistik are simulated by the application of lateral forces to the model to reproduce the same seismic distortional effects on the main tunnel issued by the previous analysis.

The two following load-cases are considered in the Sofistik analysis.

Figure 7. Sofistik loadcases for the seismic analysis.

3.5 The model phasing

The tunnel is modelled by a sequence of seven consecutive stages. The calculation steps consider the history of loads and deformations from previous phases.

For the calculation of the crack width at the serviceability limit states (SLS), the quasi-permanent combination is used. In the ultimate limit state (ULS) calculation all the loads are factored by a coefficient of 1.35. In the accidental limit state (ALS) calculation all the loads are factored by a coefficient of 1.00.

The Sofistik phases are:

- Phase 110 – Initial state: Initialization of the stresses on the Main tunnel segmental lining.
- Phase 120 – The temporary metallic structure is installed.
- Phase 130 – The cross-passage opening is excavated.
- Phase 140 – The collar is constructed (activated) and the metallic structure deactivated.
- Phase 150 – The collar is loaded with the geostatic loads described in paragraph §3.4.1.
- Phase 160 – A distortion in X direction is applied to the main tunnel in order to simulate the earthquake effects.
- Phase 170 – A distortion in -X direction is applied to the main tunnel in order to simulate the earthquake effects.

The paper focuses on the results of phases 160 and 170 in order to study the effects of the two different types of joints on the segmental lining stresses results at the proximity of the opening.

This phasing is used for both the models, one with the fixed joint and the other one with the movement joint.

3.6 The model results

The results in terms of internal stresses of the segmental lining at the proximity of the cross-passage opening are described in this paragraph

for both the model with the fixed joint and the one with the movement joint at ring number 5 and 6. In the following images the point A represents the intersection between the segmental lining and the collar.

The results shown for the seismic analysis represent the worst-case scenario in terms of internal stresses in the main tunnel segmental lining, i.e. the load-case LC 160.

N.B. The tunnel rings numbering is illustrated in Figure 3. The results in terms of stresses illustrated in this paragraph refer to the centrelines of ring number 5 and 6. Point A represents the stress distribution in ring 5 at the collar's upper beam.

3.6.1 Fixed joint

The main results in terms of axial forces and bending moment in the segmental lining are shown in the figures hereafter.

Figure 8. Sofistik results – Axial force for the seismic analysis – Fixed joint.

3.6.2 Movement joint

The main results in terms of axial forces and bending moment in the segmental lining are shown in the figures hereafter.

3.6.3 Results comparison

The maximum internal stresses comparison between the two models are resumed in the tables below for both the main tunnel lining segments analysed (n.5 & n.6) and for point A.

NOTA: Compression values are shown as negative.

Figure 9. Sofistik results – Bending moment for the seismic analysis – Fixed joint.

Figure 10. Sofistik results – Shear force for the seismic analysis – Fixed joint.

4. CONCLUSION

Table 2 summarizes the results of the seismic analysis carried out and shows the variation in terms of

Figure 11. Sofistik results – Axial force for the seismic analysis – Movement joint.

Figure 13. Sofistik results – Shear force for the seismic analysis – Movement joint.

Figure 12. Sofistik results – Bending moment for the seismic analysis – Movement joint.

internal stresses in the segmental lining for both solutions (fixed joint and movement joint).

Table 2. Internal stresses comparison between the F.J. and M.J. models.

	Fixed Joint	Movement Joint	Variation (%) F.J. && M. J.
N min (kN/m) ring n.6	-1344	-1658	+ 23.3 %
N max (kN/m) Ring 5 & at point A	+208.6	+71.2	- 65.9 %
M max (kNm/m) ring n.5	151.5	161.7	+ 6.73%
M max (kNm/m) ring n.6	-130.4	135.7	+4.06%
M max (kNm/m) at point A	151.5	-79.3	- 47.6 %
V max (kN/m) ring n.5	298.3	104.3	- 65.0 %
V max (kN/m) ring n.6	193.1	146.0	- 24.4 %
V max (kN/m) at point A	298.3	102.5	- 65.6 %
Maximum Collar seismic displacement (mm)	0	5	-

The movement joint solution leads to a general reduction of the internal stresses at the opening. For instance, at the point A, the maximum values of both the axial traction and shear force drop by more

than 60% and the maximum bending moment by about 50%.

However, we can observe a small increase of the bending moment in the remaining part of the segmental lining ring n.5 (+ 7%) and in the adjacent ring n.6 (+4%). At the same time, we can observe a slight increase of the compression level in the ring n.6 and no changes of the compression level in the ring n.5 between the two solutions. In terms of bending moment, these increases remain small and easily manageable with the steel cage foreseen for the main segmental lining, especially for the ring n.6 in which the increment of axial force leads to a global safety factor increase for the whole ring. The relative displacements between the structures remain small and don't affect the stability of the cross passage.

The findings of this study suggest that the use of the movement joint, designed as a disconnection between the secondary lining of the cross-passage and the collar is a valid mitigation measure for cross-passage intersections in segmental tunnel lining. The simplified 3D FEM analysis carried out shows that the use of such a movement joint can significantly reduce the seismic induced stresses in the segmental lining, which can help to prevent struc-

tural damage and improve the overall integrity of the tunnel. Further studies are still required for the full understanding of the problem, future lines of research could be focused on more complex 3D FEM seismic analysis such as a full dynamic modelling and collecting real cases results or carrying out physical experiments to validate the model.

Development of sustainable criteria for the Italian railway tunnel design

Franco Iacobini & Annalisa Pranno*

Rete Ferroviaria Italiana – Infrastructure Department, Rome, Italy

ABSTRACT: In recent years, RFI has been developing the challenging topic of sustainable for railway infrastructures drowning up the change management program “Sustainability on-the-go”. The program consists of ten guidelines and the first of them concerns the railway infrastructure design through the revision and the definition of standards in terms of sustainability and Life Cycle Assessment. To achieve these goals, RFI improved its Manual Standard (Civil Work Design Manual and Civil Work Technical specification for construction) in an integrated approach to implement a systemic vision of sustainability. Starting from the planning phase and then moving on to the design phase and finally to construction, RFI provides in its manuals the indications for sustainable structures.

This paper will focus on sustainability topics provided in the tunnel section of RFI Civil Works Design Manual. Overall, in the new changeling approach the design and the construction of a railway tunnels have to enhance the integration in the territory and to promote the development of the socio-territorial context. In particular, the manual has been updated providing solutions to reduce soil and resources consumption and allowing the reuse of materials and equipment. For example, the reuse of the TBMs and their component has been included. Further studies are in progress even for the definition of a LCA analysis for a tunnel, allowing a quantitative assessment of the potential environmental impacts in addition to the current required.

Keywords: Sustainability, Design, Standard, Tunnelling, RFI

1 INTRODUCTION

In October 2015, 193 United Nations countries, including Italy, signed the 2030 Agenda to define commitments to achieve the 17 global Sustainable Development Goals (SDGs) by 2030. The SDGs are intend to lead a change in the development of economic, social and environmental model and, in particular, to arrive at a way of construction that is more resilient, inclusive and economically sustainable.

Further to that, at the European level, the Green Deal defines a new growth strategy with the aim to transform the European Union into an efficient economy without net greenhouse gas emission by 2050 and a reduction of around (50-55)% by 2030 too. In this new vision of infrastructural development, Ferrovie dello Stato Italiane Group, that is one of the largest industrial companies in Italy for the mobility system, contributes in a relevant way to the SDGs. The objectives of the 2030 Agenda in which the railway infrastructures have a significant impact are a lot, such as “Good jobs and economic growth”, “Industry,

Innovation and Infrastructure”, “Reduce inequalities”, “Sustainable cities and communities”, “Responsible consumption” and “Climate Change” (Figure 1).

Figure 1. The SDGs relevant to the railway infrastructures.

Moreover, Ferrovie dello Stato Italiane Group counts more than 15 subsidiaries and one of the main ones is Rete Ferroviaria Italiana (RFI), as the manager

*Corresponding author: a.pranno@rfi.it

of the national railway infrastructure. The network managed by RFI has an extension of approximately 16800 km. The tunnels over 100 meters are 1630 and about 1536 km long, which over 50% double track (Figure 2). The particular orographic conformation has made Italy the European country with the largest number of railway tunnels and also in the next future a great number of tunnels will be put in service.

Figure 2. European railway tunnel asset.

The transportation systems are a fundamental part of our society and key sectors for the environment, due to the greenhouse gas emissions, the impact on the soil and resources and, in general, for the resilience of the country. The infrastructure's role is an essential component for the environment in particular for their long service lives.

In fact, RFI, according to the SDGs, plays a fundamental role to act the national recovery and resilience plan and up to 2026 more than three hundred kilometres of new tunnels will be put in service. The underground construction industry is the future for the development of sustainability approaches, as part of the solution to the increasing demand for space and natural resources. The main aim of RFI is to review and define its standards in terms of sustainability and Life Cycle Assessment (LCA).

2 CIVIL WORKS DESIGN MANUAL

RFI has been improving its Civil Works Design Manual and Civil Works Technical Specifications to achieve the objectives of the first guideline of its sustainability program.

In particular, the Civil Works Design Manual and the Civil Works Technical Specification are divided into different sections. The manual contains the technical requirements for the civil works design, in order to unify and to standardize the design. The objective is to provide a significant advantage in terms of costs and a improvement in the maintenance in order to gain in efficiency and timing for the entire lifetime. As a single reference document, it gathers all the

project requirements of the sector issued in recent years. The fourth section of the RFI Civil Works Design Manual concerns the design of new tunnels. In this paper the sustainability topics of the RFI Civil Works Design Manual for tunnels are illustrated.

2.1 Sustainable management of excavated soil and rock

Railway infrastructure design and construction have been widely promoted also through the national recovery and resilience plan. Accordingly, a large amount of infrastructure-related excavated soil and rock (ESR) is generated, particularly from the construction of underground works. In order to comprehend the importance of the topic, it is essential to provide an estimate of the quantities of ESR that will be produced by the tunnel sections of the RFI Civil Works Design Manual. For example, for mechanized excavation sections (Figure 3), the quantitative of ESR volumes correspond to approximately 74000 cubic meters per km for the single-track and about 127000 cubic meters per km of tunnel for the double-track (speed 200÷250 km/h).

Figure 3. Standard section for mechanized excavation (speed 200÷250 km/h).

Due to the large quantities of ESR that are excavated and removed from the tunnelling, the manual establishes that, starting from the first design phase, the management of the ESR have to be analysed to protect the environment and pursue the principles of circular economy, preserving their value as resources over time. Besides, the manual was updated to examine and support innovative technological solutions that maximize the reuse of excavated material. Reuse can occur within the same projects and/or at external sites, but anyway the waste management has to be limited to a residual condition. The management of ESR requires consideration of both environmental and social sustainability, as well as technical and economic factors. According to the physical and geotechnical properties of the material produced after the excavation process (muck), it can be used for:

- production of concrete (aggregates), for good quality muck;
- new embankments or road works, for fair quality muck;

- for filling, backfilling or environmental/land reclamation, for low quality muck. Instead, ESR that cannot be reused is usually stored in a temporary storage sites, if necessary, and then delivered to final storage sites. To sum it up, reusing excavated materials has two primary environmental advantages: a decrease in waste disposal and a decrease in the amount of raw materials extracted.

2.1.1 Authorization process

The reuse of ESR or the identification of the final storage has to be defined in the phase of the design. Furthermore, the plan of the use of ESR have to be assessed according to the specific legislation. For example, according to legislation, to identify the most suitable alternative for reuse, it's necessary to develop experimental site-specific studies for the mechanized excavation with additives. During the design phase, the samples were taken from the geognostic surveys and experimental site-specific studies were conducted with the additives that were expected to be used in the construction phase. Both environmental compatibility and eco-toxicological and conditioning studies were conducted as part of the studies.

2.1.2 RFI's best practices for the new railway lines

A sustainable and efficient management of ESR has been planned for the design of several new high-speed and high-capacity railway lines, of which some projects are already in the construction phase. Considering one of these, for example, a new high-capacity line of more than twenty kilometres long, consisting mainly of underground works, it can be estimated that there is approximately five and half million cubic meters of ESR in bench from mainly granitic and phyllite rock formation and, in the final design, it is provided to fully reuse them. The excavated materials were divided into classes of use (Figure 4). The class A is identified for the good quality of muck that can be used for the production of concrete (aggregates) for structures and precast tunnel segments, but also for new embankments. After that, the class B is for fair quality muck that can be used for new embankments. Last, the class C is used for filling, backfilling or final storage.

ESR were produced from both: conventional excavation, with or without consolidation at the excavation face; mechanized excavation, bored by an earth pressure balance shield with or without using additives for soil conditioning.

For the conventional excavation sections with consolidation at the excavation face, the average percentage of fiberglass, polyvinyl chloride and cement is estimated and the average percentage of anthropic inclusions respect the limitations of legislation. The vegetal soil, on the other hand, has been preserved since the opening of the construction site. At the end of the works, it will be utilized for naturalization, which will restore the territory to its original state.

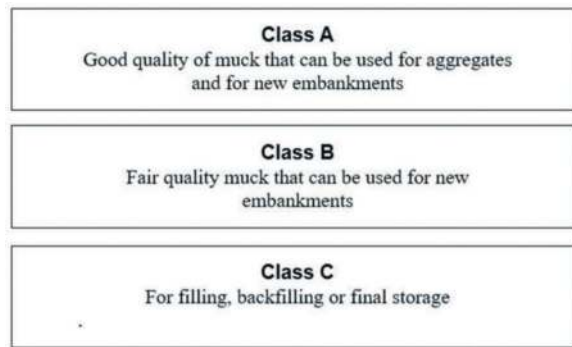

Figure 4. Reuse of excavated soil and rock.

For the mechanized excavation, for the nature of the additives used (foams) and through the treatments of crushed and screened, the ESR will be delivered to the final storage sites without any additives thanks to the drying and natural biodegradation process. Moreover, various logistical solutions have been implemented to reduce the number of trucks on the roads during the transport of excavated materials.

2.2 Sustainable management of water resources

The management of water resources is also relevant to pursue the objectives of sustainability. First of all, to preserve the purity of waters, in the railway infrastructure projects the tunnel drainage system provides a separation between the waters from rock/soil and the waters from the railway platform. The management of the water resource plays a fundamental role especially for the tunnel built by conventional excavation. To take a specific example, in conventional excavation, there is a polyvinyl chloride waterproofing membrane between primary and secondary linings. The waterproofing and drainage system intercepts water by the waterproofing of the tunnel crown, and it is collected from the longitudinal drainage pipes. The water is conveyed through transversal connecting pipes to a dedicated collection pipe. The inspection wells are also provided for maintenance. This system is separated from the drainage of the railway platform water (Figure 5).

It is important to analyze the opportunity to reuse and enhance water resources in different phases of the project and it is related to the possible interference with the aquifers present. In addition, it is relevant to enhance potentially drained water whenever possible and always in compliance with the technical, economic, and functional requirements of the project.

Figure 5. Drainage systems for conventional excavation sections.

In fact, any possible solutions should be studied to evaluate their recovery, valuation, and reuse.

To maximize the sustainable management of drained water resources, the following should be carefully assessed:

- the quantities of inflows;
- the chemical-physical quality;
- any contamination with which water may come in contact.

The aim is to identify the possible reuse of waters that can be used for agricultural, potable, industrial, fire, and other types. The full round waterproofing is an excellent solution to avoid an environmental impact on water resources. For the waterproofing in the tunnel crown, the water is conveyed through lateral collectors or a single collector under the invert and, in this case, it is configured as a drainage system with filtration motion towards the tunnel. In RFI Civil Works Technical Specification, the waterproofing have to be guaranteed by the installation of a polyvinyl chloride waterproofing membrane between the primary and secondary linings with a thickness of minimum two millimeters, accompanied by a layer of geotextile outside in order to regularize the laying surface. For a sustainable railway investment from a technical, economic and environmental perspective, it is relevant the problem of the groundwater lowering due to the possible drainage during excavation. In order to excavate safely, it is necessary to find a technical compromise. For this purpose, it is fundamental to control instability resulting from the entrance of water into the tunnel, which may necessarily lead to a lowering of the groundwater during construction, and to minimize the impact on the hydraulic conditions at the boundary. After an appropriate evaluation, if it is not possible to adopt a full round waterproofing, the first mitigation intervention consists of reducing the volumes of water drained by the tunnels.

2.2.1 RFI's best practices for the new railway lines

Considering a new high-capacity line of about ten kilometers long, consisting mainly of underground works, the estimated number of water sources in the area of study is approximately two hundred. For the

tunnels, it is provided a full round waterproofing system. Mitigation measures are implemented in the project, including replacing preventive measures and waterproofing the rock mass formation during the phase of construction. Moreover, the environmental monitoring system of the project is combined with a specific monitoring of water resources. The water resources were analyzed for the period before the construction (two years before), are analyzing during the construction phase, and will be monitored also after the realization of the works (for at least two years). The plan of water sources monitoring is relevant for the hydrogeological, geological and geotechnical information. These information are useful for the identification of measures and interventions to be acted, such as waterproofing of rock mass formation, preventive replacement interventions and, if necessary, emergency interventions. The plan (Figure 6) includes for example:

- measurements of chemical-physical parameters, such as temperature, specific electrical conductivity, fixed residue, red-ox potential, pH, turbidity, amount of oxygen;
- measurements from piezometers and wells;
- flows measures;
- hydro-chemical and isotopic analysis.

Figure 6. Water sources monitoring system.

For the specific chemical-physical water treatment for waters that come from tunnels, the waters need to be treated before being re-entered in the receivers, as provided in the RFI Civil Works Technical Specification. In conclusion, the sustainability elements of the project's construction site have been identified. Water collection and regimentation systems are used to reuse water as a resource. Treatment plants, for the waters from precipitation for instance, to reuse them as water for example for construction site toilets. Further treatment and accumulation plants for waters from the tunnelling, for the industrial reuse. Energy-efficient systems are utilized to decrease the energy consumption.

2.3 Use of "remanufacturing" for the TBM

The construction of a tunnel is interested by a series of actions: excavation, support of the cavity and removal of muck. Performing all of these activities

can be done through various methods, which are often combined together. The construction of a tunnel can be achieved through several conventional and mechanized methods. Considering the technological advancement of the industry, the TBM is definitively more used than in the past for the construction of new tunnels. The cost of a TBM, if newly built, is however averagely high, also related to the forecast of the high demands for the TBMs in the next years. For the protection of environmental and to pursue the principle of circular economy, the RFI Civil Works Design Manual provides that solutions that allow the reuse of the TBMs or their components through a process of “remanufacturing” which can be adopted since the design phase. This process is capable of establishing a complete new life cycle for the product, guaranteeing a quality level that is equivalent to the original one. The process of “remanufacturing” is defined by the “ITAttech Guidelines on rebuilds of machinery for mechanized tunnel excavation” and it is mentioned in the RFI Civil Works Design Manual. The process consists of five main phases, which are:

- complete disassembly of TBMs to their single part level;
- cleaning of all parts;
- cataloguing of all parts and visual and/or instrumental inspection;
- reconditioning parts that are worn or obsolete;

Figure 7. Screw conveyor before and after the remanufacturing process.

- reassembling and final testing for product certification and quality. Due to the complexity of the TBMs context, different methods of “remanufacturing” can be adopted for each component of the TBM, always preserving the environment. For example, laser cladding, welding or other methods can be adopted to repair the screw conveyor when the wear amount exceeds the fixed threshold (Figure 7).

The reuse of a TBM is at the moment provided in one construction procurement.

3 CONCLUSIONS

In this paper the sustainability topics for tunnels are illustrated. It is provided an overview about the reuse of excavated soil and rock, the management of the water resources and regarding to the remanufactured TBMs. Moreover, analysis are in progress to achieve the aim of the realization of sustainable tunnels through a systemic vision.

Further studies are in progress even for the definition of a LCA analysis for a tunnel, allowing a quantitative assessment of the potential environmental impacts. These results can be useful in addition to the current required regulations and standards and to completely update the manual standards.

Analysis on applicability of seismic calculation methods for shield tunnel in Shanghai area

Xin xing Li* & Hong Chen

Shanghai Tunnel Engineering and Rail Transit Design & Research Institute, Shanghai, China

ABSTRACT: At present, national and local standard have presented definitely some pseudo-static methods for lateral seismic design methods for shield tunnel in Shanghai area. These methods include response displacement method, response acceleration method, equivalent earthquake acceleration method and equivalent inertia force method. In the seismic design of field tunnel projects, there are some problems in using these methods. It includes how to select a suitable method and the results of different calculation methods are different. Based on a project case of shield tunnel, lateral seismic design using five different calculation methods is given separately in the paper. According to the results of dynamic time-history analysis, the causes of error on the calculation results of displacement and internal force are analysed. The Applicability of methods is studied in detail in terms of calculation model, determination of equivalent load, results error, and project application. The result shows that the response acceleration method has the minimum result error by compared with the dynamic time-history method. The response acceleration method is recommended as the recommended method for seismic design of underground tunnel in Shanghai area.

Keywords: Shield tunnel, Seismic design, Calculation method, Response displacement method, Response acceleration method

1 INTRODUCTION

The seismic design of underground structures is not taken care seriously until the underground station has been damaged by the Kobe earthquake in Japan. Subsequently, it sparked a widespread research trend. With the vigorous development of subway construction in major cities nationwide, China has also put forward clear requirements for the seismic design of underground structures, including subways. In 2011, the Ministry of Housing and Urban-Rural Development issued the “Notice on the Issuance of Technical Points for Seismic Design Special Demonstration of Municipal Public Facilities (Underground Engineering)”, which stated that in areas with a seismic intensity of six degrees or higher seismic defence zones, urban rail transit projects with a total construction area exceeding 10,000 square meters, such as underground stations, must undergo a special seismic design demonstration. Therefore, the research on seismic design methods for underground engineering structures has become an important concern for engineering designers (Liu et al., 2007; Tao et al., 2012; Li et al., 2014).

In recent years, Shanghai has been gradually developing and improving seismic design standard for underground structures, including the subway interval shield tunnel. In 2009, Shanghai issued the “Seismic

Design Standard for Underground Railway Structures” (Shanghai, 2009), which provides two equivalent seismic load methods for circular tunnels and other underground structures. These two methods are the equivalent horizontal seismic acceleration method and the equivalent inertial force method. The national standard issued in 2014 explicitly states the seismic design requirements for subway interval shield tunnel structures (China, 2014). It recommends two quasi-static calculation methods as seismic design methods, namely the response displacement method and the response acceleration method. The response displacement method is further divided into two cases based on the determination of seismic loads (Li et al., 2016). In the soft soil of Shanghai area, due to the specific geological conditions, it is very important to research on how to select the appropriate method among these available seismic calculation methods for specific underground tunnel projects, as well as to understand the differences and patterns in results obtained from different calculation methods.

Taking the case of circular shield tunnel projects in Shanghai subway, this paper conducts the lateral seismic calculations through the use of the response displacement method, the response acceleration method, the equivalent horizontal seismic acceleration

*Corresponding author: lxxxinyue@163.com

method, and the equivalent inertial force method. With the dynamic time-history analysis method as the standard, the results are compared and analysed in multiple aspects to identify the errors and its underlying causes. The analysis aims to further explore the rationality and applicability of seismic calculation methods and provide guidance in selecting suitable seismic calculation methods for shield tunnel structures in Shanghai.

2 SEISMIC DESIGN METHODS IN THE STANDARD

2.1 Response displacement method I

The response displacement method considers several loads, including the shear forces from the surrounding soil layers, the seismic earth pressure generated by the relative displacement of the soil layers, and the inertial forces on the structure under seismic action. To account for the constraint of the surrounding soil layers on the structure, a ground spring is introduced in the calculation model of the response displacement method (Liu et al., 2007), as shown in Figure 1.

Figure 1. Schematic of response displacement method.

According to section 6.6.4 of the national standard (China, 2014), when evaluating the relative displacement of soil layers without conducting seismic safety assessment for the engineering site, the simplified calculation formula provided in Appendix E can be used to determine the variation curve of displacement with depth and calculate the relative displacement of the soil layers.

This method is called the response displacement method I. In this method, the variation curve of displacement with depth is simplified as a cosine function curve, and the corresponding shear stress variation curve is a sine function curve. If no other information is available, the peak ground acceleration provided in the code can be selected and multiplied by the corresponding adjustment coefficient to determine the peak acceleration of the structural element.

2.2 Response displacement method II

The calculation models and principles of the response displacement method I and the response displacement method II are consistent, with the main

difference being the different methods for determining equivalent seismic loads.

According to the national standard (China, 2014), for the response displacement method, if seismic safety assessment has been conducted for the engineering site, the relationship between displacement and depth obtained from the assessment can be used to calculate the relative displacement of soil layers. This method is called the response displacement method II. In this method, the free-field displacement, shear stress, and acceleration at a certain depth, as well as the dynamic shear modulus of the corresponding soil layer at that depth, are all obtained through one-dimensional soil layer seismic response analysis.

2.3 Response acceleration method

The response acceleration method uses a soil-structure model to apply the horizontal effective inertial acceleration obtained from one-dimensional soil layer seismic response analysis at the time of maximum relative displacement of the top and bottom plates of the structure. The acceleration is applied at the corresponding depth positions in the soil and structure, simulating the seismic action through the generated horizontal inertia force (Liu et al., 2007). This method can reflect the interaction between the soil and structure, and consider the influence of complex cross-sectional structural forms and geological conditions, as shown in Figure 2.

Figure 2. Schematic of response acceleration method.

In the calculation model, the soil is represented by plane strain elements, and the structure is generally represented by beam elements, although other element types can be used as needed. When calculating the structural response under seismic action only, the bottom boundary of the model is fixed, and the vertical displacement at the two side boundaries of the model is constrained while the horizontal displacement is free.

2.4 Equivalent horizontal seismic acceleration method

The equivalent horizontal seismic acceleration method is an equivalent seismic load method proposed for analysing the seismic response of

underground structures based on the plane strain problem. It belongs to the soil-structure method, and the load is determined according to the principle of equal ultimate action effect (Shanghai, 2009). The equivalent seismic load is determined based on the principle of equal the maximum bending moment of the main components. At the same time, the maximum bending moment of the remaining components, as well as the maximum axial force and maximum shear force of each component, are calculated by multiplying a correction factors.

For circular structures of subway interval tunnel in Shanghai, by using the equivalent horizontal seismic acceleration method, the seismic acceleration is uniformly distributed in the horizontal direction. This horizontal seismic acceleration is then taken as the equivalent seismic load. The load distribution and calculation diagram can be seen in Figure 3.

Figure 3. Calculating model of equivalent acceleration method.

In the diagram, H represents the total thickness of the soil layers surrounding the subway tunnel. It has a significant impact on the seismic response of the structure. Typically, H is taken as 70m. β is the coefficient for the equivalent horizontal seismic acceleration load.

The equivalent horizontal seismic acceleration method is a simplified calculation method for seismic loads based on the response acceleration method. It can also directly reflect the interaction between the soil and structure.

2.5 Equivalent inertial force method

The equivalent inertial force method belongs to the load-structure method, and the load is determined according to the principle of equal ultimate action effect (Shanghai, 2009). The equivalent seismic load is determined based on the principle of equal the maximum bending moment of the main components. At the same time, the maximum bending moment of the remaining components, as well as the maximum axial force and maximum shear force of each component, are calculated by multiplying a correction factors.

For circular structures of subway interval tunnel in Shanghai, by using the equivalent inertial force method, the seismic inertia force is applied at the

node of the structure in the horizontal direction. The horizontal seismic inertia force and the corresponding triangular distributed horizontal soil resistance are then taken as the equivalent seismic load. The interaction between the structure and the soil is simulated by springs in the load-structure model.

The load distribution and calculation diagram can be seen in Figure 4. In the diagram, K represents the foundation coefficient of soil, P_f represents the maximum value of the horizontal soil resistance distributed in a triangular shape, which can be determined by the equilibrium condition with the equivalent seismic load in the horizontal direction, and F_I represents the equivalent horizontal seismic inertial force acting on the lining segments.

Figure 4. Calculating model of equivalent inertia force method.

3 CASE ANALYSIS AND COMPARISON

3.1 Engineering examples and conditions

The circular structure of a certain subway interval tunnel in Shanghai is constructed using the shield method. The outer diameter of the structure is 6.6 meters. The inner diameter of the structure is 5.9 meters. The width of the structure ring is 1.2 meters. The thickness of the segments is 0.35 meters. The thickness of covering soil is 20.0 meters, as shown in Figure 5. The segment material is high-strength concrete C55, and it is assembled with straight joints. The lining consists of six segments, including one

Figure 5. Cross section of subway station.

small top segment, two adjacent segments and three standard segments. The seismic analysis considers the coefficient of the joint effect and the dynamic modulus correction factor for the structural material.

The dynamic calculation parameters for the selected typical soil layers in the Shanghai area are shown in Table 1. The site category is classified as Category IV, and the nonlinear dynamic properties of each soil layer are represented by the Davidenkov fit curves (ZHANG et al., 2010).

The seismic design intensity is 7 degrees. The acceleration time history curve for the earthquake motion is taken at a 70m depth of underground with a 50-year exceeding probability of 10%, as shown in Figure 6.

Table 1. Parameters of different soil layers in Shanghai area.

NO.	Soil	Thickness /m	Depth /m	Gravity density / (kN/m ³)	Velocity of shear-wave /(m/s)

12	Silt sand mixed with coarse sand	19.02	73.7	19.8	433

Figure 6. Time history of earthquake motion.

3.2 Equivalent load parameters of different methods

According to the design peak ground acceleration standard (Li et al., 2014) to the response displacement method I, the peak ground acceleration a_{max} is taken as 0.1g for a site of Category IV with a seismic design

intensity of 7 degrees. The peak displacement u_{max} of the seismic motion is calculated as 0.105m. These values are considered as the basic parameters to determine the seismic load in the response displacement simplified method.

The basic parameters of seismic motion load to the typical soil conditions in the Shanghai is the same for both the response displacement method II and the response acceleration method. It is obtained from one-dimensional seismic response analysis. The distribution curve of the maximum relative displacement at the top and bottom of the structure, occurring at the time $T=5.56s$, is shown in Figure 7. The two red lines represent the depth of the top and bottom of the circular tunnel structure.

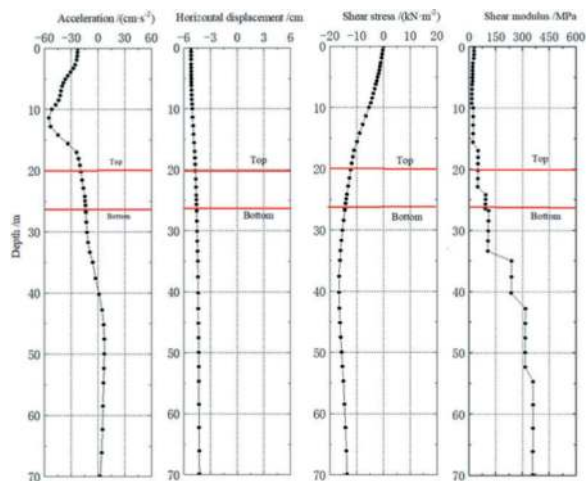

Figure 7. Load parameter distribution curve.

The relevant load parameters for the equivalent horizontal seismic acceleration method and the equivalent inertial force method of subway interval tunnel are obtained through table lookup and calculation. The acceleration coefficients and inertial force coefficients for different soil layer are shown in Table 2.

For the equivalent horizontal seismic acceleration method, the seismic acceleration load coefficient β is 0.2421. It is an important parameter to determine the applied acceleration load.

For the equivalent inertial force method, the seismic inertial force coefficient k_c is 0.68278. The maximum horizontal resistance of the triangular distribution strata P_f is 37.54kN. These two parameters are key parameters that contribute to the calculation of the equivalent seismic load in the equivalent inertial force method.

3.3 Calculation results of different methods

Seismic analysis of interval shield tunnels in typical soil conditions of the Shanghai was performed using six different seismic design methods: the response displacement method I, the response displacement method II, response acceleration method, the equivalent horizontal seismic acceleration method, the

equivalent inertial force method, and dynamic time history method. The maximum values of horizontal relative displacement of the top and bottom of the structure Dx_{max} , axial force N_{max} , shear force Q_{max} , and bending moment M_{max} were obtained. The summary of these results is presented in Table 3. The results obtained from the dynamic time history analysis method were taken as the standard, and the calculation errors of the five different pseudo-static methods were compared. The summary of these comparison results is presented in Table 4.

Table 3. Calculation results of six different methods.

NO.	seismic design methods	Dx_{max} /mm	N_{max} /kN	Q_{max} /kN	M_{max} /(kN·m)
1	response displacement method I	3.69	99.3	35.1	52.3
2	response displacement method II	1.45	28.7	12.9	18.8
3	response acceleration method	1.42	56.3	18.4	20.8

5	equivalent inertial force method	5.8	39.2	23.6	40.0
6	dynamic time history method	2.14	82.3	29.3	31.5

From the two tables mentioned above, for the error of maximum horizontal relative displacement at the top and bottom of the structure, the maximum error observed in the equivalent inertial force method is 171.0%, while the minimum error observed in the response displacement method II is -32.2%. For the error of maximum axial force of the structure, the maximum error observed in the equivalent horizontal seismic acceleration method is -67.7%, while the minimum error observed in the response displacement method I is 20.7%. For the

Table 4. Results error of different methods.

No.	seismic design methods	Results error /%			
		Dx_{max}	N_{max}	Q_{max}	M_{max}
1	response displacement method I	72.4	20.7	19.8	66.1
2	response displacement method II	-32.2	-65.1	-56.0	-40.3
3	response acceleration method	-33.6	-31.6	-37.2	-34.0
4	equivalent horizontal seismic acceleration method	-73.8	-67.7	-51.9	-74.6
5	equivalent inertial force method	171.0	-52.4	-19.4	27.0
6	dynamic time history method	—	—	—	—

error of maximum shear force of the structure, the maximum error observed in the response displacement method II is -56.0%, while the minimum error observed in the equivalent inertial force method is -19.4%. For the error of maximum bending moment of the structure, the maximum error observed in the equivalent horizontal seismic acceleration method is -74.6%, while the minimum error observed in the equivalent inertial force method is 27%. The overall comparison of relative errors calculated by different methods is shown in Figure 8.

Figure 8. Comparison of relative error of calculation results.

From the overall results, in terms of the relative errors of displacement, axial force, shear force, and bending moment, the response displacement method II and the response acceleration method show relatively smaller errors compared to the dynamic time history method. The error range of the response displacement method II is from -30% to -65%. The error range of the response acceleration method is from -30% to -40%. Additionally, the overall error of the response acceleration method is slightly smaller than that of the response displacement method II. On the other hand, the equivalent horizontal seismic acceleration method and the equivalent inertial force method show larger relative errors, with the response displacement method I being slightly better than them.

Among the five pseudo-static seismic calculation methods, the response displacement method II and

the response acceleration method are relatively better calculation methods. They show smaller relative errors compared to the dynamic time history analysis method. The response acceleration method is slightly better than the response displacement method II.

4 ANALYSIS ON APPLICABILITY OF SEISMIC CALCULATION METHODS IN SHANGHAI AREA

To the calculation methods and models, the response displacement method I, the response displacement method II, and the equivalent inertial force method belong to the load-structure models. They do not consider the interaction between the structure and the soil, and only achieve the constraint effect of the soil on the structure by setting up connecting springs. At the same time, the value of the spring stiffness has a significant impact on the calculation results. The response acceleration method and the equivalent horizontal seismic acceleration method belong to the soil-structure models. Both methods can consider the combined action of the structure and the soil, only apply an acceleration load, and are not affected by the spring stiffness parameters.

To the equivalent seismic loads, the response displacement method I, the equivalent horizontal seismic acceleration method, and the equivalent inertia force method do not require inputting seismic motion loads for seismic response analysis of soil layers. The peak acceleration of the ground design seismic motion in Shanghai site is set to 0.1g when using the equivalent horizontal seismic acceleration method and the equivalent inertia force method. The response displacement method I can achieve the actual set peak value through modification based on the peak ground acceleration. On the other hand, both the response displacement method II and the response acceleration method require seismic response analysis of the site soil by inputting seismic motion loads. At the same time, both methods can also ensure that the peak ground design seismic motion matches the actual peak value.

To the calculation results, the calculation results of the response displacement method I, the response displacement method II, and the response acceleration method do not require modification, while the results of the equivalent horizontal seismic acceleration method and the equivalent inertia force method need to be appropriately adjusted to achieve relative stability.

Compared with the results of dynamic time history analysis method, the error of the results for the response displacement method II and the response acceleration method are generally comparable, usually around 30%, which is acceptable in engineering applications. The error of the results for the response displacement method I is generally around 40%. However, the error of the results for the equivalent

inertia force method and the equivalent horizontal seismic acceleration method can be as high as 70% or even larger, which generally exceeds the acceptable range in engineering applications.

To the engineering design and practical application, the cross-section of an interval tunnel is generally not a circular structure. Sometimes the cross-section corresponding to different construction methods is often irregular, such as a horseshoe shape, a four center circle, a five center circle, etc. Compared with other methods, the response acceleration method can be applied to irregular cross-sections and has a wide range of engineering applications.

Based on the above analysis, among the five pseudo-static seismic design methods commonly used for circular shield tunnel structures in Shanghai area, the response acceleration method is recommended to use as the first choice, followed by the response displacement method II. In cases where the corresponding seismic motions cannot be obtained, the response displacement method I can be considered.

5 CONCLUSIONS

In response to circular shield tunnel structures in Shanghai's soft soil areas, a comparative analysis was conducted on five recommended pseudo-static lateral seismic design methods in current standard. Using the results from dynamic time-history analysis as the reference, the following conclusions were drawn:

- (1) Among the five pseudo-static methods, the method with the smallest error in the results is the response acceleration method, followed by the response displacement method II. The methods with the largest errors are the equivalent horizontal acceleration method and the equivalent inertia force method. The error in the first two methods is generally around 30%, which is acceptable in engineering applications.
- (2) For the equivalent horizontal acceleration method and the equivalent inertia force method, their equivalent seismic loads are not based on soil seismic response analysis, and the internal force results are determined based on the principle of equal maximum bending moments. In addition, a correction factor needs to be introduced for adjustment, resulting in significant calculation errors in both methods.
- (3) The response acceleration method can directly reflect the soil-structure interaction, avoiding the influence of factors such as springs. Its equivalent load is based on the results of soil seismic response, and the working model is simple. It is suitable for irregular sections and has a wide range of engineering applications.
- (4) For the seismic design of circular shield tunnel structures, it is recommended to prioritize the use of the response acceleration method, followed by the response displacement method II. In situations where it is not possible to obtain

corresponding seismic motion data, the response displacement method I can be considered.

Validation of joint non-linear numerical analysis with large-scale physical testing for arched cut and cover tunnels at HS2 project (UK)

Mengxiao Li*, Sotiris Psomas & Nayef Al Haddid
COWI UK LTD

ABSTRACT: High speed 2 (HS2) Project C3 includes 2 twin arched Cut and Cover precast concrete tunnels ('Green Tunnels'), totalling 5.3km in length. In these structures the precast concrete arched roofs and the precast walls (piers) are connected via concrete-to-concrete knuckle (pin) joints, the verification of which required advanced numerical analysis and physical testing. To demonstrate the significance of the knuckle joint performance, the main findings of the joint non-linear response were initially summarised, then the study focused on the experimental large-scale (full element thickness) testing carried out in CERIB (France) aiming to validate the behaviour under the installation tolerances of combined twist and lip. The test results have been analysed by adopting a non-linear Finite Element model representing the actual scale of the test specimens. The numerical model also considers the non-linear material properties and the reinforcing steel bars. By comparing the results between the physical tests, numerical test simulation and the back-analysis of FE model of the structure, some very useful conclusions can be drawn related to the reliability of the design.

Keywords: Non-linear numerical analysis, physical testing, knuckle (pin) joints, precast concrete arched roof, cut and cover tunnel, HS2 project

1 INTRODUCTION

The HS2 Green Tunnels are constructed using the cut-and-cover approach and comprise precast reinforced units, including arched roofs and side walls, along with cast-in-situ base slabs. The design represents an innovative and sustainable precast arch solution, and the benefits it offers in terms of cost saving, safety risk reduction and sustainability improvement are discussed in Smith et al. (2023) [1]. The design methodology for fire resistance and the analysis of physical fire tests are detailed in Psomas et al. (2023) [2]. The connection between the roof unit and the wall is made through a concrete-to-concrete knuckle/pin joint. To analyse the structural behaviour of the joint under loading, a full-scale 2D finite element (FE) numerical model was created in the FE structural analysis software LUSAS. Figure 1 shows half of a full-scale tunnel model. To accommodate installation deviations, the design allows for joint movement, such as a lip and twist, up to 10mm, which is also considered in the numerical model analysis [3]. Detailed analysis and findings about the full-scale tunnel model are presented by Al Haddid et al. (2024) [4].

The joint behaviour was initially investigated based on the numerical results from the full-scale tunnel model and further validated through

Figure 1. Half of a full-scale tunnel FE numerical model in 2D.

a series of physical tests. This paper focuses on the analysis of the physical tests and the calibration of the numerical modelling approach. Section 2 describes the physical test setup. The test simulation numerical model, which adopts the same modelling approach as the full-scale tunnel model, is presented in Section 3. A comparative study between the tests and numerical simulation results is conducted to assess the effectiveness and reliability of the modelling approach and is presented in Section 4.

2 PHYSICAL TESTING

Physical tests were carried out at CERIB in France, involving two types of test specimens representing the two types of tunnels. The key distinction between the two lies in the joint thickness: for type 1, the thickness is 350mm, and for type 2, it is 400mm. This design difference is attributed to the varying depth of the backfilling along the tunnel alignment. For each type, multiple tests were performed, considering various configurations within the allowable design tolerances [5]. This paper specifically concentrates on the tests carried out for type 1.

2.1 The test sample

The test sample consists of two straight reinforced concrete panels, with one representing the roof and the other representing the wall. These panels are vertically positioned with a pin joint in the middle. The geometry of the pin joint aligns with the actual joint geometry between the roof and the wall of the tunnel. Each panel is 2.49m long and 1m high, as shown in Figure 2.

Figure 2. Geometry and dimensions of the test sample for type 1 (a) transversal section (b) Longitudinal elevation (c) detail of pin-joint for top panel (left) and bottom panel (right); unit in m.

To investigate the performance of the pin joint under various configurations, capturing the allowable design lip and twist at the joint, the following scenarios were established and tested:

Regarding the material properties, the concrete is specified to achieve a C50/60 strength at 28 days. Cylinders were cast simultaneously with the test samples and were tested on the day of testing. Table 2 displays the

Table 1. The pin joint configurations.

Case no.	Lip & twist	Description	Diagram
1	0 mm	Perfect alignment where the axes of both panels are precisely aligned.	
2	+10 mm	At one end, the top panel's pin joint aligns with the bottom panel's pin joint, but at the opposite end, the top panel's pin joint axis is shifted inward by 10mm compared to the bottom panel's pin joint axis.	
3	-10 mm	At one end, the top panel's pin joint aligns with the bottom panel's pin joint, but at the opposite end, the top panel's pin joint axis is shifted outward by 10mm compared to the bottom panel's pin joint axis.	

averaged concrete strength obtained from the cast test samples. The reinforcement cages within the test samples were designed to adhere to the specifications of the units.

Table 2. Averaged concrete properties of the test samples for type 1.

Compressive strength (Mpa)	47.8
Splitting tensile strength (Mpa)	3.1
Elastic Young's modulus (Gpa)	28.3

2.2 The test set-up supporting frame

Figure 3 illustrates the test set-up supporting frame installed to maintain the vertical alignment of the sample, in front view (Figure 3a) and in side view (Figure 3b). In cases of misalignment, it ensures the initial eccentricity is achieved. The frame includes a metal plate supporting the bottom panel and four metal columns welded to the plate along the longitudinal sides of the sample. In all configurations, the bottom panel consistently aligns with the frame, while the position of the top panel varies depending on the specific configuration being tested.

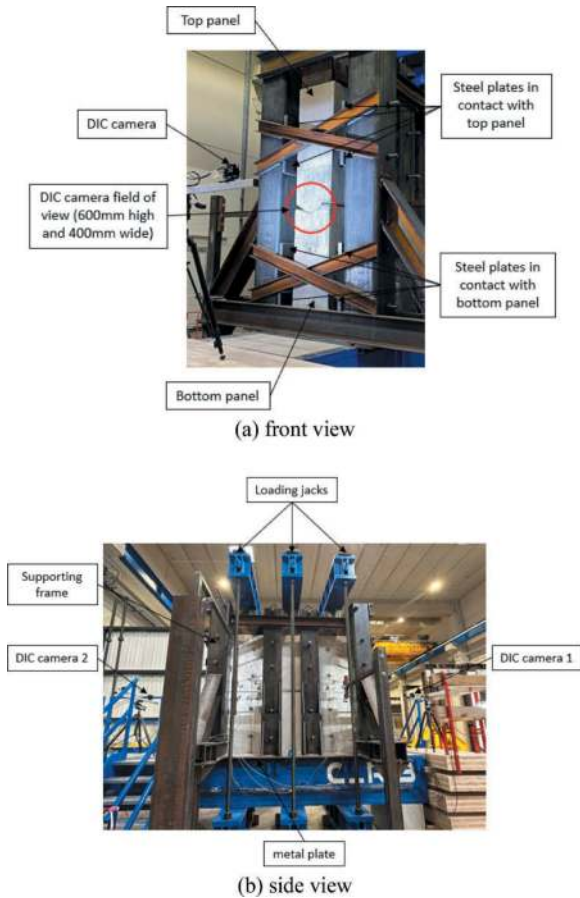

Figure 3. The test set-up.

Additionally, four steel plates are affixed to each column to provide lateral support to the top and bottom panels. It is important to ensure that the behaviour of the pin joint between the top and bottom panels of the test accurately represents the actual joint behaviour in a real-world scenario. The presence of a gap between the steel plate and the concrete surface, allowing for a certain degree of movement, can significantly impact the theoretical joint rotation. Therefore, a comparative analysis between the test simulation numerical model and the full-scale tunnel numerical model was undertaken to investigate the appropriate gap, and the results are presented and discussed in Section 3.2. To explore the pin joint behaviour more precisely during the test, two stereo digital image correlation (DIC) cameras are positioned on the front and back sides of the sample. They can capture a field of view that is 600mm in height and up to 400mm in width in the pin joint area. The surface is covered with thirteen dark speckles stamped within the field of view on a 150mm×150mm grid. The detailed location of the targets is shown in Section 4 Figure 11.

2.3 Loading

The load is applied to the test sample using three jacks, each with a capacity of 3000kN, distributed across

a steel slab with dimensions of 200mm×300mm×2490mm placed on top of the top panel. The load is applied in multiple steps, as shown in Figure 4.

Figure 4. Graph of load vs time and major loading stages.

3 NUMERICAL TEST SIMULATION

The physical tests are numerically simulated using LUSAS to validate the reliability of the modelling approach.

3.1 Modelling approach

The test simulation model includes two materials: concrete, modelled using shell elements, and steel reinforcement, modelled using bar elements. To facilitate a better comparison with the actual design of the full-scale tunnel model, the numerical model is developed in 2D. In cases with lip and twist, where perfect alignment exists on one side and lip on the other side, only the side with the lip is modelled. This side is considered critical based on the pre-numerical analysis of the full-scale tunnel model and physical test observations. The geometry of the numerical simulation model is shown in Figure 5.

Figure 5. Geometry of the numerical simulation models.

To simulate the concrete performance more accurately, the smoothed multi-crack concrete model in LUSAS is adopted (Figure 6). This model is a plastic-damage-contact model in which damage

planes form according to a principal stress criterion. The softening curve for tensile failure is determined by the specification of a fracture energy per unit area.

Figure 6. Stress/strain curve for concrete model in LUSAS.

The fracture energy required to propagate a tensile crack of unit area G_F is calculated based on FIB Model Code [6] for Concrete Structures 2010 cl. 5.1.5.2:

$$G_F = 73 \times f_{cm}^{0.18} \quad (1)$$

Where, f_{cm} is the mean compressive strength (Mpa). According to BS EN 1992-1-1 [7] Table 3.1:

$$f_{cm} = f_{ck} + 8 \quad (2)$$

The strain at peak uniaxial compression ϵ_{c1} is estimated according to BS EN 1992-1-1:

$$\epsilon_{c1} = 0.7 \times f_{cm}^{0.31} \leq 2.8 \quad (3)$$

The mass density for reinforced concrete is assumed to be 2500 kg/m^3 , and Poisson's ratio is assumed to be 0.2. The Young's modulus, the uniaxial compressive strength and the uniaxial tensile strength are obtained from cylinder tests on the testing day, as provided in Table 2. The reinforcement is modelled using a linear steel material model. The pin joint contact is modelled using the slideline feature in LUSAS, offering the advantage of not requiring prior knowledge of the contact point between two elements. Penetration, a term in contact analysis defining the relative overlap of meshes on separate contact surfaces, is influenced by the properties of the slideline. The design permits concrete surface crushing at the joint and assumes the maximum penetration to be between 1.0mm and 1.50mm at the SLS stage. The uniformly distributed line load applied to the top of the panel is calculated based on the capacity of the three jacks, totalling 9,000kN, and the loaded area of $300 \text{ m} \times 2490 \text{ mm}$. The analysis begins with self-weight loading only and then proceeds with an increment of 1% of the total external applied load. Table 3 demonstrates the key loading stages with the corresponding load factors calculated as a percentage of the design forces divided by the total applied force.

The base of the bottom panel is fixed in the vertical direction. The side supports are modelled using

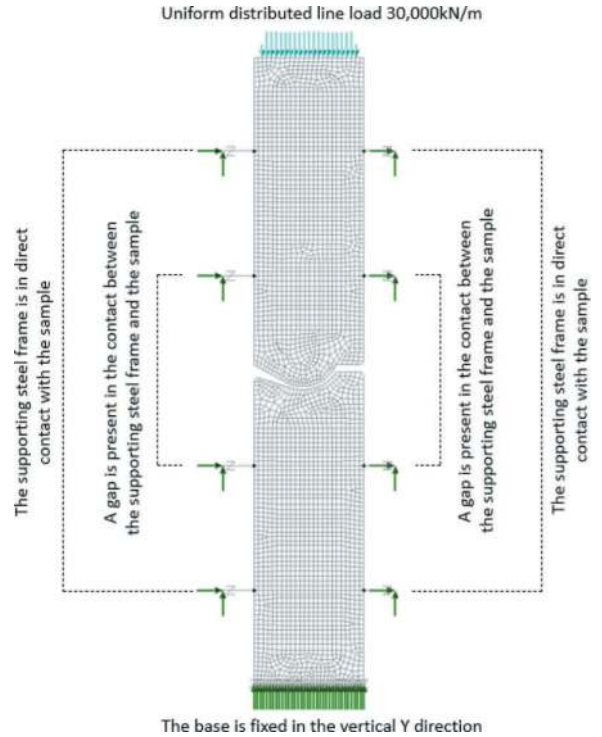

Figure 7. Numerical test simulation model.

Table 3. Key loading stages.

Loading stage	Design force/(kN)	Load factor
SLS	2125	0.24
ULS	3000	0.33
Max	7500	0.83

joint contact with compression only stiffness, which is estimated based on the property of the steel supporting frame. As mentioned in Section 2.2, allowing some movement of the panels near the joint is necessary to capture the actual joint behaviour in a real-world scenario. Therefore, a gap is left at the lateral supports for the four middle rows, while the four top and bottom rows maintain direct contact with the sample, as shown in Figure 7.

3.2 Assessment of the gap for lateral support

This section investigates the appropriate gap left between the steel plate and the concrete surface near the joint and assesses the impact of the gap on joint performance. Results from the analysis of case 3 (i.e., with a -10mm lip and twist) are presented here, as the influence of the gap is more significant compared to other cases. Four distinct scenarios were examined, considering gap sizes of 0mm (no gap), 1mm, 3mm and 5mm. To mitigate any potential impact of mesh density on the results, a consistent mesh density was applied to the pin joint area across all cases. Figure 8 presents stress contour plots (i.e., vertical compression and horizontal tension) and the joint contact length at

the ULS stage. These results are then compared to those obtained from the full-scale tunnel numerical model, as shown in Figure 9.

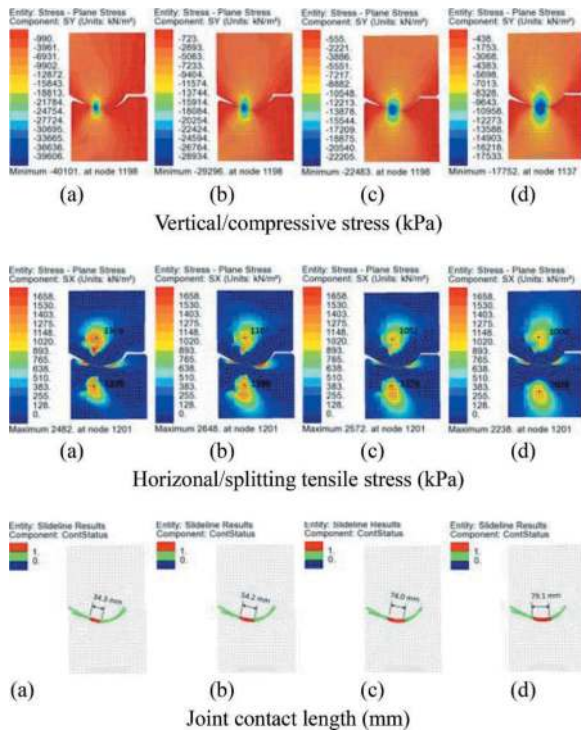

Figure 8. Results from test simulation model (a) no gap; (b) 1mm gap; (c) 3mm gap; (d) 5mm gap.

Figure 9. Results from full-scale tunnel model.

It can be observed that the compressive stress concentration occurs at the joint contact area. The maximum compressive stress SY significantly decreases with an increase in gap size, from 40.1Mpa in the case with no gap to 17.8Mpa in the case with a 5mm gap. Additionally, the contact length increases from 34.3mm in the no-lip case to 79.1mm in the 5mm gap case. This implies that a larger gap allows more joint movement towards the centre of the panel, increasing the contact area and alleviating stress concentration, resulting in more even stress distribution within the structure. The splitting tensile stress is another critical factor that impacts the design. It is noticed that localised high tensile stress appears next to the joint contact zone, but this is not the focus of this study. The area of interest lies in the splitting tensile stress zone, a distance away from the compression zone, which impacts the reinforcement design for enhancing the

tensile capacity of the concrete structure. The maximum tensile stress SX is highlighted in the top and bottom panels. Although it decreases as the gap increases, the reduction is not as significant as observed in the compressive stress. Comparing the stress distribution between the test simulation and the full-scale tunnel model, it can be seen that the scenario assuming a 1mm gap for lateral support exhibits a similar joint contact length, distribution of compressive stress and tensile stress. Therefore, a 1mm gap was determined and adopted for both the physical test and numerical model.

4 PHYSICAL TEST VS NUMERICAL SIMULATION

This Section presents the physical test and numerical simulation results for two cases: case 1, with no lip and twist, and case 2, with a +10mm lip and twist (Figure 10).

The DIC camera recorded displacement data for the thirteen targets within the pin joint area is used to analyse the joint behaviour for each case. Figure 11 shows the locations of the target points. In the numerical model, nodal displacements in similar locations are selected for comparison with the physical test results.

Figure 10. Test sample of case 1: no lip and twist (left) and case 2: +10mm lip and twist (right).

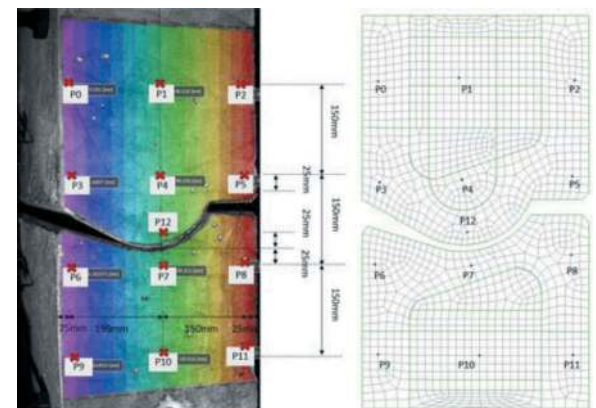

Figure 11. Targets within the pin joint area of the test sample (left) and the numerical model (right).

4.1 Case 1: No lip and twist

As shown in Figure 11, targets P12 and P7 are located 25mm above and below the centre of the joint in the top and bottom panels, respectively. The vertical differential displacement between these two targets can be used to estimate whether concrete crushing appears at the joint contact and to what extent during the test. The numerical model allows for concrete surface overlapping/penetration at the joint, assuming the maximum penetration is between 1.0mm (Figure 12a) and 1.50mm (Figure 12b) at the SLS design stage. Compressive strain developed in the 25mm depth of the concrete section in the top and bottom panels under loading is also considered. The concrete displacement is calculated based on the displacement between P12/P7 and the point at the edge of joint centre of each panel, P12'/P7'.

Figure 12. Penetration at the joint and vertical displacements of the selected nodes at the SLS stage in the numerical model.

Figure 13 illustrates the differential displacement between P12 and P7 obtained from the physical test, as well as the joint penetration and concrete displacements from the numerical model. It can be observed that the compressive strain within the concrete is minimal and can be neglected. The physical test results reveal a disparity between the displacements recorded by DIC 1 and DIC 2. This discrepancy arises because achieving perfect alignment between the two panels during the test is challenging, given factors such as the precise placement of elements and vertical alignment of the jack on top of the panel. Additionally, the two systems measure the displacement of opposite faces at a distance of 2.5m, introducing a certain level of expected variation in measurements. Overall, the differential displacement at the SLS stage ranges between 1.0mm and 1.5mm, showing good agreement with the design assumption made in the numerical model regarding concrete surface penetration.

Figure 13. Comparison of penetration at the joint between physical test and numerical model.

The vertical and horizontal displacements of each target within the top and bottom panels from the physical test are compared to that of the corresponding nodes in the numerical model and are presented in Figure 14. Numerical contour plots of von Mises stresses with the deformed shape at key loading stages are also provided (Figure 15) to further illustrate the joint performance under loading.

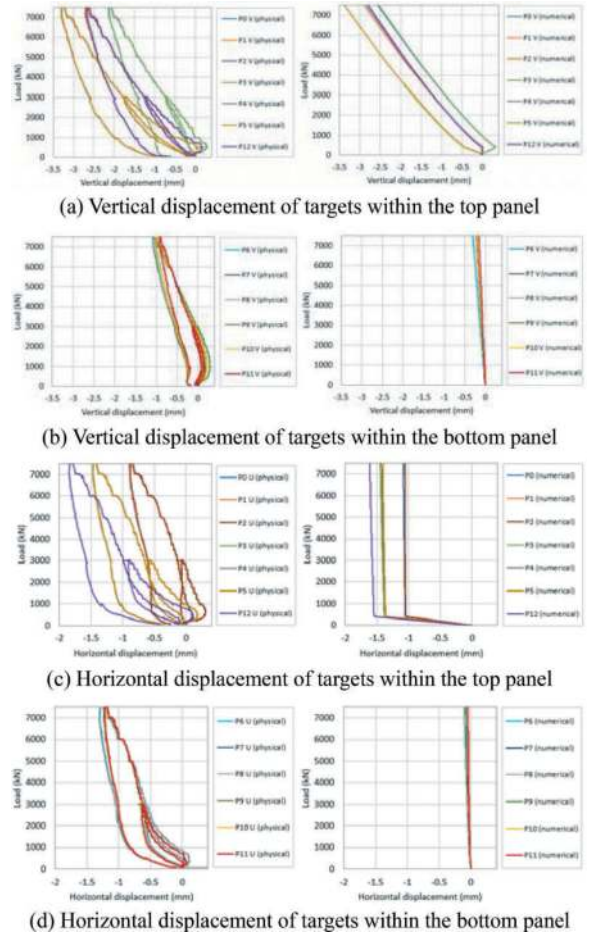

Figure 14. Comparison of displacement of targets between the physical test and numerical model.

Figure 15. Numerical contour plots of von Mises stresses.

It can be observed that there is a significant downward movement of the top panel in the initial loading stages in the numerical model. This is due to the initial gap between the two panels. Once the joint contact is established, the displacement is reset to 0, making it comparable with the physical test displacement, as contact is present in the initial stage in reality. For the top panel, P2 and P5 exhibit the largest

vertical movement, reaching up to 3.25mm under the max loading of 7500kN, while P0 and P3 show the least vertical movement. P12, positioned closest to the joint centre, experiences the largest horizontal movement, decreasing as it approaches the lateral supports that restrict the panel's lateral movement. A similar trend is observed in the numerical model. For the bottom panel, there is little difference in displacements between targets observed in both physical and numerical results. Additionally, relatively smaller displacements are observed in the numerical model compared to the physical test. As mentioned above, imperfections in the test setup impact the results, whereas the numerical model presents an idealised scenario. However, overall, the joint behaviours match between the physical and numerical results. The major movement appears in the top panel, a clockwise rotation, reducing the opening on the right-hand side of the joint.

4.2 Case 2: +10mm lip and twist

This section focuses on case 2 (i.e., with a 10mm lip and twist) and discusses the differences in joint performance between case 1 and case 2. Similar to the observations in the numerical model of case 1, concrete displacements within the 25mm section in the top and bottom panels are small (Figure 17). Due to the initial 10mm lip, the joint contact is not established at the centre of the panel; hence, there is zero penetration through the centre of the panel at the SLS stage in the numerical model, as shown in Figure 16a and 16b. Although the physical test displays a differential displacement between the two targets (P12 and P7), it is considerably smaller compared to those observed in case 1 (e.g., 0.2mm vs 1.0mm at SLS), aligning with the findings in the numerical model.

Figure 16. Penetration at the joint and vertical displacements of the selected nodes at the SLS stage in the numerical model.

Figure 17. Comparison of penetration at the joint between physical test and numerical model.

Comparing Figures 15 and 18, the contour plots of von Mises stresses for case 1 and case 2 also reveal the distinct location where initial joint contact is established and its impact on the stress distribution.

Figure 18. Numerical contour plots of von Mises stresses.

Figure 19 presents a comparison of vertical and horizontal displacements of targets in the top and bottom panels between the physical test and numerical model for case 2.

As can be observed in Figure 19(a) and 19(c), all the targets within the top panel exhibit similar vertical and horizontal displacements. This suggests that joint rotation is not significantly induced by the movement of the top panel, which is different from what has been observed in case

(a) Vertical displacement of targets within the top panel

(b) Vertical displacement of targets within the bottom panel

(c) Horizontal displacement of targets within the top panel

(d) Horizontal displacement of targets within the bottom panel

Figure 19. Comparison of displacement of targets between the physical test and numerical model.

1. For the bottom panel, case 1 exhibits a slight anti-clockwise movement, whereas case 2 shows movement in the opposite direction (clockwise) which is caused by the initial off-centre joint contact that results in imbalanced loading from the top panel onto the bottom panel. Figure 20 presents numerical contour plots of displacements of the bottom panel with deformed shapes for both case 1 and case 2, offering further insight into the differences in movement of the bottom panel.

It is important to note that there is slight difference in the displacement of the bottom panel between the physical test and the numerical model. Specifically, positive horizontal movements are observed in both cases, but the magnitude in the numerical model is higher. Regarding vertical displacement, targets on the left-hand side of the panel (i.e., P6 and P9) exhibit positive displacement in the numerical model but negative displacement in the physical test. This indicates that the rotation of the bottom panel in the physical test is not as pronounced as in the numerical model. However, since the top panel in the physical test experiences some anticlockwise rotation (i.e., positive displacements shown in Figure 19(c)), resulting in a joint contact/rotation similar to that obtained in the numerical model. Once again, there are other potential factors contributing to the differences between the test and numerical results, stemming from deviations during test setup or measurements.

In Figure 21, the vertical and horizontal strain distribution plots at the ULS design stage from the physical test and numerical model are presented. The location of the contact zone confirms the findings on joint rotation derived from the analysis of the displacement data of targets within the pin joint area. There is also alignment in the magnitude and distribution of the vertical compressive strain. For the horizontal strain, it is observed that in the physical test, positive/tensile strain also appears at the contact (i.e., edge of the concrete surface), while only negative/compressive strain is shown in the numerical model. This discrepancy maybe attributed to the concrete surface condition of the test sample, where minimal cracks appear and develop, resulting in tensile strain at the contact concrete edge.

5 CONCLUSIONS

In conclusion, this paper presents a comprehensive validation of joint non-linear numerical analysis through large-scale physical testing for arched Cut and Cover Tunnels in the HS2 project in the UK. The study focused on the investigation of knuckle/pin joints connecting precast concrete arched roofs and walls. The physical tests were carried out on specimens representing configurations within allowable design tolerances. The numerical simulation model incorporated non-linear material properties of concrete, capturing the complexities of the pin joint. The investigation also delved into the assessment of the lateral support gap,

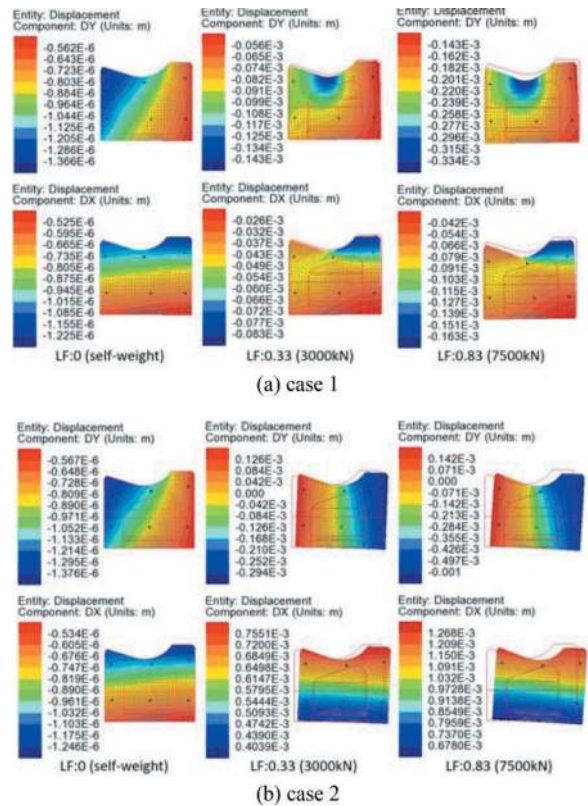

Figure 20. Comparison of displacements of the bottom panel between case 1 (a) and case 2 (b).

Figure 21. Comparison of strain distribution between physical test and numerical model.

determining the appropriate gap size to approximate the real-world joint behaviour. Comparative analyses between the results of physical test results and numerical simulations demonstrated a high level of agreement, validating the reliability and effectiveness of the design modelling approach. Although imperfections in the test set-up and variations in measurements between different monitoring systems could contribute to some disparities in the results obtained from physical tests and the numerical model. The joint behaviours, including vertical and horizontal displacements, as well as stress distributions, showed an overall alignment between the physical and numerical outcomes. This research contributes significantly to the understanding pin joint performance. The integrated approach of numerical analysis and physical testing presented in this paper serves as a valuable reference for engineers and researchers involved in the design and construction of similar structures.

ACKNOWLEDGEMENTS

The Authors would like to thank HS2 and EKFB Green Tunnels Team for granting permission to publish and for their support, respectively. Special thanks go to CERIB for the fruitful discussions regarding the physical test setup and the interpretation of the test results.

Innovative application of low-carbon and energy-saving technology in underground space: A case study of Erlangshan tunnel on Sichuan-Tibet expressway

Guojin Lin*, Jianguo Zheng, Jun Wang & Feng Yang
Sichuan Highway Planning, Survey, Design, and Research Institute Ltd

ABSTRACT: China has the largest amount of road tunnels around the world. While road tunnels greatly improve the traffic conditions in the mountainous areas, they demand enormous energy for lighting, ventilation and fire rescue. Erlangshan tunnel with the length of over 13km is the first super-long tunnel on the Sichuan-Tibet highway. Erlangshan tunnel has 4 inclined shafts with a total length of 8001m. Several innovative applications of low-carbon and energy-saving technologies are used to reduce the demand for energy in tunnel operation. i) The elevation difference between the top and bottom of the inclined shaft is utilized for water diversion and power generation, and the annual power generation of 4 million kWh is realized to meet all demands for lighting. ii) The natural wind formed by the pressure difference between two slopes of Erlangshan Mount and between the portal of inclined shaft and the tunnel is utilized. The inclined shafts are used as natural ventilation passages for auxiliary ventilation, thus, the tunnel ventilation can save 15% of energy and about 2.1 million kWh of electricity annually. iii) A rescue access between the inclined shafts is used as the high-level fire-water pond, so that the fire-water pond outside the tunnel in winter is not frozen and the pumping equipment is saved.

Keywords: Low-carbon and energy-saving technology, Erlangshan tunnel, power generation, natural wind

1 INTRODUCTION

With the rapid economic development in China, the transportation in eastern China has matured, and massive highway construction is carried out in the western China (Chen et al. 2019a; Xu et al. 2020). As the China's terrain is three-ladder shaped (high in the west and low in the east), more than two thirds of the country is occupied by mountains. Thus, a large amount of road tunnels must be constructed from the second ladder (average altitude 1000-2000m) to the first ladder (average altitude 4500m) (Chen et al. 2019b).

For the purpose of improving the transportation conditions of Ganzi, a Tibetan autonomous prefecture, and the Tibet Autonomous Region, the transportation construction of China has been gradually extended from the Sichuan Basin to the Qinghai-Tibet Plateau, with the altitude sharply rising from approximately 600m to 4,000m. There are extremely complicated conditions of geology and topography, and the tunnel accounts for 70% of the section (Wang et al. 2023a). The larger the tunnel scale is, the higher the energy consumption of

the tunnel, and the higher the safety risk of the tunnel during its operation arising out of harsh climate conditions is. Meanwhile, green energy, such as hydropower, wind energy, and solar energy, is abundant in western Sichuan province, so it is critical to how to use the green energy to solve huge energy consumption of the tunnel (Wang et al. 2023b; Zhao et al. 2023).

This paper presents a case study of Erlangshan tunnel, which employs the low-carbon and energy-saving technology to fully utilize the underground space, and the energy consumption during operation is greatly reduced. Erlangshan tunnel is the longest tunnel on the Ya'an-Kangding Express, which is part of the famous Sichuan-Tibet highway. The existing inclined shaft space of Erlangshan tunnel is fully developed for the application of green energy, so 6.1 million kWh of electricity for tunnel operation can be saved per year. 122 million kWh of electricity for 20 years of operation can be saved, equivalent to 15,000 TCE, and the CO₂ emission is reduced by 1,216,300t. The investment in the Project is only increased by RMB5.5 million, but RMB78.5 million is saved. A perfect combination of

*Corresponding author: 316605958r@qq.com

tunnel construction and clean energy utilization is realized, with an ideal quality rate of 100% and zero casualties in construction. In the context of “Carbon peak and Carbon neutralization” strategy, the effect of energy saving and emission reduction is significant, and both economic and social values are highly and widely praised by the public, which are very helpful for similar projects in the world.

2 ENGINEERING BACKGROUND

With an average elevation exceeding 4,000 meters, the Qinghai-Tibet Plateau is known as “the Third Pole of the Earth”. Sichuan-Tibet Expressway is the most convenient route to Tibet, which has the most complex geological conditions. The Ya’an-Kangding Express is 134.46km long, and it is an important part of the Sichuan-Tibet Expressway. The Ya’an-Kangding expression lies in the west of Sichuan basin, and it is located at the intersection of the Logmenshan Mountain and Qinghai-Tibet Plateau. Due to the large elevation difference, a lot of mountain tunnels have to be constructed to pass through the eastern border of the Qinghai-Tibet Plateau and the Henduanshan Mountain. There are 30 tunnels with the total length of 69533m in the express, and the

ratio of the tunnel length to the length of the total express is as high as 52%. Erlangshan tunnel with the length exceeding 13km is the keystone project, the construction of the tunnel commenced in September, 2012 and ended in December, 2017, i.e. it takes 63 months to finish the tunnel construction.

The left line of Erlangshan tunnel is 13549 in length, and the right line is 13406m in length. The tunnel with four inclined ventilation shafts is the second longest tunnel in southwest China, and the fourth-longest tunnel in China. The total construction volume of Erlangshan tunnel is shown in Table 1.

The total length of four inclined shafts reaches 8001m and it ranks the first in China, as shown in Figure 2.

The huge tunnel greatly improves the transportation of Tibet by offering safe and fast traveling, but it inevitably produces massive energy consumption, and the annual power consumption by tunnel ventilation and lighting is 10.37 million kWh and 3.63 million kWh, respectively. Besides, the fire-water pond outside the tunnel is easily frozen in winter and has poor reliability, posing serious safety hazards to the tunnel’s fire protection.

The traditional inclined shafts and underground fan rooms of an extra-long tunnel are only used for mechanical ventilation during operation.

Figure 1. Geological location of Erlangshan tunnel.

Table 1. Construction volume of Erlangshan tunnel.

Entities		Length (m)	Slope (gradient %/length m)	Elevation of the shaft entrance	Elevation of the shaft exit
Tunnel	Left line	13459	2/7005. -0.50/6477	1464.30	1572.21
	Right line	13406	2/6995. -0.50/6444	1464.50	1572.35
Shaft at Ya'an	Air supply	2305	12.58/2305	1850	1550
	Air exhaust	2246	12.96/890	1665	1560
Shaft at Kangding	Air supply	1716	13.57/1716	1890	1600
	Air exhaust	1734	13.41/1734	1890	1610

Figure 2. Layout of the shaft of Erlangshan tunnel.

To solve the problems of high energy consumption and low reliability of fire protection during operation, creative thinking is used and a series of innovative low-carbon and energy-saving technologies for inclined shafts are developed to utilize the topography, meteorology, hydrology at the tunnel site and the elevation difference between two ends of shafts.

3 INNOVATIVE APPLICATIONS

3.1 Inclined shafts for power generation

Fossil fuels (e.g. coal and petroleum) have been extensively used by humans for almost a century, releasing a lot of greenhouse gases (GHGs), e.g. CO₂. These GHGs are responsible for global warming. In the 20th century, the global average temperature was increased by 0.6°C. In the 21st century, the global warming trend has been further aggravated. To counteract global warming, the United Nations established the *United Nations Framework Convention on Climate Change* in 1992, and on April 22, 2016, the Paris Agreement was formally signed by 175 parties. Reducing carbon emissions, protecting the Earth, and protecting our homeland have become an international consensus.

Erlangshan tunnel exploits the shaft at Kangding to generate power, which has never been done in similar projects. The inclined shaft is located at the upstream of the Wuligou River as shown in Figure 3. The elevation difference between the two ends of the inclined shaft is as high as 192m. The abundant water of Wuligou River was controlled by a dam, a water diversion pipeline is set in the inclined shaft to divert water from the river at the portal of inclined shaft to the underground fan room at the bottom of inclined shaft, as shown in Figure 4. A generator set is installed in the fan room to generate power as shown in Figure 5, and the tailwater from power generation

Figure 3. Relation between the shaft and Wuligou River.

Figure 4. Procedures to generate hydraulic power.

Figure 5. Power generator in the underground fan room.

is discharged out of the tunnel via the central drainage ditch. The abundant rainfall and a large catchment area (19km²) in the region ensure stable power generation, the installed capacity is 730 kW and the annual power generation of 4 million kWh is realized, meeting all requirements for lighting.

3.2 Inclined shafts for auxiliary ventilation

The Erlangshan Mountain is the first natural barrier on the Ya'an-Kangding Express and it is the watershed of the Qingyi River and the Dadu River. The eastern slope of the Erlangshan Mountain has a humid subtropical climate with an annual rainfall of over 2,000mm, while the western slope is located in a famous dry-hot valley and has subtropical monsoon climate, with an annual rainfall of only 660mm. Thus, Mount Erlang is called "rainscreen of western Sichuan" with a distinct difference in the climate between two ends.

Figure 6. Climate difference between two ends of the Erlangshan tunnel.

Before the tunnel construction, two years of meteorologic observation was carried out, and the direction and magnitude of nature wind was closely recorded. As shown in Figure 7, the data analysis

indicates that the wind blows from the entrance of the tunnel to the exit with the probability of 63%, and it blows in the reverse direction with the probability of 37%. The direction of the nature wind also varies with seasons, and it blows from the portal of shaft to the bottom in summer, while a chimney effect dominates in the winter, and the wind blows from the bottom to the portal of the winter.

Figure 7. Mode of nature wind.

The inclined shafts bring about the motion of natural wind, and inclined shafts are used as the natural ventilation passages for auxiliary ventilation of the tunnel during operation, so that the ventilation requirements can be met during the period of low traffic volume. The annual energy consumption of ventilation is reduced by 15% and 2.1 million kWh of electricity is saved per year.

Figure 8. Auxiliary ventilation passage.

3.3 Water pond for fire protection in the inclined shaft

The water pond provides the water for the fire rescue of the highway tunnel. As shown in Figure 9, the conventional tunnel fire water supply usually adopts a constant high pressure water supply system with

a high-level water pool. The water supply is designed to accumulate water in the reservoir, and then use a water pump to pump the water to the low-level pool to form a backup water source. Then, use a water pump to lift the backup water source to the high-level pool to form a constant high pressure water supply.

Figure 9. Conventional fire water supply system.

The high-level pond is usually placed in a high slope and buried in the soil to keep the elevation difference and avoid being frozen. The work is difficult and expensive to finish and it also destroys the surroundings.

To solve the problem that the fire-water pond outside the tunnel is frozen in winter, a high-level fire-water pond is set in the inclined shaft. The passage between inclined shafts, which served as the rescue access during construction, is used as the high-level fire-water pond of the tunnel, and a branch pipe is set for the pipeline of water diversion and power generation to supply water for the fire-water pond, and the pond is always filled with water to realize fire protection with artesian water, without requiring a lot of pumping equipment; the year-round positive

(a) Location of the high-level pond

(b) Diagram of the fire water supply system

Figure 10. Fire water supply of Erlangshan tunnel.

temperature and head water differential in inclined shafts ensure safety and reliability of the system.

In the Erlangshan tunnel, the existing inclined shaft space is fully utilized for the application of green energy, so 6.1 million kWh of electricity for tunnel operation can be saved per year. 122 million kWh of electricity for 20 years of operation can be reduced, equivalent to 15,000 TCE, and the CO₂ emission is reduced by 1,216,300 tons. The investment in the project is only increased by RMB5.5 million, but RMB78.5 million is saved; both economic and social benefits are remarkable.

4 CONCLUSION

In the Project, the existing space of inclined shafts and underground fan room of the Erlangshan tunnel is fully used, and the inclined shafts for tunnel ventilation are first utilized for water diversion and power generation to supply power for tunnel lighting; inclined shafts are first used as natural ventilation passages for auxiliary ventilation; a high-level artesian water pond for fire protection of the tunnel is first set in the inclined shaft. And 6.1 million kWh of electricity for tunnel operation can be saved per year. 122 million kWh of electricity for 20 years of operation can be reduced, equivalent to 15,000 TCE, and the CO₂ emission is reduced by 1,216,300 tons; in the context of “Double Carbon” strategy, the effect of carbon reduction is significant.

The low-carbon and energy-saving innovative application of inclined shafts realizes the low-carbon operation of the Extra-long Highway Tunnel. No safety accidents occurred during the construction. The ideal quality rate is up to 100%.

The Project won the following awards: grand prize of CHTS Science & Technology Award 2021, 2021 China National Quality Engineering Award, 2021 Civil Engineering Li Bing Award of Sichuan Province, first prize of 2020 CHSDA Excellent Design Award of Highway Traffic, second-class achievement prize of 2020 Green Construction Design Level Evaluation of China, and “Safety Engineering” of 2018 Highway and Waterway Construction Project of China, and applied for 7 patents.

ABSTRACT: At present, the design concept of tunnel and underground engineering is to reduce the construction cost under the condition of ensuring engineering safety, and economy is the main assessment index of engineering construction scheme comparison. With the implementation of China's carbon emission and carbon neutrality strategy, reducing carbon emission has gradually become the goal pursued by the project construction. Therefore, in the process of comparing engineering design scheme and construction scheme, carbon emission will gradually become an important indicator of engineering construction scheme comparison. Based on the carbon emission coefficient method, gives the tunnel and underground engineering survey and design, build and the operation of carbon emission calculation method, with the shield tunnel, tunnel and underground engineering and low carbon design concept and method, combined with the engineering case, from the application of low carbon effect, from earthwork excavation and supporting structure materials of the hole layout of low carbon effect. Relying on the practice of Beijing-Zhangjiakou high-speed railway project, the implementation effect of low-carbon design concept is analysed. The main conclusions are as follows: (1) the carbon emission of materials is relatively large in the construction process of shield tunnel; (2) Proposed low-carbon design concepts for tunnels and underground engineering, including the application of prefabricated structures, the use of group cave layout design scheme, gabion ecological retaining walls, ventilation and lighting of underground stations, and green operation of large-scale facilities; (3) The prefabricated structure replaces cast-in-place structure and the group hole arrangement replaces single-hole large-section scheme with significant low-carbon effect. The research shows that the proposed low-carbon design concept and method of tunnel and underground engineering has a good application prospect, and is of great significance to promote the low-carbon design of tunnel and urban underground engineering.

1 INTRODUCTION

By the end of 2021, there will be 17,532 railway tunnels in operation, with a total length of about 21,055 km, and 8,644 railway tunnels under construction and planning, totalling 21,680 km, the construction of which will generate a large amount of carbon

emissions. (Gong et al., 2022) With the implementation of the strategies of carbon peaking and carbon neutrality, the transport sector is a key focus area of the above strategies. Tunnels are the most energy-intensive part of the transport infrastructure and it is particularly important to analyse their carbon emissions from a life cycle perspective. (Miliutenko et al., 2012). The carbon

*Corresponding author: tzydglg@126.com

reduction, carbon saving and carbon sink role of tunnels and underground engineering has a broad prospect, and it is of great significance to analyze the carbon emission law of tunnels and underground engineering as well as the design concepts and methods to reduce carbon emission to achieve the target of “Carbon Peak and Carbon Neutral” in China.

There is no unified standard for tunnel carbon emissions, and the problem of calculating tunnel carbon emissions is more prominent, mainly reflected in the lack of a unified boundary, and the range of carbon emissions calculation varies greatly among different studies. Huang et al. (2015) analysed the impact of tunnel excavation using drilling and blasting methods on the environment.

Xu et al. (2016) studied the emission of tunnels during the physicochemical stage. Guo et al. (2016) studied the carbon emissions of ventilation equipment and materials during tunnel construction. Xiao et al. (2018) analysed the electricity consumption of shield tunnels using the emission coefficient method. Wang et al. (2019) investigated the carbon emissions from the physical and chemical phases of shield tunnelling in metro projects. Dong (2016) calculated the carbon emissions of a shield tunnel in Hengqin New Area by preparing a quota. Fei et al. (2017) studied the carbon emissions during the production, construction and operation phases of a road tunnel material. Chen (2017) considered carbon emissions from vehicle operation in the calculation of carbon emissions during the operation period of road tunnels. He (2015) established a carbon emission quota list for civil engineering of cut-and-cover metro stations based on the life cycle assessment theory, and analysed the impact of burial depth and station width on the carbon emissions of the construction process. Li et al. (2016) established a metro life cycle carbon emissions measurement model, which divided the life cycle into five phases: production of building materials, transport of building materials, on-site construction, operation and maintenance, and carried out a case study. Huang (2019) analysed the carbon emissions from the production-transportation-construction of prefabricated components for shield tunnels with other materials.

Based on the carbon emission coefficient method, this paper gives the calculation method of carbon emission of tunnels and underground projects, analyses the main factors of carbon emission in the process of engineering construction, puts forward the concepts and methods of low-carbon design of tunnels and underground projects, and analyses the low-carbon effect of assembled structure and group hole arrangement in conjunction with case studies. It also relies on the engineering practice of Beijing-Zhangzhou high-speed railway to analyse the implementation effect of low-carbon design concept. Through the above research, it can provide a basis for the low-carbon design of tunnels and urban underground engineering and promote the application of low-carbon design.

2 CALCULATION METHOD FOR CARBON EMISSIONS FROM TUNNELS AND UNDERGROUND ENGINEERING

In tunnel and underground engineering, the entire life cycle mainly includes the survey and design stage, construction stage, and operation stage. This article provides carbon emission calculation methods for different stages based on the carbon emission coefficient method.

2.1 Carbon emissions during tunnel survey and design phase

The survey phase mainly involves carbon emissions generated by on-site drilling, survey, and other work. The design phase mainly involves the energy consumption of designers and equipment such as computers during the design process. The carbon emissions of personnel and labor force are the product of the total number of working days of labor force and the carbon emission factor of working days. By calculating the number of working days required for each job, the total number of working days of the labor force can be calculated. Some scholars have also conducted research on the carbon emissions generated by the labor force. (Wang et al., 2012)

2.2 Carbon emissions during tunnel construction phase

The calculation range of carbon emissions during the tunnel construction phase includes the carbon emissions generated by completing various sub projects and the carbon emissions generated during the implementation of various measures and projects; The calculation time boundary should be from the start of the project to the completion and acceptance of the project. According to the GB/T 51366 Calculation Standard for Building Carbon Emissions, the formula for calculating carbon emissions during the construction phase is as follows:

$$C_{JZ} = \frac{\sum_{i=1}^n E_{jz,i} EF_i}{A} \quad (1)$$

Where, C_{JZ} is the carbon emissions per unit area of the construction phase (kgCO_2/m^2); $E_{jz,i}$ is the total energy use of type i in the construction phase (kWh or kg); EF_i is the carbon emission factors for energy type i (kgCO_2/kWh or kgCO_2/kg); A is the building area (m^2).

The energy consumption during the construction phase includes four stages: production materials, material transportation, construction machinery, and labor consumption.

Taking a certain subway shield tunnel as an example, the outer diameter of the segment is 6m, the thickness is 0.3m, and the ring width is 1.5m. It is prefabricated with C50 concrete, and the total length of the section is 3500m. The proportion of carbon

emissions from materials used during construction and the carbon emissions from machinery used are shown in Figure 1-2.

Figure 1. Carbon emission of shield construction.

Figure 2. Proportion of energy consumption and carbon emission of construction equipment.

2.3 Carbon emissions during tunnel operation phase

The calculation range of carbon emissions during the operation phase should include the carbon emissions of HVAC, lighting and elevators, renewable energy, railway tunnels, and underground engineering carbon sink systems during operation. The carbon emissions during the operation phase are determined based on the different types of energy consumption and carbon emission factors of each system. The total carbon emissions per unit building area (C_M) are calculated using the following formula:

$$C_M = \frac{[\sum_{i=1}^n (E_i E F_i) - C_p] y}{A} \quad (2)$$

$$E_i = \sum_{j=1}^n (E_{i,j} - E R_{i,i}) \quad (3)$$

Where, C_M is the carbon emissions per unit of engineering area during the operation phase (kgCO_2/m^2); E_i is the annual energy consumption of the i -th type of building (unit/year); $E F_i$ is the carbon emission factor for Class i energy; $E_{i,j}$ is the i -th energy consumption of the j -type system (unit/year); $E R_{i,i}$ is the i -th type of energy consumed

by the j type system provided by the renewable energy system (unit/year); I is the type of terminal energy consumed, including electricity, gas, oil, etc; J is the energy consumption system, including heating, air conditioning, lighting systems, etc; C_p is the annual carbon reduction of the green space carbon sink system ($\text{kgCO}_2/\text{year}$); Y is the engineering design life (years); A is the building area (m^2).

The energy consumption of the HVAC system during the operation phase includes cold source energy consumption, heat source energy consumption, transmission and distribution system energy consumption, and end air treatment equipment energy consumption. The greenhouse gas emissions generated by the use of refrigerants in HVAC systems should be calculated using the following equation:

$$C_r = \frac{m_t G W P_r}{1000 y_e} \quad (4)$$

Where, C_r is the carbon emissions generated by the use of refrigerants (tCO_2/year); R is the type of refrigerant; m_t is the refrigerant charging capacity of the equipment (kg/unit); y_e is the service life of the equipment (years); $G W P_r$ is the global warming potential of refrigerant r .

3 LOW CARBON DESIGN CONCEPTS FOR TUNNELS AND UNDERGROUND ENGINEERING

The construction process of tunnels and underground projects is a carbon emission process. In order to achieve the goal of “carbon peak and carbon neutrality”, the principle of reducing carbon emissions should be implemented in the feasibility study, preliminary design, construction drawing design, and construction process of the project, and design schemes, construction methods, and building materials with lower carbon emissions should be selected. From the perspective of low-carbon design, the following three principles should be followed: firstly, reduce emissions, that is, reduce pollutant emissions and energy consumption during the construction process, and achieve the goal of reducing emissions by saving raw materials and improving prefabrication rates; The second is multi convergence, which refers to the integration of comprehensive management methods from multiple aspects, reducing the building area and increasing vegetation coverage; The third is durability, which refers to the development of corrosion-resistant and carbonization resistant building materials with high reliability and toughness. The principle of green design guides the construction direction of tunnels and underground engineering, and the low-carbon design concept requires the use of various low-carbon technologies to achieve it. The implementation path of the low-carbon design concept includes low-carbon line selection and station setting technology, low-carbon building design technology, low-carbon structural

design technology, low-carbon ventilation and air conditioning technology, and low-carbon waterproof and drainage technology. The principles of low-carbon design and the implementation path of low-carbon design concepts for tunnels and underground engineering are shown in Figure 3-4. The engineering design concept with the goal of reducing carbon emissions is to reduce carbon emissions as one of the main goals pursued by the project. While ensuring safety, in the process of comparing and selecting engineering design solutions, the principle of minimizing carbon emissions is replaced by the previous principle of minimizing economic costs. The focus is on considering the carbon emissions throughout the entire life cycle of the project, analyzing the total energy consumption and proportion of carbon emissions in each stage, and optimizing the design comparison. The ultimate design concept is to achieve energy-saving and carbon reduction in tunnels and underground engineering. The design concepts for energy conservation and carbon reduction in tunnel and underground engineering are presented from four aspects: the application of prefabricated structures, optimization of excavation methods for large underground spaces, design of green retaining walls such as edges and slopes, and green operation.

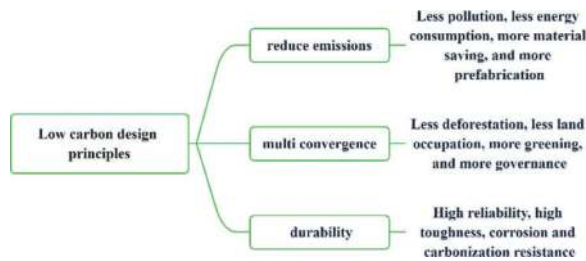

Figure 3. Low carbon design principles.

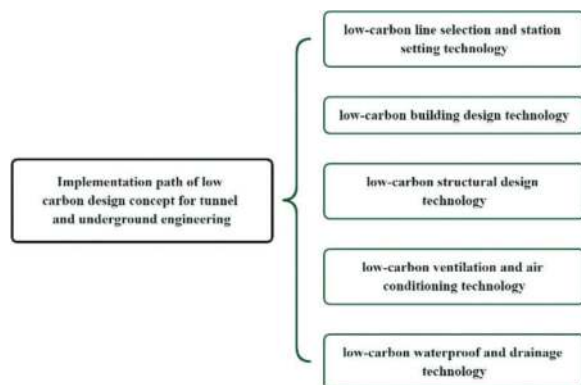

Figure 4. Implementation path of low carbon design concept for tunnel and underground engineering.

3.1 Application of prefabricated structures

During the tunnel excavation process, including advanced support, earthwork excavation,

construction and demolition of temporary structures, construction of initial support, secondary lining and other structures, and grouting reinforcement, each process generates energy consumption. Especially in the process of shotcrete, there is a high loss of materials and a large amount of dust, which requires measures such as dispersing water to reduce dust. Adopting prefabricated structure, compared with cast-in-place, it has better maintenance conditions, fewer materials, lower material loss, and saves template energy consumption. Therefore, prefabricated structure has good carbon reduction ability. Taking the single hole and single track tunnel in the subway section as an example, the carbon emissions of prefabricated structures and cast-in-place structures will be analyzed.

The design of a shield section of Beijing Subway is as follows: the excavation radius of the shield cutter head is 3.2m, the outer diameter of the C50 shield segment is 6.2m, the inner diameter is 5.5m, the thickness is 350mm, the ring width is 1.2m, and the grouting thickness is 1.0m. There are 24 bolts between the segments.

A single track and single hole section of Beijing Subway. The design situation is as follows: a horseshoe shaped cross-section with a soil cover thickness of 6.51-10.33m, and the cross-section is shown in Figure 3. The grouting thickness is 1.5m; The initial support is made of C25 concrete with a thickness of 300mm; The secondary lining concrete adopts C40 concrete with a thickness of 300mm.

The carbon emissions during the construction phase of single hole and single line tunnels in the subway section of the above two types of construction are closely related to material consumption, transportation, installation, etc. This section only considers carbon emissions from material usage.

Based on the design of two tunnel sections, the consumption of various materials can be calculated separately, and combined with existing research (Li et al., 2022), the carbon emission factors for the same material can be given, as shown in Table 1 below.

Table 1. Materials carbon emission factor.

Material type	carbon emission factor (kg/m ³)	Material usage (m ³)	
		shield tunnel	mined tunnel
C25 concrete	289.44	/	8.37
C40 concrete	432.29	/	6.00
C50 concrete	563.89	6.43	0
cement mortar	400.94	12.82	48.55

For prefabricated segments of shield tunnels, excess losses are not considered for shield segments and bolts, and 10% losses are considered for grouting; For underground tunnels, 20% loss is considered for the initial support of spraying, 5% loss is considered for the secondary lining, and 10% loss is considered for grouting. Based on Table 1 and Equation (1) above, the carbon emissions of the shield tunnel segment are calculated to be 9337.31kg, and the emissions of the underground tunnel are 27,389.59kg.

The carbon emissions of prefabricated pipe segment structures are 34.09% of the carbon emissions of concealed excavation support structures. It can be seen that prefabricated structures have certain advantages and application prospects in carbon reduction.

3.2 Design scheme for group caves

With the intersection of multiple lines and multi-functional transportation types, stations are currently in a large-scale state. The design of a large space can create a good underground environment, but it will inevitably be accompanied by large-scale earthwork excavation. According to the station function, a dispersed layout scheme of group tunnels is adopted, which is to set up tunnel groups composed of independent tunnels. The support effect of rock walls and slabs between the group tunnels is fully utilized to improve the overall stability of the group tunnels, reduce tunnel excavation volume, and reduce tunnel support costs. Compared with direct excavation of large sections, it has better energy-saving and carbon reduction functions.

Next, relying on the Badaling Great Wall railway station Project of Beijing Zhangjiakou High speed Railway (see Figure 4), and considering different earthwork excavation quantities and tunnel support structures, the carbon emissions of two schemes of single tunnel and group tunnel layout are analyzed. The single hole layout is to design the four tracks, platform, and station hall of the station in a super large span tunnel, with a tunnel excavation span of 44m and a height of 27m. A concrete medium slab is set up in the single tunnel, with the upper layer being the station hall layer and the lower layer being the platform layer. The layout scheme of group tunnels is to set independent tunnels to form a group of tunnels according to the Functional requirement of the station. Nine single tunnels are arranged within the range of 90m in length and 44m in width to give full play to their respective functions and make full use of the supporting role of rock walls and slabs between the group tunnels to improve the overall stability of the group tunnels.

The construction process of the above two types of tunnel construction is closely related to carbon emissions and material usage, transportation, and installation. This section considers material usage and carbon emissions from soil and rock excavation.

Based on the design of two types of tunnel sections, the consumption of various materials and the amount of earthwork excavation can be calculated separately. Combined with existing research (Li, 2022), the carbon emission factors for the same material and earthwork excavation can be given, as shown in Table 2 below.

Table 2. Materials and earthwork carbon emission factor.

Material type	carbon emission factor (kg/m ³)	Material usage (m ³)	
		Large-span single-hole tunnel	Group tunnel
earth-rock excavation	17.95	972.58	831.85
C40 concrete	432.29	348.61	116.21

Based on Table 1 and Equation (1) above, the emission of a single large-span tunnel is calculated to be 168182.92kg, and the emission of a group tunnel is 65,167.33kg.

The carbon emissions of group tunnel are 38.75% of the carbon emissions of single tunnel. It can be seen that group tunnel has certain advantages and application prospects in carbon reduction.

3.3 Green retaining wall design of side slope

Gebin ecological retaining walls are used as retaining structures for tunnel slopes, waste disposal areas, and other structures. On the one hand, they can maintain the stability of the stacked waste soil, and on the other hand, they can penetrate water and provide necessary growth beds for vegetation growth, laying a solid foundation for surface environmental greening. Choosing the waste soil from tunnel excavation as the filling material in the gabion not only achieves the reuse of waste soil, but also saves the production of traditional concrete retaining walls, which has important prospects for carbon reduction applications. Below is an example to show the carbon reduction situation of Gebin Ecological Barrier.

Design Overview: The retaining wall is 10m long and 8m high, with a base width of 4.5m and a cross-sectional area of 22.5m². The total filling volume of gabion is 225m³. The size of the Gebin unit is 2m × 1m × 1m, mesh size 8cm × 10cm, steel wire diameter 2.7/3.7mm, coated with Galfan and plastic. The density of gabion is 9.5kg/m³, and the equivalent density of filled stone is 1750kg/m³. The traditional plan considers concrete retaining walls with a R_{ck} rating of 45, an equivalent cross-sectional area of 18.9m², and a total filling volume of 189m³.

The transportation of materials for two types of retaining walls also has carbon emissions. Generally,

when using tunnel waste, the transportation distance of waste slag for Gebin ecological retaining walls is smaller than that of traditional concrete retaining wall materials. Therefore, the carbon generated by material transportation for Gebin ecological retaining walls is smaller than that of traditional concrete methods. Due to significant differences in transportation distances between different projects, the carbon emissions during the material transportation process of the two options will be ignored in the following text.

According to research results (Wang, 2012; Zhang, 2018), the carbon emission factors per unit of building materials (1m^3 concrete, 1t steel, 1t PVC) required for the two types of retaining walls are 363.7kg, 2062.4kg, and 9019.1kg, respectively.

The source of stone used to fill the mesh box in the retaining wall in the case is the waste slag from the tunnel. The total amount of stone to be filled (considering a 5% loss) is $225\text{m}^3 \times 1750\text{kg}/\text{m}^3 \times 1.05=413.44\text{t}$, the total amount of gabion (considering 5% loss) is $225\text{m}^3 \times 9.5\text{kg}/\text{m}^3 \times 1.05=2.24\text{t}$, the total amount of concrete required for traditional concrete retaining walls (considering 5% loss) is $189\text{m}^3 \times 2300\text{kg}/\text{m}^3 \times 1.05=456.44\text{t}$.

According to equation (1), the carbon emissions of Gebin ecological retaining wall and traditional concrete retaining wall are calculated to be 617.8kg/m and 7217.7kg/m, respectively. The carbon emissions of Gebin ecological barrier walls are only 8.6% of the carbon emissions of traditional concrete barriers, reducing carbon emissions by over 90%. It can be seen that the Gebin ecological barrier has good carbon reduction and environmental protection effects.

3.4 Design of green operation mode for stations

During the operation of the station, energy will be consumed. Taking Beijing as an example, the total annual power consumption of the operating network in early 2020 was 2.19 billion kilowatt hours, including train traction, power lighting, and station energy consumption. Scholars have conducted explorations on low-carbon and green operation models from the perspectives of train operation management mode (Yu, 2022), introduction of green and clean energy such as photovoltaic power generation or ground source heat pumps (Zhu, 2021), and low-carbon design of equipment such as vehicles, ventilation, and air conditioning (Li, 2022).

From this, it can be seen that there is still great room for improvement in green operation of stations, especially underground stations. Research on station energy consumption shows that the energy consumption of ventilation and air conditioning systems, lighting equipment, and escalators accounts for over 80% of the station's energy consumption (Shi, 2022). For underground stations, combining the characteristics of warm winter and cool summer in the ground, utilizing the train piston wind effect to transfer the heat from the ground into the station space can effectively reduce energy consumption

and carbon emissions in terms of temperature control; Stations can also reduce energy consumption and carbon emissions in terms of station lighting by adopting photovoltaic power generation, introducing intelligent lighting systems, and cleverly utilizing ground light; The introduction of intelligent control systems for large-scale equipment can intelligently control the operation of equipment based on passenger flow characteristics, achieving manned operation and unmanned suspension, effectively reducing energy consumption and carbon emissions.

4 LOW CARBON DESIGN PRACTICE - TAKING THE BEIJING ZHANGJIAKOU HIGH SPEED RAILWAY AS AN EXAMPLE

Relying on Beijing Zhangjiakou High speed Railway, the application effect of typical carbon reduction design concept is introduced from four aspects: Tsinghua Garden Tunnel, New Badaling Tunnel and Badaling Great Wall railway station, slope green protection, and energy saving operation mode of Badaling Great Wall railway station.

4.1 Tsinghua garden tunnel

The Tsinghua Garden Tunnel of Beijing Zhangjiakou High speed Railway is located in Haidian District, Beijing. It enters the ground from the south of Xueyuan South Road to the south of Fifth Ring Road, north of Qinghua East Road, and exits the ground from the south. The total length of the tunnel is 6020 m, with an inner diameter of 11.1 m and an outer diameter of 12.2 m. It successively passes through 7 main municipal roads and 106 important municipal pipelines in total, including Xueyuan South Road, North Third Ring Road, Zhichun Road, North Fourth Ring Road, Chengfu Road, Qinghua East Road, Shuangqing Road, and also passes through 3 subway lines, namely Line 10, Line 12, and Line 15, The entire line runs in close parallel with Metro Line 13, which is currently one of the high-risk large diameter shield tunnels with the highest number of important buildings and structures traversed by China Railway.

During the practice of Tsinghua Garden Tunnel Project, many technologies were adopted based on the low-carbon design concept to reduce carbon emissions. These technologies include low-carbon route selection technology for tunnels, carbon reduction construction technology for shield tunnels based on fully prefabricated assembly, carbon reduction construction technology for deep and large shield wells based on permanent utilization of underground walls, green environmental protection treatment technology for large-diameter slurry shield tunneling mud, zero water reduction construction technology for tunnels based on grouting sealing. In addition, carbon sinks are further offset by setting up the Jingzhang Site Park on the ground of the tunnel. The application of these low-carbon design technologies helps to reduce the

impact on the environment and promote the development of underground engineering towards a more sustainable and environmentally friendly direction.

4.1.1 *Fully prefabricated structural design*

Tsinghua Garden Tunnel shield segments, structures under the track and auxiliary grooves are all prefabricated and assembled structures. It is the first tunnel in China that has been fully prefabricated and assembled, and an assembly robot has been developed, which has realized the industrialized, mechanized, professional and intelligent construction of shield segments, structures under the track and auxiliary grooves.

Compared with cast-in-place structures, prefabricated structures are produced in a factory with better curing conditions, higher concrete strength, and better quality, resulting in less material usage; Secondly, centralized manufacturing and maintenance of prefabricated structures result in low material loss and low energy consumption for measures; Thirdly, the prefabricated structure saves a lot of template consumption and energy consumption during template installation and dismantling. In addition, the prefabricated structure also avoids dust and wastewater pollution generated by cast-in-place construction. The calculation and analysis show that the carbon emission of prefabricated structure is 246.4kg/m less than that of cast-in-place structure, the shield section of Tsinghua Garden Tunnel is 4.45km long, and the carbon emission of prefabricated structure under track is 1096.5t less. After the promotion of this technology, based on the planned length of 387km of railway shield tunneling, it will reduce carbon emissions by 95,300 tons.

4.1.2 *Increase in surface greening area*

The Tsinghua Garden Tunnel eliminates the division of the old Beijing-Zhangjiakou Railway from the city, and cancels the level crossings such as Sidaokou and Wudaokou, which significantly reduces the traffic congestion in the area and reduces the automobile exhaust emissions. In the fifth ring road of Beijing Zhangjiakou High speed Railway, large diameter shield tunnels are used to penetrate the urban core area. At the same time, the old Beijing-Zhangjiakou Railway ground line is demolished and transformed into Beijing Zhangjiakou Heritage Park and urban green belt, integrating tunnel construction into urban development, significantly reducing noise and vibration pollution, and releasing urban space. The planned Jingzhang Ruins Park is 9km long and about 20m wide, adding 180000 square meters of green belt area to Beijing, with an annual carbon sequestration of over 2000 tons.

4.2 *New badaling tunnel and badaling great wall railway station*

The new Badaling Tunnel is a control project of the whole line of Beijing-Zhangjiakou Railway, with

a total length of 12.01km. It continuously passes through Juyong Pass, Shuiguan, Badaling Great Wall and other important scenic spots, passes through the Great Wall three times, and passes through the century old Beijing Zhangjiakou Railway and Shifosi Village with ultra shallow burial. It is the longest tunnel along the line, the most stringent environmental protection requirements, and the most tense construction period.

Badaling Great Wall railway station is an underground station in the Badaling Tunnel, located below the Guntiangou Parking Lot in Badaling, Yanqing, Beijing, and adjacent to Badaling Great Wall. The station has a total length of 470m, a total width of 80m, an underground construction area of 398,500 square meters, a buried depth of 102m on the track surface, and a passenger lifting height of 62m. It is currently the largest high-speed railway underground station in China in terms of burial depth and lifting height; The most complex underground excavation tunnel group station in China currently has multiple levels of stations, a large number of tunnels, complex tunnel types, and dense intersection nodes; The single tunnel excavation span of the crossover section at both ends of the station reaches 32.7m, making it the largest single arch excavated railway tunnel in China.

In the design process of Badaling Great Wall railway station, a number of low-carbon design technologies were applied to reduce carbon emissions and improve environmental protection. These technologies include: green line selection technology of underground station line, green design technology of underground station building selection, low-carbon construction technology of tunnel based on self-bearing of surrounding rock, groundwater cleaning and sewage separation drainage and sewage treatment technology of water source protection area, air dust removal and purification technology of tunnel in scenic spot, reduction and recycling technology of tunnel spoil, energy saving and emission reduction technology of underground station making full use of ground temperature, train piston wind and solar energy, and green design technology of underground engineering blanking. Through the application of these low-carbon design technologies, the construction of Badaling Great Wall railway station has greatly reduced the impact on the environment and reduced a lot of carbon emissions.

4.2.1 *Optimization of station location selection*

Based on the green route selection technology of underground station line, Badaling railway station has studied three station schemes, namely Guntiangou, Chadaocheng underground station and Chengjiayao ground station. The distance from the entrance of the Great Wall Trail is approximately 6km from the ground station and 2km from the underground station of Chadaocheng; Guntiangou Underground Station is only 250m away from the Great Wall Cableway Dengcheng Pass and 800m

away from the Great Wall Walkway Dengcheng Pass, which is 6km shorter than the ground station. This plan is to set up a station underground at the entrance of Badaling. It takes only 30 minutes for tourists to travel from the urban area to the scenic spot by car. Therefore, a large number of tourists give up taking buses and minibuses and choose to take high-speed rail to visit the scenic spot. According to the annual transport of 2.6 million tourists and the average travel distance of 70 kilometers, the carbon emissions of Badaling tourists alone will be reduced by 1820 tons each year.

4.2.2 Station architectural design plan

During the design period, the advantages and disadvantages of 9 layout schemes, including single tunnel, triple arch, three tunnels, dome, and group tunnels, were compared and analyzed. The carbon emission analysis of each scheme was also supplemented. Now, an example is given to compare the carbon emissions of single tunnel centralized layout and group tunnel dispersed layout.

The single-hole centralized arrangement (referred to as the large-span scheme) is to design the four-lane, platform and station hall of the station in a super-large-span tunnel. The tunnel excavation span reaches 44 m and the height reaches 27 m. A concrete medium plate is set up in the large-span tunnel, the upper layer is the station hall layer, and the lower layer is the platform layer. The scattered layout scheme of group holes is to set up independent tunnels to form a tunnel group according to the functional requirements of the station, and make full use of the supporting role of rock walls and rock plates between the group holes to improve the overall stability of the group holes.

Comparing the two schemes, the emission of a single tunnel with a large span is 182.8 t/m; The emission of group tunnel is 77.8 t/m; The carbon emissions of group tunnel are 42.57% of the carbon emissions of single tunnel. The large span scheme has an excavation area of 1023.7m²/m per linear meter, while the group tunnel scheme has an excavation area of 844.8m²/m per linear meter. The station platform is 450m long, and the dispersed arrangement scheme of group tunnels reduces rock excavation by 80000 m³ compared to the centralized arrangement scheme of single tunnels, saving energy consumption for slag transportation and land for slag stacking, and reducing carbon emissions during the construction period by about 17000 tons.

4.2.3 Optimization of structural design methods

Due to the need of setting the crossover line, the excavation span of the tunnel at both ends of the Badaling Great Wall Station is 32.7 m, and the excavation area is 418.9 m². According to the collapse arch theory, the thickness of the secondary lining of the tunnel reaches 2m, the excavation span of the tunnel will increase to 36.3m, and the excavation area of the tunnel will reach 622.9m². Low-carbon construction technology

of tunnel based on self-bearing of surrounding rock. The self-bearing theory of surrounding rock of super-long-span tunnel, the component design method of bearing arch of surrounding rock, the self-bearing support measures of pre-stressed anchor net supporting rock shell and the excavation method of super-long-span tunnel are put forward. The self-bearing of surrounding rock is realized. The new method has reduced the tunnel span by 8%, the excavation area by 20%, and the lining thickness by 70%.The thickness of secondary lining is successfully reduced to 0.6m, and the excavation per meter of the maximum span is reduced by 125.77m². In total, the excavation amount is reduced by 20,500 m³, and the carbon emission is reduced by 4400 tons.

4.2.4 Station stealth design scheme

The Badaling Great Wall Station is located in the world cultural heritage protection area. How to realize the station function, facilitate the convenient travel of tourists, and avoid the impact on the scenic environment, and integrate with the natural and cultural landscape is the focus of design thinking. In order to shorten the travel distance of tourists as much as possible and reduce the damage to the surface vegetation of the scenic spot, the tunnel method is adopted to cross the scenic spot. The Badaling Great Wall Station adopts the underground station scheme, and the only surface entrance and exit top is also covered with green vegetation. Reduce the area of 40,500 m², the annual increase in carbon sinks of about 1500 tons.

5 CONCLUSIONS

With the implementation of China 's carbon emission and carbon neutralization strategy, reducing carbon emission has gradually become the goal of engineering construction. The calculation method of engineering carbon emission is given, and the low-carbon design concept and method of tunnel and underground engineering are put forward. Based on the case of Beijing-Zhangjiakou high-speed railway, the effect of the above low-carbon design scheme is analyzed. Through the above research, the main conclusions are as follows:

- (1) The calculation method of carbon emission coefficient in three different stages of survey and design, construction and operation in tunnel and underground engineering is established.
- (2) The carbon emission law in the construction process of tunnel and underground engineering is analyzed. The material carbon emission of supporting structure accounts for a large proportion in the construction process.
- (3) The low-carbon design concept of tunnel and underground engineering is put forward, including the application of prefabricated structure, the design scheme of group hole layout, gabion ecological retaining wall such as side slope,

ventilation, lighting and green operation of large facilities in underground stations.

- (4) Combined with engineering cases, the rationality of low-carbon design of prefabricated structure replacing cast-in-place structure and group hole arrangement replacing single hole large section scheme is compared and analyzed.
- (5) The implementation of the Beijing-Zhangjiakou high-speed railway case shows that the proposed low-carbon design concept of tunnel and underground engineering has a good application prospect.

Design of the REM Aéroport de Montreal's P5 Ventilation shaft

Michael Mains*

AECOM, Burnaby, Canada

Jaeseoung Lee & Verya Nasri

AECOM, New York, USA

ABSTRACT: The Réseau Express Métropolitain (REM) is a new 67km automated light rail project with 26 new stations. It is the largest project undertaken by the City of Montreal in over 50 years and once completed will be 4th largest automated network in the world. The ADM P5 shaft is located at the western terminus of the project's underground airport branch, which consists of two underground stations, and roughly 250m of cut and cover, 3 km of TBM, and 300m of drill and blast tunnels. The shaft is approximately 42m deep with a challenging 24m in soft saturated soils overlying limestone and shale bedrocks. The shaft was designed using deep internally braced and permanent secant pile walls over bolt supported rocks. The innovative approach of integrating the ground support into the permanent structure with a novel semi-drained design allowed for an accelerated construction schedule, reduced carbon footprint, and significant savings in material quantities and costs. This paper presents the state-of-the-art design approach of the P5 shaft, and the innovative solutions employed to overcome complex site and geo-structural conditions.

Keywords: Deep Excavation Design, Permanent Secant Piles, Rock Support, Airport Tunnel

1 INTRODUCTION

The Réseau Express Métropolitain (REM) is a new regional light rail project located in the City of Montreal, Canada. The project adds 67km of new double track and 26 new stations and will connect Montreal's South Shore, North Shore, West Island, and the Pierre-Elliott Trudeau International Airport with the city's downtown core. The project, illustrated in Figure 1) effectively doubles Montreal's existing metro network which, for context, consists of roughly 70km of double track across four lines. The project has been widely recognized for its numerous innovations not only from a project delivery and finance perspective, but also

Figure 1. REM key plan with P5 Shaft location identified.

from an engineering and technical perspective. Among these innovations is the design and construction of the project's P5 Ventilation shaft located at the Pierre-Elliott Trudeau Airport (denoted herein as the ADM P5 Shaft). This paper provides an overview of the shaft's design and the innovations implemented to overcome significant site and geologic constraints.

2 CONTEXT

2.1 Project location

The ADM P5 shaft is located at the end of the approximately 3km long EPB TBM tunnel which makes up the project's underground airport branch. The shaft is one of three underground structures on this branch (the other two being stations) and serves as one of two ventilation points for the entire tunnel branch of the project. A more detailed plan of the airport branch alignment is shown in Figure 2 below.

2.2 Geological and hydrogeological setting

The subsurface conditions at the P5 shaft location consists of approximately 20m of soft saturated soils overlying bedrock with a groundwater table located approximately 7m below grade. The upper soft ground stratigraphy consists of approximately 3m of fill over

*Corresponding author: Mike.Mains@AECOM.com

Figure 2. REM airport branch alignment.

5m of soft clayey silt with SPT N values in the range of 0 to 2. The soft clay overlays a more competent 10 to 12m thick layer of dense gravel/sand and/or glacial till with SPT N values in the order of 28 to 64.

The rock horizon is located at a depth of approximately 20m. The top 4 to 5m of rock is highly weathered and consists of very poor quality calcareous shale with limestone bands and an RQD in the range of 0 to 48%. For the purposes of design, this upper 5m of rock is treated as soil. The rock underlying the weathered zone is competent and consists of approximately 50% limestone and 50% bedded shale with RQD in the range of 88% to 100%.

3 DESCRIPTION OF THE ADM P5 STRUCTURE

The ADM P5 shaft consists of one level of above grade superstructure and nine underground levels which contain six floors of mechanical and electrical equipment, most notably two jet fan and damping systems for tunnel ventilation each weighing over 34 tonnes. The bottom of the shaft connects to the turn-back tunnel of the REM airport station located roughly 300m away. The shaft had to be designed to accommodate a strict over height restriction of 18m during construction and an encroachment limit of only 5m beyond the structure's perimeter due to its location at the airport. The structure is rectangular in plan with a rough footprint of 21m long by 18m wide.

3.1 Support of Excavation (SOE)

The shaft required an approximate 42m deep excavation, 24m of which was in soft soils and very poor-quality rock. Due to the higher permeability and relatively shallow groundwater, the support of excavation in this softer ground had to consist of a watertight shoring system. Further, strict encroachment limitations prevented the use of tie-backs and forced an internal bracing to support ground loads.

Ultimately 22m long secant piles with concrete walers, braced internally with temporary pipe struts was selected as the most appropriate SOE solution. The secant piles would be installed from a 3m deep pre-excavated platform to reach a total depth of 25m from surface. The reinforcement in each secondary pile would then be extended 3m upward and encased in a cast-in-place concrete wall so that grade could be reinstated to its original level. The secant piles were embedded 1.0m into the underlying competent rock and a 1.0m rock bench was left in place to aid toe anchors in ensuring stability of the pile toe.

Figure 3. SOE system for the ADM P5 shaft.

The bottom 17m of excavation was in competent bedrock and could be supported by much lighter support consisting of 4m long CT rock bolts spaced at 1.8m to 2.5m center with 100mm of steel fiber reinforced shotcrete.

3.2 Permanent structure

The internal structure consists of a multi-level steel structure, with all the levels being underground except the first floor which is above grade to provide the access to the shaft. The main lateral force resisting systems are moment frames in both directions for the above grade structure and direct load transfer to the ground for the below grade structure. An isometric view of the permanent structure is shown in Figure 4.

One of the major innovations of the P5 shaft design was to incorporate the secant piles, walers, and rock support into the permanent structure and to provide a "semi-drained" structure. The design team recognized early on that providing a fully tanked

Figure 4. Isometric view of the P5 permanent structure.

below grade structure designed to support 35m of hydrostatic pressure would lead to prohibitively large structural elements. On the other hand, a fully drained structure would require constant and permanent dewatering and would lead to prohibitively large operating costs over the life of the structure.

The solution ultimately adopted was to fully waterproof the upper 25m of the shaft while leaving the underlying rock portion drained. A steel girder system would provide both the lateral capacity for ground, seismic and hydrostatic loads as well as carry all gravity loads for the upper five floors. The underlying rock's hydraulic conductivity was low enough that relieving hydrostatic pressures would require a very low flow rate that could be easily managed throughout the life of the structure. Thus, no ground or hydrostatic loads needed to be carried by the lowest four levels of structural framing if this portion of the shaft was drained. The only lateral loads experienced by the steel frame in rock are those resulting from restraining seismic drift of the structure thereby allowing a considerable reduction in all structural elements in this lower half of the shaft.

This allowed for the SOE system to be incorporated into the final structure which led to significant material cost savings, allowed for an accelerated construction schedule, and lowered the carbon footprint of the structure.

4 DESIGN

The ADM P5 Shaft has been designed according to Load and Resistance Factor Design (LRFD) for a design life of 125 years. The design process was a collaborative effort between the architectural, MEP, structural, and geotechnical disciplines. All coordination was done through a regularly updated and clash detection BIM model covering all disciplines. Since the majority of the structural elements serve both as temporary SOE as well as permanent structure, the final structural design had to be fast-tracked. Normally in a design-build context, it is

beneficial to begin construction of the temporary SOE while design of the final structure proceeds concurrently. For the ADM P5 shaft, all later stage analyses like seismic, special case loads, and detailing had to be fully flushed out prior to construction of any element of the shaft. Collaboration in the BIM environment and weekly coordination meeting allowed the design team to arrive at the final design configuration in the least possible number of iterations.

4.1 3D Soil-Structure Interaction (SSI)

Upon completion of the architectural design along with some preliminary sizing of structural members, it was possible to determine the minimum space proofing required for the shaft excavation. This allowed the SSI to proceed in parallel to the permanent structure design thereby fast tracking the design of the overall structure.

The SSI modelling, using PLAXIS 3D as shown in Figure 5, confirmed the stability of the excavation, predicted excavation induced deformations, and allowed for the determination of structural demands throughout the entire excavation sequence.

Figure 5. 3D plaxis model.

Two SSI models were developed. The first model was carried out with the secant piles modelled as linear elastic plates with isotropic stiffnesses. This model approximated more or less the real "global" behaviour of the shaft and was thus considered suitable for the deformation analyses. However, a limitation of the linear-elastic constitutive model is that secant pile plate will continue to pick up load regardless of whether the structural capacity of that element is exceeded. Secant piles have very high bending resistance about the horizontal axis but have very little bending capacity about the vertical axis. It is, therefore, necessary to prevent the secant pile plates in the model from spanning between the shaft

corners and artificially lowering the structural demands in the walers. Thus, a second model where the k_{22} stiffness was set to a negligible value to ensure that all bending about the vertical axis is concentrated on the walers and that the correct forces would be considered in design. The moment and shear envelopes in the scant pile wall as well as the strut loads of this second model were then extracted and used in the structural calculations. The directionality of bending stiffness is illustrated in Figure 6.

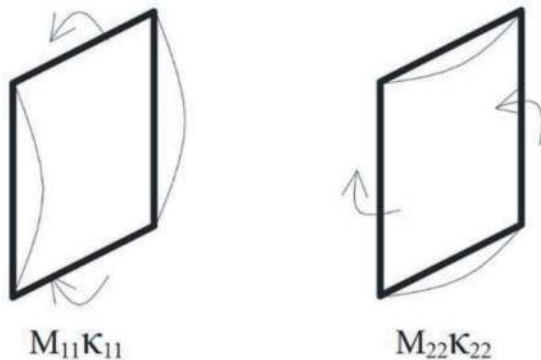

Figure 6. Schematic of bending stiffness in the wall plate.

4.2 Secant pile wall design

The secant pile wall consists of alternating unreinforced primary piles and W610 reinforced secondary piles with an average center to center pile spacing of 700 mm.

Figure 7. Typical secant pile layout.

The structural capacity of the secant piles was verified against the forces extracted from the SSI model as well as those extracted from a secondary limit equilibrium model which accounted for a seismic load case. Two approaches were used. The first was to treat the secant pile like a composite concrete and steel column subject to both bending and compression. The second approach was to verify the concrete and wide flanges independently using a strain compatibility approach.

Similar to a traditionally reinforced concrete beam or column, the compressive forces tended to have a beneficial impact on the capacity of the member when using the composite member approach.

Compression in the secant pile originated from two sources. First were the gravity loads generated

by the structure itself. In the ADM P5 shaft, the gravity loads from the top five levels were transferred directly into the secant pile walls, causing compression. Although these gravity loads were easily calculated, there will always be uncertainty with respect to how fast the gravity loads are shed into the surrounding soils by friction.

The second source of compression was the down-drag originating from negative skin friction. As excavation of the shaft proceeds, the surrounding ground settles and tries to pull the secant pile wall down with it. In the case of the ADM P5 shaft, the toes of the secant piles were socketed into stiff bedrock preventing this downward movement from occurring. This created a compression in the wall.

In the finite element calculation, the assumptions required to be conservative when estimating down-drag were not the same as those required to be conservative when calculating bending moments. For example, higher interface friction between the wall and ground produced higher compression but lower bending forces. Thus, it is often better to ignore compression when using the composite member capacity calculation.

However, with secant pile lengths exceeding 23m, the down-drag compression can be significant and potentially govern when using the strain compatibility method.

Therefore, as a due diligence measure both scenarios (compression and no compression) were verified using both the composite member and strain compatibility approaches.

4.3 Rock support design

Competent rock is located for roughly the bottom 17m of excavation which is supported by 4m long CT rock bolts spaced at 1.8m to 2.5m centres with 100mm of steel fiber reinforced shotcrete.

The rock support was designed both empirically and with the use of the finite element method. The overall stability of the excavation was demonstrated in the 3D SSI model using conservative rock mass properties without modelling the rock reinforcing elements.

Subsequently, the rock reinforcing was design using the empirical method based on the Q system support chart and Barton's (2013) recommendations for shaft support design as shown in Figure 8.

The permeability of the rock was very low, except for at localized joints which may produce higher levels of seepage. The rock support is treated as a drained system and to prevent hydrostatic build-up, infiltration at these locations is directed down behind the shotcrete to a sump located below the invert slab by way of strip drains. Additionally, a provision for additional injection grouting was included in the design to mitigate the risk of encountering zones with higher-than-expected fracturing and seepage. A spray-on waterproofing membrane (Masterseal 345) was also incorporated into the design to prevent

Figure 8. Rock support selection based on barton (2013).

any dampness from infiltrating into the shaft interior space in the permanent condition.

Similar to the secant pile wall, this reinforced rock perimeter wall is incorporated into the final structure, which meant that all elements needed to withstand a 125-year design life. The primary degradation mechanism for rock bolts is corrosion, which was mitigated by using CombiCoat® protected CT-bolts which provide at least a 125-year design life. See Figure 9 for rock support details.

Figure 9. Rock support schematic.

4.4 Permanent structure design

In order to capture the various load states associated with a complex build-out sequence, the permanent steel frame was designed using a combination of 3D structural analysis using the RAM Structural system V17 software with additional 2D frame analyses to model the walers and excavation support frame.

Figure 10. 3D structural model.

The structural frame at each floor in the soft ground portion supports all lateral earth pressure, hydrostatic, and seismic loads. Since the walers are used for both the temporary and permanent conditions, the temporary corner struts at each level had to be installed at the same elevation as the floor frame which would eventually support all lateral loads in the system. Consequently, the walers had to be designed to support these loads with multiple cases of differing support locations in different load and construction scenarios.

To optimize member sizes, compression girders were separated into two categories. First, static members were defined which would carry all lateral loads transferred after removing the temporary corner struts. Second, additional seismic members were added to carry eventual extreme loads cases like seismic, which could be installed after temporary strut removal. Both member types would also act as the principle girders in the gravity load framing. These additional seismic struts were required on two levels since the loads on these two levels generated under the seismic condition were too large to be carried by reasonably sized members as shown in Figure 11.

To design these main strut girder elements, the 3D structural analysis was used to determine the gravity loads and lateral loads required to restrain the seismic drift of the full 45m “tall” structure. Multiple 2D frame analyses of all load scenarios we then

Figure 11. Example lateral support system with static struts shown in red and seismic struts shown in blue.

carried out to determine the axial loads in the struts, including from seismic earth pressures. The results of the 3D and 2D modelling were then used in a combined stress analysis to properly size the lateral support elements.

4.5 Waler design

Concrete walers were designed to support all four levels of internal bracing. Although the supply chains for large steel members were already established for the REM project due to several other steel framed stations on the project nearing completion, large cross-section steel walers would still have been associated with long lead times. Since waler construction was on the critical path, long lead times would cause unacceptable delays to the schedule. Consequently, concrete walers were selected to provide an overall faster construction schedule. Additionally, cast-in-place concrete can more easily accommodate eventual deviations of the secant piles from their theoretical position, thus were more adaptable to the Field condition.

To save space, connections of all temporary and permanent steel elements were embedded into the concrete, as illustrated in Figure 12.

Figure 12. Strut knife plate connection embedded in waler.

4.6 Waterproofing design

The waterproofing system at the ADM shaft was designed using two philosophies. The upper secant pile portion of the shaft is, in theory, already watertight. However, eventual defects can potentially be found at the joints between primary and secondary piles which can cause minor leakage. Thus, the secant piles are first covered with an initial layer of shotcrete to preserve the pile's concrete. Strips of Delta Drain MS-20 are then placed at all joints to direct any eventual leakage down to an internal drainage system inside the shaft. Since the shaft's primary use is for MEP support equipment, two additional protections in the form of a Dolenco Drain mat and an impermeable layer of Masterseal 345 is layered on top of the drain to protect the shaft from dampness. The waterproofing is then capped with an additional layer of shotcrete for durability. Figure 13 provides a cross section of this configuration.

A similar system was implemented in the lower rock portions of the shaft. Since this part of the project was drained, all seepage captured by the drain mat could be carried down below the invert slab, which is underlain by 600mm of free draining gravel fill. This under-slab drainage directs water to a 2.5m deep sump from which it can be pumped-out of the shaft to the storm water discharge system.

Figure 13. Waterproofing system in secant pile shaft.

5 CONCLUSIONS

The design of the REM ADM P5 Ventilation Shaft was a particularly interesting endeavor due to its significant depth and limited working area. Its location at the Pierre-Elliott Trudeau International Airport imposed strict height and encroachment restrictions which in large part drove some of the fundamental principles of the design. The design of the SOE and permanent structure also had to incorporate potential construction issues such as supply chain influences and secant pile installation tolerances.

The design team was not only able to accommodate these challenges, but also implemented considerable innovations such as a novel “semi-drained” shaft condition and the incorporation of SOE elements into the permanent structure design.

The project demonstrated how strong collaboration between engineering disciplines and innovation in design can lead to significant benefits in cost and schedule for a project even when the design schedule is fast-tracked.

Tunnels and stations design of Montreal Blue Line

Verya Nasri*

AECOM, New York, USA

ABSTRACT: The development of the Montreal metro Line 5 also known as Blue Line Extension toward the northeast are located between the existing Saint-Michel station and Anjou. It consists of 6-km long single double track tunnel, five new stations and six auxiliary structures. Most of tunnel length (5.5 km) will be excavated by a 9.6 m diameter shielded rock TBM and supported by a precast segmental tunnel lining system. Based on the project master schedule, the five stations will be built first and then the TBM will skid through the already built stations. For the inter-station tunnels, the shielded rock TBM excavation method with segmental liner installation was selected based on the existing geotechnical challenges, evaluation of the project construction cost, schedule and risk, noise, and vibration. TBM will be fitted for probing and pre-excavation grouting to control water inflow into the tunnel during the excavation in fractured limestone and shale formation under the downtown of Montreal where lower rock quality and high water infiltration rates are anticipated. The latest development in segmental liner technology and the latest segmental liner design code ACI PRC-533.5-20 were used for the design of the tunnel segmental liner of this project. The stations and auxiliary structures will be built using the controlled drill and blast method or roadheader. Two thin layers of shotcrete separated by a layer of spray on membrane will be used as the initial and final liner of the stations and auxiliary structures resulting in significant construction cost and time savings. This paper presents major design aspects of the TBM tunnel and mined station caverns of this major project in Montreal, Canada.

Keywords: TBM Tunnel, NATM Tunnel, Rock Cavern, Shaft, Transit Tunnel, Sustainability

1 INTRODUCTION

The extension of the Blue Line metro is an integral part of the Montreal strategic plan for the development of public transit (Nasri, et al., 2023). The Société de Transport de Montréal (STM) plays the role of public body initiating and managing the project. This major infrastructure project provides for the addition of five underground stations and seven auxiliary structures connected by nearly 6.0 kilometers of a double track tunnel (Bakhshi and Nasri, 2022). It also includes an underground storage track and maintenance facility. The project cost is estimated at about \$6.4 billion CAD and its expected service date is in 2029. For the first time in North America, Blue Line extension metro system is designed with a single side-by-side track tunnel without a separating center wall. This will be the first use of a TBM in the history of the STM which will speed up the excavation process, reduce noise and vibration impacts and contribute to the infrastructure quality of extended section of Blue Line.

The extension of the Blue Line of the Montreal metro will allow approximately 25,600 users during

the morning peak period to benefit from a reliable and fast service, and above all from improved access to the infrastructure network of public transport. This will be equivalent to removing 5,300 cars from the city streets and reducing the travel time between the two ends from currently 40 minutes by bus to only 15 minutes. Each station will have a main entrance and a secondary entrance located diagonally at each of the intersections and connected by underground pedestrian walkways. To ensure that they are universally accessible, the stations will all be equipped with escalators and elevators in main entrances. The final design of the project is completed, and the underground work package is now out for bid.

Construction will begin with underground stations and auxiliary structures, followed by the excavation of tunnels to connect them. Most of the tunnel (5.5 km) will be excavated by a 9.6 m diameter shielded rock TBM and supported by precast segmental lining system and a segment of the tunnel (about 0.5 km) will be excavated by roadheader and supported by shotcrete initial and final liners. The underground stations and

*Corresponding author: verya.nasri@aecom.com

auxiliary structures shafts will be excavated by drill and blast method and their tunnels will be mined using roadheader and supported by shotcrete initial and final liners following the New Montreal Tunneling Method used in the construction of REM project (Nasri et al., 2021). Figure 1 shows the layout of the tunnel, underground stations, and auxiliary structures.

2 GEOLOGICAL SETTINGS

Based on the geological map of the island of Montreal and as shown in Figure 2, the project route would be in the following geological formations

- Deschambault formation only for the small portion of the tunnel in the south.
- Montreal (Saint Michel and Rosemont members) formation.
- Tetreauville formation in the north.
- Intrusive in the form of dykes and/or sills which can be present in the rock mass randomly.

The Deschambault formation consists typically of a bioclastic crystalline limestone, thick-bedded, cross-bedded, containing several coquina and fragmented shell beds. Limestone is light grey to dark, slightly brown, and varies from very fine to very coarse grained. Bedding is irregular and the numerous basins and tabular cross bedding are accentuated by the presence of argillaceous laminae. Otherwise, shale beds are sparse or non-existent, although more present at the top of the formation.

The Montreal Formation is predominantly limestone with thin shale interbeds. It is made up of a wide variety of lithologies (semi-crystalline, micritic or crystalline limestones), but clayey limestone in thin and irregular beds and very bioturbated predominates. The formation is subdivided into two wildlife areas corresponding to two members: the member of Saint-Michel at the base, and the member of Rosemont at the top. The Rosemont member is defined as the upper member of the Montreal Formation. The Rosemont member is mainly composed of limestone with thin interbedded shale. It consists of a wide variety of lithologies (semi-crystalline, micritic or crystalline limestones), but typically includes argillaceous limestone with wavy bedding. Its chemical composition indicates that it is slightly dolomitic.

The Tetreauville formation consists of a dense, dark bluish gray limestone, occurring in beds of 2 to 15 cm, alternating with beds of shales of 2 to 6 cm. The limestone is clayey, micritic, clean and in places contains crystalline lenses a few centimetres thick. Generally, the shale and limestone beds are very clearly separated from each other, which distinguishes this formation from other units of the Trenton group. When exposed to air, limestone takes on a characteristic light yellowish colour. In several places, a strong smell of petroleum emanates from the rock.

Figure 1. Layout of the tunnel, underground stations, auxiliary structures, and the tunnel section.

The intrusive rocks mainly include gabbro, syenites and carbonatites. They occur in the form of sills and dykes that are distributed randomly in the surrounding sedimentary rocks. When intact, these rocks are generally more resistant and more abrasive than their sedimentary host to which they have sometimes induced a slight contact metamorphism.

The sedimentary formations in Montreal area form a series of open northeast/southwest trending synclinal and anticlinal folds characterized by shallow dips. The project is located along the southeast flank of the Villeray anticline, parallel to its axis that is plunging towards northeast. Given the structural complexity of the Island of Montreal and the probable extension of the pre-identified faults (named Saint-Vincent-de-Paul I and II), these faults could potentially be encountered along the northern part of the tunnel route. There are signs of a glaciotectionic phenomenon in the area of one of the auxiliary structures which causes tilting of large rock fragments from 1 to more than 3 m thick.

Except a few meters of fractured/weathered zone observed on the top of the bedrock and at the locations of localized fractured zones, the rockmass is competent in general with RQD > 75. The quality of bedrock usually gets better with increase in depth due to increase in fracture spacing. In the competent rock mass, the discontinuities have fair to good surface quality. Based on the Rock Mass Rating (RMR) Classification system, the rockmass is mostly classified as Classes II and III, with occasional Class IV. Using the Geological Strength Index (GSI) rockmass

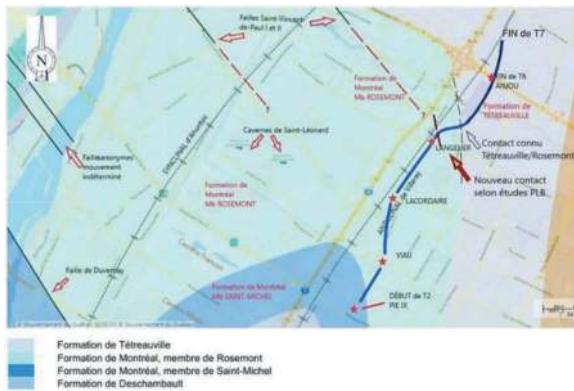

Figure 2. Geological Map of the project route.

characterization method, the GSI of the rockmass varies in the range of 47-77, corresponding to the RMR Classes of III to II.

The results of laboratory tests on intact rock samples give the average range of values of 25-27 KN/m³, 90-120 MPa, 40-50 GPa, and 0.8-1 for Unit Weight, Uniaxial Compressive Strength, Young Modulus, and Cerchar Abrasivity Index, respectively. The groundwater table is approximately at the interface of soil and rock. The hydraulic conductivity varies between 4×10^{-4} cm/sec to 1×10^{-6} cm/sec. Typically, the hydraulic conductivity of rock mass reduces with increasing depth. Majority (about 85%) of Lugeon readings are small (Lugeon values less than 5). High horizontal stress condition is present in Montreal Formation with K_0 in the range of 1.5-2.5.

3 PRECAST SEGMENTAL LINING

The rolling stock used for this project are running on pneumatic wheels and are energized by third rail. The internal diameter of the tunnel is determined as 8,600 mm considering construction tolerance of 100 mm on the radius. This tolerance which is required by ACI 533.5R-20 includes production tolerances of segments, tolerances of placement of ring centrelines and ring ovalization following the ring erection. For TBM tunnel, a watertight circular one-pass lining system with precast concrete segmental rings is adopted. The size of the segmental ring is defined by the internal diameter, thickness, and length of the ring. The internal diameter of the tunnel is determined as 8,600 mm after the space-proofing exercise. The thickness of segments is initially considered as 350 mm, which was validated for structural capacity against all governing load cases. Length of the segmental rings is 1.80 m, which was optimized considering the alignment curvature (curve radius of 250 m) and the efficiency of tunnel works. As shown in Figure 3, the ring geometry consists of seven (7) ordinary segments and one small key segment, almost 1/3rd of the size of the ordinary segments. This configuration is

referred to as a 7+1 ring. The arc angle and curved length of the reverse key segment are designed slightly smaller than other ordinary segments. Consequently, the arc angle and curved length of the key segment is slightly larger than one-third (1/3rd) of the ordinary segments. Together with tapered longitudinal joints of segments, this optimized design inherently prevents creation of crucifix joints in the tunnel, despite all relative rotations of the ring during TBM navigation of curve and tangent drives (Figure 4). To create staggered longitudinal joints, the angles between ordinary segment joints and tunnel axis is considered as 80. The ring taper is designed based on the radius of the tightest curve in the alignment, the length of the ring, and the outer diameter of the tunnel. Total ring taper is 100 mm or ± 50 mm at the centreline of the key and reverse-key segments.

The proposed segmental ring geometry and configuration have an important advantage over any other segmental ring configurations. The proposed ring configuration inherently prevents the creation of crucifix joints, which are more susceptible to groundwater leakage. In comparison to ring designs in which some of relative rotations of the ring are prevented to negate crucifix joints, this optimized ring design allows for all possible relative ring rotations. This leads to less deviation from theoretical tunnel alignment, a more accurate lining installation, and less construction tolerances required for the segmental rings, which directly impacts the gasket watertightness resistance and sealing performance of tunnel.

A universal ring system is proposed for the TBM tunnel, and the key segment can be located anywhere in the tunnel for turning the ring into any desired direction: up, down, left, right, and their combinations (Figure 5). The main advantage of this system is the simplification of segment production and ring installation because of the requirement of only one type of formwork set, which yields significant cost savings. The segmental ring geometry is designed as rhomboidal or parallelogrammatical-trapezoidal segments, consisting of ordinary segments in the shape of parallelogram, a normal key, and a reverse key segment in the shape of trapezoid (Figure 4). In comparison with other (i.e. hexagonal, rectangular and trapezoidal systems) systems, the rhomboidal segment system is the most advanced system because it prevents crucifix joints, has a higher sealing performance, features a continuous ring build from bottom to top, and is compatible with a dowel connection system.

The tapered longitudinal joints provide a major advantage over rectangular systems by preventing early gasket friction during segment insertion in the ring assembly phase, which facilitates the use of fast connecting dowels in circumferential joints. Longitudinal and circumferential joints are designed as completely flat joints, which are advantageous for load transfer between the segments and the rings,

compared to other types of joints. In addition, flat joints are proven to have superior sealing performance. Bolt connection was designed for the longitudinal joints and dowels were chosen for connecting rings in the circumferential joints, as these require less construction work for the segment formwork and less manpower in the tunnel during the installation, when the insertion is automatically performed by the TBM erector. The SOF-FAST dowel system was designed and chosen as the dowel connection device system for circumferential joints. This type of dowel reduces construction tolerances and offsets between segments of adjacent rings and limits ring roll and segment stepping, all of which improve gasket performance and reduce the possibility of cracking due to joint misalignment. The gasket for sealing joints between segments is designed as an anchored gasket, which offers a much higher pull-out resistance, compared to a conventional glued gasket system. The designed gasket provides a water pressure resistance exceeding the maximum groundwater pressure in the entire alignment, by accounting for the relaxation factor for tunnel service life (125 years) and any potential gaps and offsets between segment gaskets due to construction tolerances. At the specified gap and offset of 5 mm and 10 mm respectively, the water resistance of the designed gasket profile is 10 bar, which provides a safety factor of more than 3 at the location of maximum groundwater pressure in the alignment.

Figure 3. Geometry and configuration of the segmental ring.

Figure 4. Developed plan on intrados of the ring in tangent alignment.

From the structural design point of view, performed analysis and design procedures follow the

latest ACI codes (ACI 533.5R-20 and ACI 544.7R-16) and the ITA guideline (ITA Report no. 22, 2019), and satisfies the intended objectives of the project during construction and service life of the tunnel. The structural design was carried out using the load and resistance factor design (LRFD) design method recommended by the aforementioned codes. Precast tunnel segments are designed to be made of very high-strength, double hooked-end fibre-reinforced concrete (FRC). FRC segments are superior for crack control and more cost effective overall and are therefore the preferred solution for this project. Minimum compressive strength of the concrete at 28-day and at the time of stripping (demoulding) was designed as 60 MPa and 15 MPa, respectively, to satisfy the structural demand for governing load cases and the durability of the tunnel for its intended service life. An optimized concrete mixture was designed for production of segments to achieve a high early-age strength for stripping (demoulding) and a high-performance concrete for long-term durability. Designed steel fibre satisfies the serviceability requirements by limiting time-dependent effects of creep on crack opening. Ductility requirements are guaranteed in conventional fibre dosages of less than 40 kg/m³, by providing an ultimate bending moment higher than the cracking bending moment. Minimum required fibre content for segment reinforcement of 40 kg/m³ and residual flexural strengths of 4.8 MPa at 28 days and 2.4 MPa at the time of formwork stripping were designed based on the required structural demand, obtained from analysis discussed above.

4 UNDERGROUND STATIONS AND AUXILIARY STRUCTURES

The new line has five underground stations and seven auxiliary structures. The stations have typically a cut and cover main entrance box and a mined tunnel which contains the station side platforms. This tunnel is excavated by roadheader and supported by permanent bolt and shotcrete liner. The auxiliary structures are located between the stations to provide emergency exit according to the NFPA 130 requirements. They are also used to house a tunnel ventilation plant and a tunnel drainage facility. Figure 6 shows a typical underground station and auxiliary structure.

For the support of excavation system, the design included shotcrete with rock bolts. Prior to bolting, a first layer of 5cm of steel fibre reinforced shotcrete, designed specifically for the cold Montreal temperature, is sprayed onto the rock. The rock bolts are installed on top of this first layer. The shotcrete and the bolts represent the initial support of the excavation. Once the rock bolts are installed, a spray-on waterproofing membrane is applied on top of this first shotcrete layer and the rock bolts' end hardware. This is later covered by an additional 5cm of steel

fibre reinforced shotcrete. Figure 7 shows the details of the initial liner with bolt and shotcrete, spray-on waterproofing membrane and the shotcrete final liner. With the spray-on waterproofing membrane, the designed support system represents both the initial and the final liner.

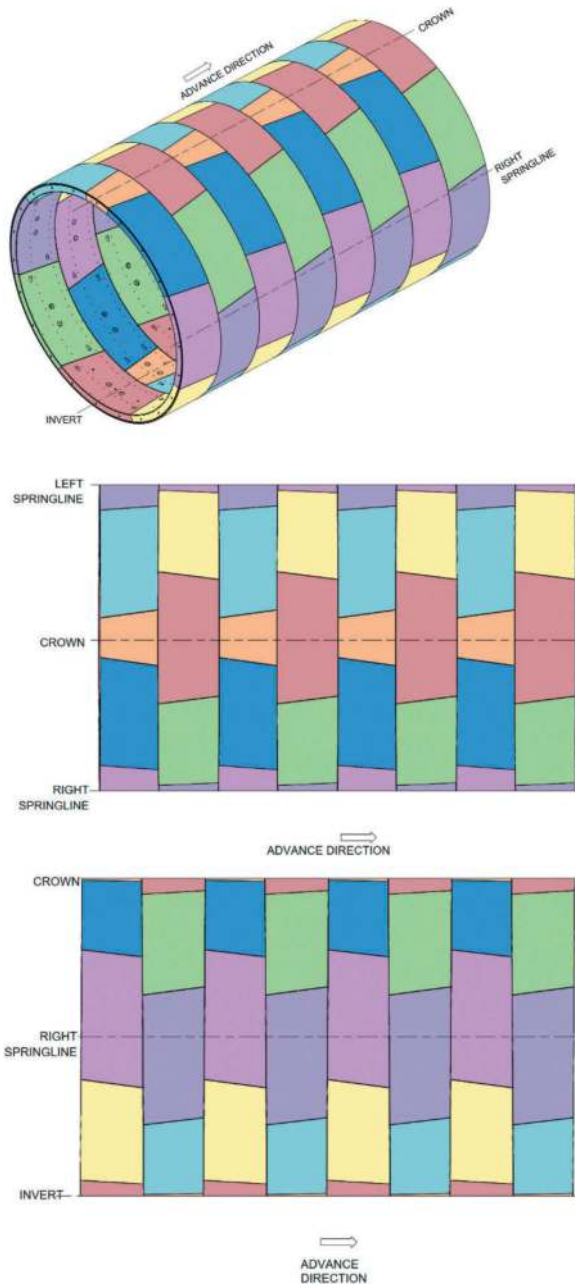

Figure 5. Negotiation of tunnel alignment by rotation of key segment in a tangent drive (from top to bottom, isometric view, plan view, elevation view).

The first use of this configuration in North America was for a pump station cavern in Indianapolis, but the first use of this approach for a major transit station in North America was in the Edouard Montpetit Station, Montreal (Nasri et al., 2020). Advantages of this configuration are numerous, both in

terms of design and constructability, compared to the typical approach consisting of an initial temporary support, a sheet membrane, and a permanent cast in place concrete final liner. Effectively, the initial liner, which would typically be considered only as temporary support, now serves as both temporary and permanent, as this configuration allows load transfer from the initial lining to the final lining. As a result, the overall lining thickness is reduced compared to a typical design. In terms of constructability, the use of a spray-on waterproofing membrane instead of typical sheet membrane represents labour saving, less logistics with no formwork, and is much easier to work with, particularly where excavation configuration varies. Note that the selected spray-on membrane is not well-suited for cases with high water inflow and large water head.

Figure 6. Typical underground station (top) and auxiliary structure (bottom).

Durability has always been a critical factor in the permanent structure design for transit systems. The durability requirements for this project include a lifespan of 125 years. Hence, all materials used as part of the permanent structure and lining had to be selected or designed accordingly.

Durability of the rock bolt is ensured using CombiCoat® protected CT-bolts, as manufactured by Vik Ørsta. The main degradation mechanism for rock bolts is corrosion, against which the protective properties of the CombiCoat® coating system include

hot dip galvanizing, phosphating, and epoxy powder coating. In addition to these protective layers, the rock bolts will be fully grouted, which means that they are not expected to be exposed to oxygen. In terms of durability, these fully grouted CombiCoat® CT-bolts are designed to last at least 150 years as estimated by the research group SINTEF in 2016.

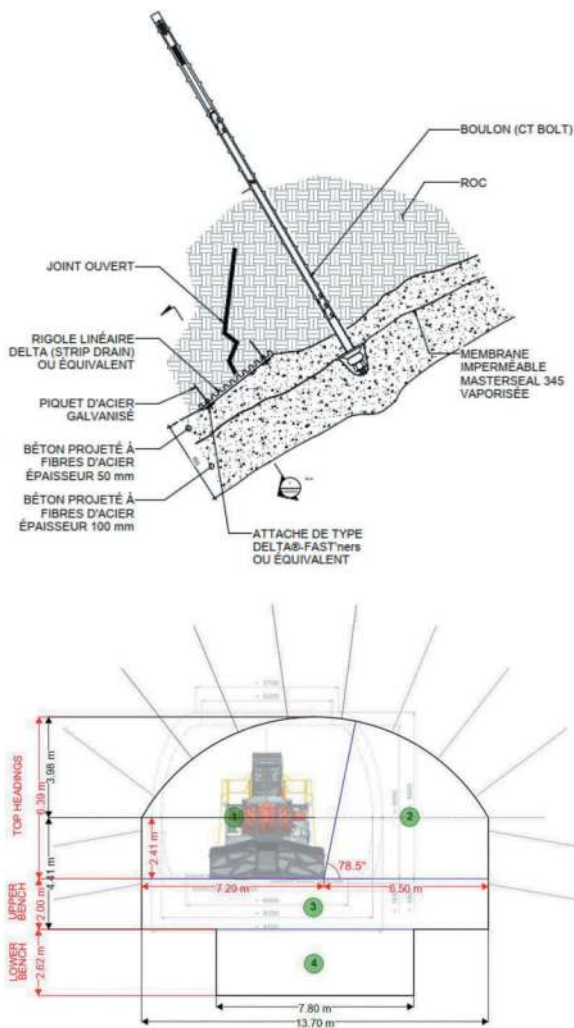

Figure 7. Initial and final liner system (top) and excavation sequence (bottom).

The steel fiber reinforced shotcrete main degradation mechanisms include corrosion of the steel fiber, mainly by the effect of carbonation and the ingress of chlorides, sulfide/acid attack, granular alkali reaction, and freeze and thaw cycles. The durability requirement for this project is higher than the normative ACI or Eurocode standards. As such, the design was developed based on an exposure class type of approach. The mix designs were developed using laboratory-based formulations designed to resist the different degradation mechanisms identified above. The formulations were based on various tests as specified by Fib 34, including ASTM C1202, NT Build 492-99, ASTM C457 and AASHTO TP-95-14.

For waterproofing, MASTERSEAL® 345 spray-on membrane manufactured by BASF was selected for this project since it has been used on numerous tunneling projects with design service life more than 100 years. This membrane is based on a copolymer of ethylene and vinyl acetate mixed with fast setting cement which forms a layer of polymer (plastic) and acts as a barrier against water penetration. Water can diffuse through the membrane in the form of steam, but if water pressure is applied, the long chain polymers are brought together, and the water movement is prevented. This membrane was designed specifically for use in underground structures. In addition to its inherent durable chemical composition, the key component of this membrane in terms of durability resides in the fact that it is sandwiched between two layers of steel fiber reinforced shotcrete, limiting its exposure to temperature changes and UV rays, which would be the two main degrading mechanisms.

5 CARBON FOOTPRINT REDUCTION

The construction industry is a major producer of CO₂ emissions. Huang et al. (2018) reported that in 2009, the total CO₂ emission of the global construction industry including building and infrastructures was 5.7 billion tons, accounting for 23% of the total CO₂ emissions produced by global economic activities. The significant impact of the construction industry largely arises from the embodied carbon in the primary construction materials, cement and steel. IEA (2020) reported that in 2019, the cement industry emitted 2.4 billion tons of CO₂ corresponding to around 7% of world energy sector emissions which is approximately 1/3rd of total CO₂ emission of the construction industry. In addition, approximately half of the global steel production is directed towards the construction industry, and 44% of construction industry's steel consumption is used for reinforcement. This represents a contribution of 1.5% to the world's CO₂ emissions, solely originating from steel rebar. Among various construction processes, tunnel construction results in a significant amount of CO₂ emissions because almost all tunnels are lined with reinforced concrete and utilize various high energy consuming equipment for excavation. Embodied carbon and high energy consumption can be minimized through three distinctive ways. The first method includes decreasing the overall quantity of reinforced concrete utilized through design optimization. The second approach is lowering the embodied carbon within each unit volume of the reinforced concrete by reducing the usage of portland cement and steel rebar. This can be established by substituting portland cement in the concrete mix by supplementary cementitious materials (SCM), opting for fibre reinforcement in lieu of rebar, and aggregate grading optimization using Tarantula Curve (Taylor, 2015) which reduces the cement paste in the unit

volume of concrete. The third approach involves enhancing equipment efficiency through the development of excavation and construction machines powered by non-fossil fuels. This last approach already applies to TBM tunnels; hence, the first two methods should be employed in bored tunnels to minimize the carbon emissions.

The focus of this section is on the calculation and reduction of embodied carbon of precast concrete segmental lining system. The evaluation of CO₂ emission reduction is carried out by comparing the carbon emissions of a baseline design, featuring conventional reinforcement and concrete mix designs, to an optimized design with a low-carbon concrete mixture.

A typical bored tunnel with the size and geological conditions of the Blue Line tunnel often has a concrete lining thickness of 400 mm when reinforced with rebar. A typical mix design to achieve 50 MPa concrete includes 475 kg/m³ of ordinary portland cement and a water-to-cement (w/c) ratio of 0.38. Also, a typical reinforced concrete segment in this size, have at least 80 kg/m³ of steel rebar. In comparison, the structural design was optimized with reducing the segment thickness to 350 mm and using ground granulated blast furnace slag and silica fume SCMs as partial cement replacement by 22% and 5%, respectively. In addition, steel fibre with a dosage of 40 kg/m³ is designed as standalone reinforcement. The reduction in segment thickness achieved with fibres can be primarily attributed to the concrete cover requirements of 60-75 mm on both intrados and extrados rebar to ensure the durability against corrosion when designing according to Canadian code CSA A23.1:19 (2019). In contrast, when subjected to chloride exposure, corrosion in steel fibre reinforced concrete is limited to just a few millimetres from the surface, and nonetheless, does not lead to spalling cracks and is not regarded as a durability issue. The CO₂ emission of the baseline and the optimized final mix designs for unit volume of concrete can be calculated using the following Equation.

$$\text{Mass of CO}_2\text{eq} = \text{CO}_2\text{eq Factor} \times \text{Material Quantities} \quad (1)$$

where CO₂eq Factor is the amount of equivalent CO₂ per unit mass (1 kg) of material from Environmental Product Declarations (EPDs). In this design, EPA 530-R-08-007 (2008), Life 365 (2010), and Hammond and Jones (2008) were used as references for CO₂eq factors of cementitious materials while CO₂eq factor of steel fibre was taken from the supplier's EPD. Table 1 summarizes the detail of CO₂ emission calculation for the unit volume of baseline concrete mixture designs. As shown in this table, embodied carbon of the baseline and the optimized final mix designs are 601 and 387 kg CO₂eq/m³, respectively. Now considering the design optimization using a 350 mm thick segment in comparison

with the baseline lining thickness of 400 mm, embodied carbon of these two options for a unit length of tunnel, and total embodied carbon are calculated and summarized in Table 2. Results of calculations indicate that in Blue Line tunnel segments, using structural design optimization, adopting a moderate SCM concrete mixture and opting for fibre reinforcement in lieu of rebar, the embodied carbon is reduced by 44%. The total carbon saving through design optimization is 13,177 tons of CO₂eq.

Although Designer has successfully adopted a 70% cement replacement by ground granulated blast furnace slag in the concrete mix design in cast-in-place tunnel lining applications, such high slag content has proven to be challenging for precast segments. This is because precast applications, and especially precast tunnel segment production, require very high early-strength requirements of 13-15 MPa within 6-24 hours of casting for safe stripping from formwork. Achieving such high early-strength using high dosages of slag has posed difficulties. Nonetheless, for the upcoming projects, increasing the slag content to 40-45% are being considered for precast concrete segments. Together with use of 5% silica fume, it is expected that around 50% of cement can be replaced by SCM for future projects. This level of cement substitution holds a significant potential for carbon footprint reduction in the future.

Table 1. Embodied carbon in unit volume for the baseline and the optimized final mix designs.

Mix Design Components	CO ₂ eq Factor	Baseline Reinforced Concrete Mixture (OPC)			Moderate SCM Concrete Mixture with Fiber		
		Mass (kg/m ³)	CO ₂ eq (kg/m ³)	% Replacement by Mass	Mass (kg/m ³)	CO ₂ eq (kg/m ³)	% Replacement by Mass
Portland Cement	0.92	475.0	437		346.8	319.1	
Slag	0.1466	0.0	-	0%	104.5	15.3	22%

6 CONCLUSION

The extension of the Montreal Blue Line metro toward the northeast consists of a 6-km long two-track tunnel, five new stations and seven auxiliary structures. These underground stations and auxiliary structures will be built first using mainly roadheader when practical, and drill and blast excavation method. Then, TBM will be used to excavate tunnels connecting these structures. This is the first time in North America that a Metro system is designed with a single side-by-side track tunnel without a separating centre wall. For supporting the excavation of stations and auxiliary structures two thin layers of shotcrete combined with permanent rock bolts and a sandwiched layer of spray-on waterproofing membrane are used for both initial and final liners of these underground structures resulting in a more sustainable solution and an optimized design and construction process. The final design of the project is recently completed, and the construction is planned to start at the beginning of 2024.

Influence of calculation method on the design of the secondary lining

Juraj Ortuta* & Martin Bakoš

Amberg Engineering Slovakia, s.r.o., Bratislava, Slovakia

ABSTRACT: Tunnels have become among the most complex structures in the mountainous terrain of the country. Here, it is not only the complexity of the actual implementation that is at issue, but also the complexity of the actual design preparation of such a structure. The first design problems occur right at the beginning, which relates to the engineering-geological survey and the description of the environment in which the tunnel will be implemented. Another problem is the static calculation itself, which involves the values determined by the geologist, which must be unified in a certain way for the sake of idealization. The static calculation is currently carried out using the finite element method, in which it is possible to simulate the stamping process as well as the actual construction of the tunnel.

This paper will deal specifically with the effects of different calculation procedures on the sizing of the secondary lining and the influence of these procedures on the result, which mainly affects the economic aspects related to the optimization of the design.

Keywords: Calculation method, Secondary lining, Numerical modelling, Geotechnical aspect

1 INTRODUCTION

One of the signs of a modern state is also advanced infrastructure and developed transport system. The priority of every government is to connect large agglomerations using a road network, especially a motorway network. This effort has been transferred to the development of motorways across territories which are not always associated with an ideal topography. Financial problems and price increases are associated with this, mainly due to poor geological conditions and several other resulting problems, such as the delay in construction, or completing of already started construction sections.

Tunnels are among the most complex structures in the mountainous relief of the countryside. This is not only about the complexity of the implementation itself, but also about the complexity of the design preparation of such an object. The first design problems appear at the very beginning. They relate to the engineering-geological survey and the description of the environment in which the tunnel will be built. Another problem is the static calculation itself, which includes the values determined based on survey results, which must be unified in a certain way due to idealisation. Currently, the static calculation is mainly done using the Finite Element Method, where it is

possible to simulate the tunnel excavation process, as well as the construction of the tunnel itself.

The paper will dedicate itself to the influence of different calculation procedures on the dimensioning of secondary lining and the influence of these procedures on the results, which affects the economic aspects associated with the optimisation of the design.

2 SEARCHING FOR CORRECT VIEWING OF ROCK MECHANICS

The development of underground construction engineering at the beginning of the 20th century, but especially after the Second World War, brought with it increased requirements for soil and rock mechanics from the point of view of finding and processing such methods of designing reinforcement for the lining of underground workings, which would be technically and economically subordinate to the practice. A significant shortcoming was the fact that rock mechanics only dealt with one side of the problem, namely the issue of rock pressure acting of the lining, while the other side, the design of reinforcement, was pushed aside. The theories of structural mechanics were developed without respect to the specifics that will appear in the case of excavation

*Corresponding author: jortuta@amberg.sk

support as a building structure in the underground. Therefore, the old calculation procedures, not respecting the significant differences in the behaviour of reinforcement in comparison with other building structures, persisted.

In underground construction, this problem is manifested in the still used method of analogy based on empirical experience and not exact knowledge of natural processes. This leads to the overdimensioning of structures to secure the static calculation in case of unexpected or unknown influences. Exact mathematically refined theories of building structures collide with shortcomings in the knowledge of the processes existing in the rock mass. This raises several ambiguities in the function of reinforcement as such, mutual influence of rock environment and reinforcement and the like.

Rock mechanics has passed through several stages of its development. In the first stage, it was the recognition of explanatory functions. That is, the effort to find theories clarifying the processes that a geotechnical engineer encounters underground. The second stage is associated with the effort to find out the causes of rock pressures and other phenomena underground. The development of the cognitive function was the cause of the development of in situ observations, the development of laboratory methods, mathematical and physical modelling. Of course, this stage is still alive and still requires a lot of work. But it also forms a transition to the third stage, the prognostic stage. This highest stage of the development of science strongly demands that science flexibly responds to changes in natural and technical conditions during the implementation of underground constructions.

3 THEORETICAL BASES

Determining the load acting on the lining of underground structures has always been one of the basic and most difficult tasks of a geotechnical engineer. In contrast to the tasks faced by a static engineer in the framework of building and building structures with relatively precisely given external loads, the role of the geotechnical engineer in underground construction is incomparably more difficult. It is not only due to the indeterminacy of the load acting on the structure, but mainly to a different concept of the function of the lining.

The current understanding of the lining as an interacting and stabilising element in the rock-lining system assumes that our knowledge of the strength and deformation properties of rocks forming the rock mass and the material of the lining meets the requirements for solving the task. But here we encounter a whole range of difficulties, even though research (mainly in situ) of rock properties from the point of view of the stability of underground workings is still developing. All of this is mainly related to the fact that the rock as a representative of the mass fulfils the role only

partially, because its strength and deformation properties in most cases do not correspond to the behaviour of rock blocks. This difference between the behaviour of the element and the whole system is primarily the result of the complex genesis and the process of development of the rock mass that it passed through during its existence. These are internal as well as external influences. One of the most important is the influence of tectonic processes, which caused several discontinuities, and thus a change in its mechanical properties. These circumstances, together with other anomalous changes in stress in space and time, created a very complex system of variables which must be considered in a certain way in the static calculation. In this phase, it is usually necessary to use the experience of a geotechnical engineer and correct the numerical result with the empirical factor.

Currently, there are several theoretical solutions which are usually offered without a critical approach and without further defined conditions of validity, and thus the applicability of the solution. However, the experience of the person solving the problem plays a very important role here.

4 MATHEMATICAL MODELLING IN GEOTECHNICS

The rock mass through which the underground working is driven, must be examined as a system with its structure given by the number of elements and mutual relations, i.e. focus on structure and behaviour. If the examination of these regularities of the real systems is difficult or even impossible, the original system is replaced with another, simplified, a so-called model. This model can be real (modelling with equivalent materials) or abstract (mathematical). An analogy must exist between the original and the model so that the model can forecast the development of the original. The basis is to decide which model is most appropriate for the given task. Even though one of the basic characteristics of a person is the ability to create abstract models corresponding to objective reality, the mathematical formulation of the models is very complex and sometimes even impossible. It follows from this fact that no model system can contain all the properties of objective reality. Therefore, deviations between the behaviour of the original and the results obtained from the model must always be considered. To maintain the acceptable degree of adequacy between the original and the model, the model is constructed to produce approximately the same behaviour as the original. Therefore, the model must be constantly verified and supplemented, especially when new information is obtained (for example, during design or during the actual excavation).

Geotechnical problems and the necessity for mathematical modelling can be divided into four areas according to the amount and quality of information (Figure 1). For creating models, area 4, within which the maximum amount of knowledge and a lot of data

is available, is ideal. In area 3, it is customary to rely on statistical processing of data and the search for empirical correlations. Unfortunately, most geotechnical tasks are from areas 1 and 2. Models created within these areas should not become routine, as they cannot be fully verified and require a pragmatic approach. It is often better to create several simple models than one complex model. Simple models can subsequently be improved and modified.

However, it is necessary to understand that the mathematical model is only a tool for understanding and solving the model. It is necessary to perceive not only its strengths, but also its weaknesses. It is important to realise that the mathematical model is not a solution, because it only imitates reality, and even not completely exactly.

Data	3. empiric correlation + statistically predicted data	4. knowledge + real data
	1. pragmatic approach	2. incomplete data

5 DEVELOPMENT OF MATHEMATICAL MODEL AND CALCULATION METHOD USED

Choice of material constitutional relationship and subsequent input of rock or soil parameters into the calculation is one of the most important and at the same time most problematic tasks in the modelling of the structure using the Finite Element Method. The main task of the material model is to describe the behaviour of the rock or soil as reliably as possible. Therefore, the correct choice of the material model is directly connected with the correct modelling (Figure 2).

Figure 2. Projection of plasticity surfaces onto the deviator and meridian planes.

Material models can be divided into two groups, namely linear and non-linear. For the calculations of larger structures, non-linear models are the only option to minimise the uncertainty of the result, because linear soil models, for example, in the

calculations of underground structures such as tunnels (Figure 3), provide completely unrealistic results.

Modelling using the Finite Element Method is a rather complex process. Most geotechnical engineers try to solve a complicated task on the first attempt. Subsequently, if the task does not converge, it is difficult to find the cause and a new model must be developed.

Figure 3. Double-tube tunnel model, overburden thickness in the model ranging from 20–25m, excavation width 12.6m and height 10m, axial distance between tunnel tubes 30 metres.

The modelling procedure could be summarised in several points:

1. Complete modelling of the structure.
2. Soils/rocks and contact elements are entered as elastic ones (linear models).
3. Generation of a coarse network.
4. Modelling of all calculation phases.
5. Calculation of all phases.
6. First assessments:
 - If the calculation ended with an error, the structure is probably entered incorrectly (the beam has many internal joints, the rockbolts are not fixed in the structure, etc.).
 - If the calculation ended in the last phase, it is necessary to check the deformations, and thus also the reality of the specified parameters. In the case of a plastic model of the soil, deformations are always greater than in the case of elastic one. If they are already large at this stage, adjustment is needed, and it is not necessary to approach the calculation with a non-linear model.
 - If the calculation ended without errors and the deformations correspond to reality, it is possible to proceed further.
7. Changing the linear material model to a non-linear one (Mohr-Coulomb, Drucker-Prager, Hardening Soil Model, etc.).
8. Calculation of all phases and repeated assessment according to point 6.
9. Refinement of the finite element mesh and final calculation.

When choosing the right non-linear rock model, it is necessary to have as much engineering-geological information as possible about the place where the structure will be located. It assumes that every constitutive relationship describing the material has certain limitations. Mohr-Coulomb, Drucker-Prager, as well as the modified Mohr-Coulomb model can be included in the group of models based on the classical Mohr-Coulomb fracture conditions. A common feature of these models is unlimited elastic deformation under the assumption of geostatic state of stress (Figure 2).

The second group of models consists of the Hardening Soil Model, the modified Cam Clay, the generalised Cam Clay and a hypoplastic model. These models already have a consolidation mechanism built in them, and their use is unsuitable for calculation in a location that is disturbed by cracks or fractures.

6 MODELLING OF THE CONSTRUCTION PROCEDURE AND ASSESSMENT OF THE SECONDARY LINING

As part of the study, a static calculation of a double-tube tunnel (Figure 3) was carried out using a geotechnical approach. The GEO5 2023 program, the Tunnel module was used as the software.

The tunnel overburden is 24 metres high, and the geology covers the entire rock environment. There are genetically diverse Quaternary soils there, passing into the bedrock. These are representatives of the Cretaceous rock, from marlstone to limestone.

In general, a variably thick eluvial layer characterised by gravelly to stony clay is developed on the surface of the bedrock. The thickness is affected by erosive processes in the past. The geotechnical parameters used in the calculation correspond to these assumptions.

The primary lining was modelled and, in the next stages, also the secondary lining. This was statically assessed based on internal forces determined by calculation.

The first variant represented a geotechnical approach, where the overall composition of the double-shell lined tunnel is already considered within the framework of the creation of the model.

The second variant was an assessment commonly used in practice, namely the modelling of the excavation procedure with the involvement of contact stresses, while the calculation of the primary lining was the last step of the construction phase and the calculated contact stresses were transferred to the classic static assessment of the secondary lining.

A (geotechnical approach):

(Model creation phases, the part of which is also secondary lining)

1. Determination of primary geostatic state of stress.
2. Modelling of the excavation of the top heading of the lefthand tunnel tube (LTT),

installation of anchors, the activation of the excavation.

3. Installation of the top heading vault primary lining made from fresh concrete.
4. Increasing the material characteristics of hard concrete for the top heading.
5. Modelling of the excavation of the side walls, installation of anchors, the activation of excavation.
6. Installation of fresh concrete primary lining of walls.
7. Increasing the material characteristics of hard concrete for top heading.
8. Modelling of the excavation of the top heading of the righthand tunnel tube (RTT), installation of anchors, the activation of the excavation.
9. Installation of the top heading vault primary lining made from fresh concrete.
10. Increasing the material characteristics of hard concrete for top heading.
11. Modelling of the excavation of the side walls, installation of anchors, the activation of excavation.
12. Installation of fresh concrete primary lining of walls.
13. Increasing the material characteristics of hard concrete for top heading.
14. Modelling of the LTT secondary lining.
15. Modelling of the RTT secondary lining.
16. Removing anchors from the model.
17. Removing primary lining from the model, simulating its degradation.
18. Loading of the lining with temperature: summer.
19. Loading of the lining with temperature: winter.

B (static approach):

(Creation phases for the determination of contact stresses)

1. Determination of primary geostatic state of stress.
2. Modelling of the excavation of the top heading of the LTT, installation of anchors, activation of the excavation.
3. Installation of the top heading vault primary lining made from fresh concrete.
4. Increasing the material characteristics of hard concrete for the top heading.
5. Modelling of the excavation of the side walls, installation of anchors, the activation of excavation.
6. Installation of fresh concrete primary lining of walls.
7. Increasing the material characteristics of hard concrete for top heading.
8. Modelling of the excavation of the top heading of the RTT, installation of anchors, the activation of the excavation.
9. Installation of the top heading vault primary lining made from fresh concrete.
10. Increasing the material characteristics of hard concrete for top heading.

11. Modelling of the excavation of the side walls, installation of anchors, the activation of excavation
12. Installation of fresh concrete primary lining of walls.
13. Increasing the material characteristics of hard concrete for top heading

The main difference from an optimisation point of view is that in the static approach to the overall assessment, the contact stresses are fully transferred to the secondary lining. It is caused by the fact that within the model, a theoretical layer (representing the waterproofing which prevents seepage) is introduced between the primary and secondary linings, eliminating shear forces. In this way, the interaction of the primary lining is eliminated, and the secondary lining is dimensioned for the total, often even unrealistic, load.

In the geotechnical approach, this usual view was not applied to the optimisation and the waterproofing layer was omitted. It is the fact that shear forces are also transferred to the secondary lining, but by retaining the primary lining, the overall load on the secondary lining was reduced to such an extent that the overall dimensioning assessment was much more favourable.

The output of the geotechnical approach to the calculation of the secondary lining according to approach "A" provides the internal forces, based on which the reinforcement will be designed (Figure 4).

Figure 4. The resulting distribution of internal forces in the secondary lining without the influence of temperature on approach A (maximum values: a) normal force (N) 259.9kN; b) bending moment (M) 22.7kNm).

The result which is required for the design of the reinforcement in the case of a combination of geotechnical calculation and classical static calculation according to approach "B", is, as mentioned above, the pattern of distribution of contact stresses (Figure 5), which will be transferred to the model of the secondary lining. Subsequently, a calculation is carried out to determine the internal forces and the reinforcement is designed (Figure 6).

In the statics practice, the method of designing and assessing structures according to limit states has been used in recent decades. Reaching one of the limit states (bearing capacity, deformation, formation of cracks) depends on many factors.

Calculations according the first group of limit states are made regarding the breaking of the critical

cross-section of the lining. The critical cross-section is understood as that part of the lining in which the bearing capacity will be exhausted under a certain way of stressing. When it is assumed that the lining will be used in elasticity (the formation of plastic joints is not allowed here), the critical cross-section is determined by the overall loadbearing capacity. The calculation will therefore prove that the loadbearing capacity of the lining is sufficient when interacting with the rock mass and ensures permanent stability.

Figure 5. Distribution of calculated contact stresses for approach B (maximum value: $\sigma = 352.8\text{kPa}$).

Calculations according to the second group of limit states are made with a focus on the strain in the lining, the formation and behaviour of cracks. This is used for checking whether the deformation of the lining does not exceed the limit values which would cause problems during normal tunnel operation. By calculating the occurrence and behaviour of cracks. It is demonstrated that the utility of the tunnel will not be impaired by the permeability of the lining or the corrosion of the reinforcement.

Figure 6. The resulting distribution of internal forces in the secondary lining without the influence of temperature for approach B (maximum values: a) normal force (N) 1592.48kN, b) bending moment (M) 869.24kNm).

While the assessment of the lining according to the first limit state is strictly required, the assessment of the occurrence and behaviour of cracks is usually only part of the static calculation of the lining

regarding the requirement for resistance against inflows of groundwater.

7 TWO APPROACHES

After determining/calculating the internal forces in the secondary lining, it was possible to proceed with the reinforcement design and the overall static assessment of the reinforced concrete structure.

The first differences already appeared in the magnitude of the calculated values. However, the checking on the distribution of forces and states of stress showed the correctness of the calculation and thus confirmed the theory, how important it is to take into consideration the behaviour of the rock mass from the point of view of rock mechanics and interaction with the structure being designed.

An important difference is that in the geological calculation of cross-sectional forces, the gradual degradation of the primary lining was considered already during the calculation. This degradation was introduced directly as a calculation step with gradual loss of strength characteristics. This degradation is

represented in the model by the omission of the primary lining as an element and replacing it with a surface to which the material parameters are introduced. This means that when the primary lining was carried out using C20/25 concrete grade, its degradation represents a reduction of the parameters to the values of C12/16 concrete. For concrete as such, the uniaxial pressure is clearly given, and with the help of the Hoek-Brown criterion it was possible to calculate the parameters needed as an input to the calculation.

Since a double-shell tunnel is in question, it is appropriate to retain the interaction of the primary lining, which loses its function over time, but never loses it completely. In this way, it is possible to reduce the mechanical properties over time, but at the same time does not lose them completely.

The Table 1 summarises the overall assessment (due to space, it is only a part of the table).

The results show that during the further strengthening and stabilisation of the rock vault, such values of the strength characteristics were achieved where it was possible to completely omit the reinforcement and it was sufficient to use unreinforced concrete. In the most stressed places, where reinforcement was necessary, it

was possible to proceed at least to its profile reduction (Table 2).

After drawing the reinforcement of one block in detail, it was demonstrated how important it is to know how to correctly connect geotechnics with classical statics and to find the right moment when the calculated values are transferred from the mathematical model to the final assessment of the critical cross-section.

A correctly chosen method of modelling and its subsequent interpretation usually leads to optimisation, which is associated with savings. In this case, almost 37% of the reinforcement within the block is saved and that is only because the mathematical model contained the entire construction process and considered all aspects of the rock environment together with elements that are part of the excavation and lose their function only gradually.

8 CONCLUSION

At the beginning of any static geotechnical calculation, it is necessary to ask the basic questions which modelling is associated with and on which the next procedure depends what will be modelled and what results provided by the static calculation are expected. Each such analysis has its own specifics that must be respected. It is important to be aware of this principle during the individual phases of static calculation and construction of underground workings.

As it was shown in the paper, the correct interpretation of the behaviour of rock mass leads to optimisation of the design and economic savings in the implementation of the working.

It should also be pointed out here that the usual structural element used in double skin lining is intermediate foil insulation. This, in addition to its primary function of waterproofing, prevents the transfer of shear loads from the primary to the secondary lining. In the classical calculation procedure, the contact stress is given to the model, which is calculated to form a “minimum” layer where shear is allowed to occur. In the optimization construction of the computational model, this layer is neglected, and the secondary lining was also loaded with shear forces. Thus, the secondary lining was loaded to the maximum (although in a real situation this will not be the case). However, a comparative calculation showed that the stress reduction while keeping at least a minimum function of the primary lining was such that it was worth proceeding with retaining the shear stresses, without undersizing the cross section and retaining all the necessary properties to ensure stability.

It is important to emphasise that the correct description of the mechanical properties of rock is mainly based on experience, but not least also on theoretical training, already at university. Without these fundamentals, it is impossible for a geotechnical engineer to fully understand what the nature is trying to tell him, but it is for a completely other discussion.

Research on smart design and innovation of Jiaozhou bay second tunnel

Liqing Qu, Xiang Li, Minglun Tan & Hua Jiang*

Qingdao Guoxin Jiaozhou Bay Second Submarine Tunnel Co., Ltd, Qingdao, China

Mingqing Xiao & Wenhao Sun

China Railway Siyuan Survey and Design Group Co.,Ltd, Wuhan, Hubei, China

ABSTRACT: The Second Jiaozhou Bay subsea tunnel has many characteristics, such as super long, super large, super deep, complicated geology, difficult ventilation and smoke extraction, difficult evacuation and rescue, complicated cross-straits connection, and many restrictions on construction conditions. In order to build the second Jiaozhou Bay subsea tunnel scientifically, safely and economically, combining with the characteristics of the project, this paper studies the key issues of the ultra-long undersea tunnel such as the site-selection, the construction-method, the burial-depth, the section-arrangement, the ventilation and smoke extraction, the evacuation and rescue, and draws the following main conclusions. 1) The concept of geological route selection should be emphasized in the overall design of ultra-long undersea tunnel, which is the key to reduce construction and operation risks, control investment and guarantee the construction period. 2) It is an important content of the overall design of ultra-long undersea tunnel to compare and select the appropriate construction method and determine the reasonable burial depth according to the specific geological and construction environment conditions. 3) The second Jiaozhou Bay subsea tunnel is arranged by two main tunnels and an intermediate service tunnel. The air duct is set on the top of the main tunnel in the sea section, and the innovative ventilation scheme of section 2.5 is put forward. The service tunnel is also used as the fresh air channel, which solves the ventilation problem of the ultra-long undersea tunnel. 4) A management center is set up at the entrance of both ends of the tunnel, and an emergency management station is set up at the entrance of the service tunnel. Moreover, a complete evacuation and rescue system composed of the service tunnel, the transverse passage of people and vehicle, the evacuation stairs and longitudinal escape channel on the lower part in shield section, which can ensure the operation safety of the ultra-long undersea tunnel.

Keywords: Subsea road tunnel, The overall design scheme, Select routes according to geology, The service tunnel, Selection of construction method, Ventilation and disaster prevention

1 INTRODUCTION

As an effective way to solve the problem of traffic blocking on both sides of the sea, subsea tunnel has gradually become the main way to cross the strait (bay) with its remarkable advantages such as small impact on the marine environment, all-weather traffic, and no impact on the sea channel [1-5]. At present, the longest subsea tunnel in the world is the Seikan Tonneru subsea (railway) tunnel in Japan, which was built from 1971 to 1988, with the total length of the main tunnel of 53.9 km. After 2000, China's underwater tunnels entered a stage of rapid development. By the end of 2021, there were about 260 underwater tunnels under construction in China, covering railway, highway, subway, municipal and other fields, involving shield method, drilling and

blasting method, immersed tube method and other construction methods. Qingdao Jiaozhou Bay Tunnel is the longest subsea road tunnel in operation at present in China, with a total length of 7,797 m, which was constructed by drilling and blasting method [6-8].

Second Jiaozhou Bay Subsea Tunnel is located between the existing Jiaozhou Bay Tunnel and the Jiaozhou Bay Cross-sea Bridge (Figure 1). It is an all-weather cross-sea channel connecting the main urban area of Qingdao and the New Area on the west shore. It adopts the 3-tunnel layout with "two-way six-lane main tunnels + intermediate service tunnel". The main line (the southern route) tunnel is 14,373 m long, with a design speed of 80 km/h, and its function is positioned as an urban expressway, with a lane width of 3.5 m+2×3.75 m, and net lane-height of 4.5 m. Second Jiaozhou Bay Subsea

*Corresponding author: jianghua142857@126.com

Tunnel is the largest subsea road tunnel in Asia at present, and it is also the longest subsea road tunnel in Asia. Its section undersea is about 10.5 km long. The condition in the sea area don't allow to set a vertical shaft there. It has many characteristics, such as super length, super size, super depth, complex geology, difficult ventilation and smoke exhaust, difficult evacuation and rescue, complex connection on both the banks, and many restrictions on construction conditions. See Table 1 for its project construction scale.

Figure 1. Location map of the second Jiaozhou Bay subsea tunnel.

Table 1. Scale of project construction.

Ramp N3	557
Ramp C	452
Ramp D	468

In combination with the second submarine tunnel in Jiaozhou Bay, this paper studies the overall design scheme of the tunnel from the aspects of tunnel site selection, buried depth selection, construction method selection, service tunnel setting, tunnel cross-section layout, ventilation and smoke exhaust and evacuation rescue of super long submarine tunnel, so as to provide reference for similar engineering design.

2 PROJECT CONSTRUCTION CONDITIONS

2.1 Marine environment

Jiaozhou Bay is located in Qingdao City on Shandong Peninsula, which is a harbor shore with typical

mountainous bedrock, and whose geomorphic pattern is obviously controlled by structure and lithology. The water depth of the bay is shallow in the northwest and deep in the southeast. The submarine terrain inclines from north to south, with a large belly and a small mouth. A deep-water trough with a depth of 30~40 m at the mouth of the bay extends into the bay in a north north-west direction. There are five waterways (east-west) in the bay from east to west that converge at the mouth of the bay and then lead to the open sea. The raised positive landforms are between the waterways, which are the main channel for the ebb and flow of the tide in Jiaozhou Bay.

2.2 Engineering geology

2.2.1 Geological structure near the site

The bedrock in Jiaozhou Bay can be generally divided into sedimentary rock distribution area and igneous rock area. The surface layer is mostly covered by Quaternary strata, and the bedrock in some low-lying areas of the seabed is exposed. There are many fault zones distributed in the areas near the site, such as Cangkou Fault, Xindao Fault, Pishikou Fault, Wanggezhuang Fault, etc. Affected by the faults, the rocks in the fault zones are mostly broken. And there are fault gouge and mylonite formed in most of the zones, and mainly broken zones and cataclastic rocks on both sides of the fault zones, forming permeable channels, which have a great impact on the tunnel construction.

2.2.2 Characteristics of rock and soil mass in the site area

As shown in Figure 2, on the north side of the lithologic boundary is mainly breccia sedimentary rock, with bedrock surface elevation of -50 ~ -70 m, and on the south side is mainly granite and tuff igneous rock formation, with bedrock surface elevation of -10 ~ -30 m. The Quaternary overburden above the bedrock surface mainly includes silt, silty clay, medium coarse sand, coarse sand and gravelly sand.

2.3 Hydrogeology

In the sea area, the permeability coefficient of rock stratum is 0.003~0.282 m/d, which is slightly ~ weakly permeable; the permeability coefficient of sand layer and breccia layer is 5~40 m/d, which is medium~strong permeability; the permeability coefficient of silt and clay layer is 0.05 ~ 1 m/d, which is weak permeability. The slightly weathered zone of the local bedrock has developed with tensile fractures. The hydrological test results show that its comprehensive permeability coefficient is up to 20 m/d, and there is a possibility of water gushing. According to the analysis results of groundwater sampling, the environmental action level of marine chloride is III-E, and the chemical corrosion level is V-E.

3 RESEARCH ON TUNNEL SITE AND ROUTE LOCATION SCHEME

3.1 Tunnel site scheme

According to the plan of Qingdao high-speed highway network, the Second Jiaozhou Bay Subsea Tunnel starts from Huaihe East Road on the side of Huangdao in the west and is laid toward the east under Liugongdao Road. After crossing Jiaozhou Bay, it is connected to the existing Hang'an Viaduct. The geological conditions in Jiaozhou Bay are complex. The bedrock in the sea area north of the lithological boundary shown in Figure 2 is sedimentary rock, and the igneous rock in the south. Meanwhile, the boundary divides Cangkou fault into the middle section and the south section, and according to the seismic safety evaluation, it is predicted that the fault quantity in the middle section is large. According to the geological structure and geological conditions of the site, and the connection requirements for the road network on the both banks, two tunnel site schemes of the southern route and the northern route are proposed, and the landing points of the two schemes on Huangdao bank are basically the same.

Figure 2. Tunnel address scheme in Jiaozhou Bay.

According to the southern route scheme, after entering the sea from the Huangdao shore, the tunnel obliquely crosses the southern section of the

Cangkou fault, underpasses the Mati Reef, bypasses the sedimentary rock area, and lands at the freight yard on the west side of Qingdao Port. The tunnel is mostly located in the igneous rock stratum, and the minimum clear distance between the route location and the lithologic boundary is about 200 m. The northern route plan is set on the west side of Cangkou Fracture. After crossing the middle section of Cangkou Fracture at a large angle, it lands at both banks of Haibo River. The tunnel is partially located in igneous rock and partially located in sedimentary rock. It crosses the lithologic boundary twice.

3.2 Construction scheme of tunnel in sea area section

The longitudinal section of this scheme is shown in Figure 4. The drilling and blasting method is used for the tunnel to cross the Huangdao land area and the sea area on the Huangdao side with good integrity of surrounding rock. The shield method is used to cross the muddy soil and broken rock strata on the Qingdao side (geological survey shows that the rock mass near the Cangkou fracture is broken). At the granite section with good surrounding rock near the boundary between granite and tuff, the shield receiving chamber is built by expanding excavation to realize shield receiving.

4 STUDY ON THE OVERALL SCHEME OF TUNNEL ENGINEERING

4.1 Deeply buried tunnel and longitudinal section scheme

4.1.1 Study on burial depth of the drilling and blasting section of the tunnel in the sea area

If the burial depth of subsea tunnel is too shallow and the bedrock cover at the top is too thin, the stability of surrounding rock is poor, the risk of collapse and water gushing during construction is high. Therefore, the cost of supporting measures is high, the construction progress is slow, and the water leakage during operation is large, but the energy consumption of vehicles during operation is reduced. When the tunnel is deeply buried, the surrounding rock is stable, but the slope increases, the fuel consumption

Figure 3. Schematic diagram of the northern and southern route scheme.

Figure 4. Longitudinal section.

of vehicles increases during the operation period, and the function of connecting lines on the two banks may not be realized. Therefore, the burial depth of the tunnel should be reasonably determined. At present, the methods for determining the burial depth of subsea tunnels at home and abroad mainly include Norwegian subsea tunnel construction experience method, Japanese minimum water inflow method and numerical calculation analysis method^[9-14].

According to the Norwegian experience method, the surrounding rock quality of the granite section of the Huangdao side of this tunnel is good. The minimum thickness of the overburden rock of the tunnel in the section with shallow water depth (average 13 m) is 25 m, and that in the section with deep water depth (maximum 49 m) is 30 m. The quality of surrounding rock in the sea area at the Qingdao end is poor, and the minimum thickness of the overburden rock of the tunnel is 40 m.

According to Japan's calculation formula of the minimum water inflow, and taking three working conditions, namely, the deepest point 49 m of the sea area, the average depth of the Huangdao sea area 20 m + the strong permeable overburden 8 m, and the water depth of the west side of the Cangkou fault 30 m + the strong permeable overburden 45 m, to calculate, the results show that the overburden thicknesses with the minimum water inflow is 25 m, 20 m, and 40 m respectively.

The FLAC 3D software is used to calculate the displacement and bending moment of the supported vault in the initial stage under different overburden rock thicknesses of the tunnel roof, and analyze the displacement of the vault and relationship between bending moment of lining and the overburden thickness, to determine the minimum overburden thickness of the tunnel. According to the calculation results, the minimum overburden thickness of the tunnel in the section with the thick Quaternary overburden or strongly weathered layer should be 30 m.

According to the above analysis results and combined with the construction experience of Jiaozhou Bay subsea tunnel in Qingdao, the design principle of overburden rock thickness of this project is comprehensively determined as follows:

- ① When the total thickness of water depth + weak overburden is greater than 30 m, the minimum overburden rock thickness of the tunnel is 30 m;
- ② When the total thickness of water depth + weak overburden is less than 30 m, the minimum overburden thickness of the tunnel is 25 m;

- ③ Reliable technical measures shall be taken to ensure construction safety in the section with insufficient overburden rock thickness.

4.1.2 Longitudinal section scheme for the sea area section

According to Code for Design of Urban Underground Road Engineering [15], the maximum allowable longitudinal slope of the main line tunnel of this project is 5%, and the general value is 3%. Due to the limitation of the minimum overburden soil thickness for shield at the sea entering point at the Qingdao end, the longitudinal slope of 4% is adopted locally, and the maximum longitudinal slope of other sections is less than 3%. According to the above-mentioned design principle of overburden rock thickness, combined with the burial depth of bedrock surface in the sea area section, two longitudinal section schemes are studied. According to Scheme 1, the lowest point is located in the middle of the drilling and blasting section in the sea area (shown by the purple dotted line in Figure 5), and the lowest point elevation of the route is -112 m. According to Scheme 2, the lowest point of the longitudinal section of the route moves about 1.0 km to the west based on Scheme 1, and the lowest point elevation is about -115 m.

The elevation of the lowest points of the two schemes and the minimum overburden rock thickness of the tunnel are basically the same. Considering that the tunnel is excavated from west to east in the drilling and blasting section during the construction period, the section about 5 km from the lowest point to the east in Scheme 2 is constructed down the slope, and the drainage pipeline leaking during the operation period is short (about 1.0 km shorter than that in Scheme 1), so Scheme 2 for the longitudinal section is recommended after comparison for selection.

Considering that reducing the burial depth of the lowest point can improve the operating conditions and reduce the fuel consumption of vehicles, on the basis of Scheme 2, the schemes of reducing the minimum overburden rock thickness by 10 m and by 20 m respectively compared with the recommended scheme are studied. According to the research results [16] of the influence of automobile road slope on the fuel consumption of 100 kilometers, the oil consumption after the tunnel burial depth is reduced is estimated. Assuming that the traffic volume is 80,000 vehicles/day, when the tunnel burial depth is reduced by 10 meters, the annual fuel consumption can be reduced by about RMB 14 million yuan. According

Figure 5. Longitudinal section of the tunnel.

to the 100-year cycle calculation, assuming that the yield is 5%, the corresponding present value is RMB 278 million yuan. When the burial depth of the tunnel is reduced by 20 m, the present value corresponding to the reduced fuel consumption cost is RMB 556 million yuan. However, when the overburden rock thickness decreases by 10 m and by 20 m, due to the relative deterioration of surrounding rock, the cost of strengthening the supporting structure and grouting for water blocking will increase, and the construction period will be extended. According to calculation, the project cost will increase by about RMB 400 million yuan and RMB 600 million yuan respectively (the impacted range is about 800 m), and the construction period will be extended by 6 months and 12 months respectively. It can be seen that it is unreasonable to further reduce the overburden rock thickness in terms of life-cycle cost, construction safety and duration.

5 VENTILATION AND SMOKE EXHAUST SCHEME

5.1 Operation ventilation standard

Considering the long distance, large construction scale and long construction period of this tunnel, values for the ventilation is taken according to PIARC2019 standard, and the ventilation standard of 2 times /h is added, as shown in Table 2.

Table 2. Ventilation and health standards.

Traffic Conditions	Vehicle Speed (km/h)	CO Concentration (cm ³ /m ³)	Dust Concentration (m-1)	NO ₂ Concentration (cm ³ /m ³)
Normal	80~50	70	0.005	1
Normal	40~30	70	0.007	1
Whole course block	20	70	0.007	1
Local block (2 km)	10	70	0.007	1
Closing the tunnel		200	0.012	—

Usually, the tunnel is dominated by buses and small- and medium-sized trucks. Under special conditions, large trucks can pass. Because the tunnel building length exceeds 14km, in order to improve the fire safety of tunnel, it is designed according to

50MW for the fire scale of large trucks, and the critical wind speed is 2.4 ~ 3.1 m/s.

5.2 Operation ventilation scheme

Due to the requirements of environmental assessment and navigation in Jiaozhou Bay, no ventilation shaft is set in the sea. After a ventilation shaft is set in the off-shore position in the Huangdao land section, the length of the ventilation section of the sea area section tunnel is about 10.5 km, which is the road tunnel with the longest ventilation section in China. Combined with the actual situation and cross-section layout of this tunnel, three ventilation schemes are put forward:

Scheme 1: A vertical shaft is set up on the Huangdao shore for ventilation in two sections.

Scheme 2: 2.5-section ventilation mode of setting a vertical shaft on Huangdao bank: the vertical shaft on the Huangdao shore is used for air supply and exhaust, and the top air duct of the service tunnel and the main line tunnel in the sea area section is used to supplement air supply and exhaust.

Scheme 3: 2.5-section ventilation mode of setting a vertical shaft on the Huangdao shore for the northern route: A centralized purification machine room is set in the sea for the southern route, while the air supply and exhaust are supplemented by the air ducts at the top of the service tunnel and the main line tunnel in the sea area.

The ventilation mode of Scheme 2 is shown in Figure 7. In this scheme, a air supply and exhaust shaft is only set up on the Huangdao shore. The whole length of the tunnel is divided into two large ventilation sections. The sea area section is divided into two small ventilation sections by using the service tunnel (fresh air duct) and the top air duct (exhaust duct) of the main line tunnel, the ventilation mode is between 2 sections and 3 sections, so it is called 2.5-section ventilation.

The comparison results of various ventilation schemes are shown in Table 3.

All three schemes can achieve the ventilation effect of the design standard, in which the installed power and operating energy consumption are considered. 2.5-section ventilation is recommended.

5.3 Fire smoke exhaust scheme

According to the current “Code for Fire Protection Design of Buildings” [17], the tunnel with a length greater than 3,000 m shall adopt sectional longitudinal or key smoke exhaust methods. The tunnel

Figure 6. Ventilation mode of section 2.5 with a shaft on the shore of Huangdao.

Table 3. Comprehensive comparison table of operation ventilation scheme.

Comparison Item	Scheme 1:	Scheme 2:	Scheme 3:
Ventilation section length	2-section ventilation	2.5-section ventilation	2.5-section ventilation for northern route + purification for southern route
Maximum wind speed of 20 km/h	2,950 m, 10,950 m	2,950 m, 7,950 m, 3,000 m	2,950 m, 7,950 m, 3,000 m
Total installed power	4.6 m/s	3.6 m/s	4.6 m/s
100-year operating expenses	11,400 kW	8,314 kW	9,644 kW
100-years equipment cost	RMB0.96bn	RMB0.85bn	RMB0.89bn
Others	simple	an air supply room set in the sea, and complicated control	an air-supply machinroom and a purification machine room set in the sea, and complicated control

lengths of land sections for the northern and southern are 2,973,m and 3,146,m respectively. After comprehensive comparison for selection of the longitudinal smoke exhaust and key smoke exhaust in the land area from the aspects of smoke exhaust effect, people evacuation and equipment configuration, it is recommended to adopt the longitudinal smoke exhaust scheme, and while two smoke exhaust ports for the northern route is added so that the length of the longitudinal smoke exhaust section does not exceed 3,000 m.

The tunnel in the sea area section between the ventilation shafts on both shores of the river is about 10.5 km long. In order to solve the problem of smoke exhaust in the super-long ventilation section,

three schemes, namely, the sectional longitudinal smoke exhaust scheme (Scheme 1) with the top smoke exhaust duct + the connecting flue (that is, the flue connecting the north and south tunnels with a distance of about 3,500 m); the sectional longitudinal smoke exhaust scheme (Scheme 2) of setting the smoke exhaust duct combined with the service tunnel; and the key smoke exhaust scheme (Scheme 3), are studied. The advantages and disadvantages of the three schemes are shown in Table 4.

All three schemes can meet the requirements of Code for Fire Protection Design of Buildings. Considering that this tunnel is a super-long subsea tunnel in a city, there are as many as 350 smoke outlets in the

Table 4. Selection table of comprehensive comparison of smoke extraction schemes in sea section.

Comparison Item	Scheme 1	Scheme 2	Scheme 3
Smoke exhaust effect	The longest spread range of smoke reaches 3 km, and the smoke exhaust effect is poor when a fire occurs in the blocking condition.	The longest spread range of smoke reaches 3 km, and the smoke exhaust effect is poor when a fire occurs in the blocking condition.	Theoretically, the upstream and downstream smoke shall be controlled above the clear height, but the requirement for the air tightness of the smoke exhaust system is high.
Smoke-influenced range	large	large	small
People evacuation	One-way evacuation from upstream of fire source	One-way evacuation from upstream of fire source	Evacuation from both upstream and downstream of fire source.
Exhausted smoke volume	Greater than 300 m ³ /s	Greater than 300 m ³ /s	Theoretically, greater than 240 m ³ /s
Civil work investment	A smoke exhaust duct is added at the top of the sea area section, which will increase the civil work cost by RMB 130 million yuan.	The service tunnel section is increased by 25 m ² , which will increase the civil work cost by RMB 350 million yuan.	Same as Scheme 1
Number of smoke outlets	Totally there are 6 groups of smoke outlets	Totally there are 6 groups of smoke outlets	Totally there are 370 groups of smoke outlets.
Control model	In case of fire, a group of smoke outlets downstream of the fire source shall be opened, and the control mode is simple.	In case of fire, a group of smoke outlets downstream of the fire source shall be opened, and the control mode is simple.	In case of fire, six groups of smoke outlets downstream of the fire source shall be opened, with many mode combinations and complicated control.
Reliability	high	high	low

conventional key smoke exhaust mode (the spacing between smoke outlets is 60 m), which requires extremely high air-outlet sealing and installation, and the control in case of fire is complicated and the reliability is low. The longitudinal smoke exhaust control is simple, which is applicable for tunnels with infrequent traffic congestion. The line connection condition at both ends of this project is good, and a perfect traffic monitoring system is set there. A toll station is set at Huangdao entrance and a inspection booth is set at Qingdao entrance, which can avoid frequent traffic jams. Moreover, the sectional longitudinal smoke exhaust scheme of the top smoke exhaust duct + connecting flue does not need to increase the section of the service tunnel, which can reduce the civil work cost by RMB 220 million yuan compared with Scheme 2. After comprehensive comparison, it is recommended to adopt sectional longitudinal smoke exhaust scheme of the top smoke exhaust duct + connecting flue (Scheme 1), as shown in Figure 7.

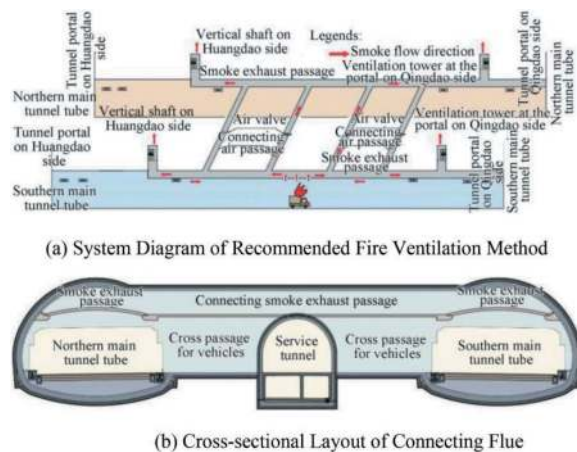

Figure 7. Schematic diagram of fire smoke extraction scheme.

6 CONCLUSIONS AND SUGGESTIONS

By studying the key problems in the overall design of Second Jiaozhou Bay Subsea Tunnel Project, the following conclusions are obtained:

- (1) For subsea tunnels under complex geological conditions, a reasonable tunnel site is very important for the project construction. Through detailed comparison for selection of schemes of southern and northern routes, Second Jiaozhou Bay Subsea Tunnel Project highlighted the geological concept of route selection, based on which the southern route scheme with relatively good engineering geology was selected, which is of great significance for controlling project investment, reducing project risk and ensuring construction period.
- (2) Super-long tunnels may cross various geological units or strata with very different properties. It is one of the important contents of the overall

design to compare and choose the construction methods, select the appropriate construction methods by section and determine the reasonable burial depth in combination with the specific geological and construction environment conditions. According to the specific construction conditions, the Second Jiaozhou Bay Subsea Tunnel adopted the construction methods of drilling and blasting, shield and cut-and-cover excavation. Through the research of reasonable buried depth, taking into account the tunnel construction and operation conditions, the tunnel longitudinal section layout was reasonably determined.

- (3) In extra-long subsea tunnel, a service tunnel generally has the functions of advanced leading pilot tunnels, auxiliary tunnels for construction, operation maintenance, and emergency rescue. The layout of two main tunnels plus one intermediate service tunnel is adopted in the sea area section in Second Jiaozhou Bay Subsea Tunnel, and an air duct is set at the top of the main line tunnel. According to the requirements of this project, the 2.5-section ventilation technology is innovatively put forward, and the service tunnel is used as the fresh air passage, which solves the ventilation problem of the 10.5km-long ventilation section of the tunnel without increasing the investment in civil work, and can provide reference for similar tunnel projects in the future.
- (4) A perfect evacuation and rescue system is formed through making full use of the management centers set at the openings at both ends of the tunnel, the emergency management station at the Huangdao end, the service tunnel, the pedestrian and vehicle cross-passages, the evacuation stairs in the shield section and the longitudinal evacuation passages at the lower floor, so as to ensure the operation safety of the super-long subsea tunnel in case of traffic accidents and fire conditions.

Application of a confinement-dependent spalling criterion for tunnels in highly stressed brittle rock

Masoud Rahjoo

The University of British Columbia, Vancouver, Canada
AECOM, Burnaby, Canada

Erik Eberhardt*

The University of British Columbia, Vancouver, Canada

ABSTRACT: Tunnelling experiences in highly stressed brittle rock suggest that commonly used numerical tools, and more specifically the rock strength criteria available, need to be revised for robust prediction and design where stress fracturing is encountered (e.g., spalling, strainbursting). Missing is the recognition that brittle failure is sensitive to confinement, exhibiting extensional fracturing under low confinement and shear fracturing under high confinement. Conventional rock strength criteria such as Mohr-Coulomb and Hoek-Brown were developed based on experiences and observations dominated by shear failure of weak or heavily fractured rock masses. This paper reviews the influence of confinement on spalling and the application of a confinement-dependent extensional fracturing criterion with a shear transition derived for brittle rock failure. The criterion is developed for use with 3-D numerical stress analyses and is validated against results assessing the location and depth of failure for spalling observed during the advance of a deep tunnel in massive rock. Comparisons using conventional rock strength criteria and their adaptation for brittle rock failure show that these can either significantly under- or over-estimate the depth and extent of failure if they do not adequately capture the susceptibility to spalling initiation under low confinement at the tunnel boundary or the limiting influence of confinement on suppressing stress fracturing as failure extends into the rock mass away from the tunnel boundary.

Keywords: Tunnelling, High stresses, Spalling, Depth of brittle failure, Confinement dependency

1 INTRODUCTION

Tunnels in highly-stressed massive rock are susceptible to brittle fracturing, resulting in behaviours ranging from progressive non-violent spalling and dilative bulking to sudden and violent strainbursting. These conditions have pushed engineers and designers to the limits of conventional empirical and numerical design capabilities. Of issue is that the rock strength criteria most commonly used, Mohr-Coulomb and Hoek-Brown, were developed based on experiences and observations in lower-stress environments where instability was dominated by shear failure of weak and heavily jointed or faulted rock masses (Kaiser & Kim, 2008). A common misconception in the use of these criteria is that brittle fracturing is associated with tensile stresses and shear fracturing is associated with compressive stresses. This gave rise to the use of shear-based criterion with tension cut-offs (e.g.,

Mohr-Coulomb, see Labuz & Zang, 2012; Hoek-Brown, see Hoek & Martin, 2014).

However, evidence from laboratory and field observations shows that brittle failure occurs through extensional fracturing under low confinement where the rock is tangentially compressed (Eberhardt et al., 2016). Also missing in existing strength criteria is the recognition that brittle failure is sensitive to confinement, exhibiting extensional fracturing under low confinement and shear fracturing under high confinement (Figure 1a). The challenge for robust design where brittle failure conditions are expected reduces to the development of a strength criterion that is capable of assessing both extensional and shear failure.

Efforts to account for extensional fracturing include Martin et al.'s (1999) use of the Hoek-Brown criterion with brittle parameters ($m = 0$, $s = 0.11$) and Diederichs' (2002) multi-linear envelope separating spalling from shear failure as a function of confinement. The latter is commonly referred to as the "s-shaped"

*Corresponding author: erik@eoas.ubc.ca

criterion, and its application makes use of the Hoek-Brown yield criterion to simulate crack initiation and a subsequent “residual strength” threshold to reflect the transition to shear (Diederichs et al., 2010).

Figure 1. (a) Illustration of low-confinement dominated by extensile brittle fracturing (spalling) and high-confinement dominated by shearing. (b) Conceptualization of spalling criteria (after Diederichs, 2002).

This paper applies these principles, for which we present the application of a confinement-dependent extensional and shear fracturing criterion derived for brittle rock failure. First, we provide a short review of the influence of confinement on brittle fracturing and efforts to develop a corresponding criterion. We next present the criterion together with its parameterization and then results assessing the location and depth of failure for spalling observed during the advance of the Mine-By Experiment (MBE) tunnel at the Atomic Energy of Canada Ltd.’s Underground Research Laboratory (AECL-URL). Results are compared against the use of the conventional Hoek-Brown criterion and its use with brittle failure parameters. The findings demonstrate that the consideration of confinement on stress fracturing is critical for evaluating the location and depth of spalling around a tunnel in highly stressed brittle rock.

2 CONFINEMENT-DEPENDENT SPALLING CRITERIA

2.1 Extensional fracturing and spalling initiation

In a review of existing strength criteria and their use for brittle rock, Rahjoo (2019) noted that the use of

Mohr-Coulomb and Hoek-Brown limits the consideration of extensional fracturing to tensile loading conditions that transit to shear fracturing right at $\sigma_3 = 0$. In reality, however, extensional fracturing also occurs in compression under low confinement. At the laboratory scale, this has been characterized in terms of the crack initiation and crack damage stress thresholds (Bieniawski, 1967; Martin, 1997; Eberhardt et al., 1998). At the tunnel scale, Read & Martin (1996) thoroughly investigated the damage zone and spalling that developed in the massive granitic rock around the AECL-URL’s MBE tunnel. They characterized the spalling mechanism as initial cohesion loss followed by the mobilization of friction. Martin (1997) suggested that the crack initiation threshold would be an appropriate criterion for determining the extent of a damage zone. He proposed the following criterion for crack initiation, σ_{ci} :

$$\sigma_1 - \sigma_3 \geq \sigma_{ci} \quad (1)$$

Comparing this with the Hoek-Brown criterion (Eqn. 2), where σ_c is the uniaxial compressive strength, Martin et al. (1999) suggested that it can represent crack initiation if using the brittle parameters, $m = 0$ and $s = 0.11$ (Eqn. 3):

$$\sigma_1 = \sigma_3 + \sqrt{m\sigma_c + s\sigma_c^2} \quad (2)$$

$$\sigma_1 = \sigma_3 + \sqrt{0.11\sigma_c^2} \quad (3)$$

As a design parameter, σ_{ci} marks the stress at which new cracks initiate and begin to propagate (Diederichs et al., 2010), and near the excavation boundary where confining stresses are low and crack propagation can easily transition to unstable crack propagation and spalling, it represents the lower bound long-term in-situ rock strength under which spalling initiates (Martin, 1997; Diederichs et al., 2004).

2.2 Confinement and spalling limit

Wawersik & Fairhurst (1970) noted that adding moderate confining pressures could eliminate the development of spalling in laboratory compression testing. The importance of confinement in limiting crack propagation and spalling has been demonstrated experimentally and numerically by various authors, as summarized by Eberhardt et al. (2016). Read et al. (1998) considered an upper limit for the effect of low confinement on unstable cracking potential based on the ratio of minimum to maximum principal stresses:

$$\frac{\sigma_3}{\sigma_1} \leq R_{spalling}, \quad R_{spalling} = 0.05 - 0.1 \quad (4)$$

This ratio defines a limit for stress states under which microcracks can easily grow, coalescing to form macro-scale fractures. It also defines a transition from extensional fracturing to shearing. The combination of the crack initiation criterion and spalling limit (Eqns. 1 and 4) defines a dual criterion that characterises the favourable stress state for spalling. This is reflected in Diederichs (2002, 2007), who proposed a composite in-situ strength envelope for brittle rock, with segments corresponding to a lower bound strength of crack/damage initiation under low confinement, an upper bound strength involving shear under high confinement, and a transition zone between these related to the spalling limit (Figure 1b).

2.3 Formulation and implementation

Rahjoo (2019) extended the work of Read et al. (1998) and Diederichs (2002, 2007) to develop and formulate an integrated 3-D confinement-dependent strength criterion that captures both extensional and shear fracturing, and their sensitivity to σ_3 as well as σ_2 , both of which act as confinement in 3-D. However, as a first step towards validation, as well as the equally important step of parameterization, a simplified version is presented here aligned with Read et al. (1998) utilizing Eqns. (1) and (4).

These are implemented using the 3-D boundary element program EX3 by Rocscience. Although the use of the boundary element method restricts the analysis to elastic stresses and, therefore, does not account for the effect of stress redistribution as failure progresses, this is generally acceptable for brittle failure in massive rock (Martin et al., 1999). Of specific interest to the analysis of spalling failure, the computational efficiency of the boundary element method allows for a more straightforward implementation of a user-defined spalling criterion and visualization of the 3-D spalling that develops, which requires a very fine mesh discretization and stress grid.

To implement, we need to define a mathematical formulation that uniquely gives each of the zones defined by extensional stress fracturing (i.e., spalling) and shearing under compression. These are as follows:

$$\text{crack initiation} : \sigma_1 \geq N_{ci}\sigma_3 + \sigma_{ci} \quad (5)$$

$$\text{spalling limit} : \sigma_1 \geq N_{sp}\sigma_3 \quad (6)$$

$$\text{spalling/shearing transition} : \sigma_3 \leq \sigma_{ss} \quad (7)$$

$$\text{compressive stress} : \sigma_3 \geq 0 \quad (8)$$

In the above, N_{ci} is the crack initiation gradient, N_{sp} is the spalling limit gradient, and σ_{ss} is the spalling to shear transition stress. These are discussed in

more detail later in the paper when describing the parameterization of the model.

Next, we need a summation method. It is noted that different numerical analysis software have different functionality with respect to allowing user-defined criteria. In EX3, filtering of the different zones can be achieved by applying a log10 function. This is implemented as:

$$\begin{aligned} & \log_{10}(\sigma_1 - N_{ci}\sigma_3 - \sigma_{ci} + 1) \times \log_{10}(\sigma_1 - N_{sp}\sigma_3 + 1) \\ & \times \log_{10}(\sigma_3 + 1) \end{aligned} \quad (9)$$

$$\begin{aligned} & \log_{10}(\sigma_1 - N_{ci}\sigma_3 - \sigma_{ci} + 1) \times \log_{10}(-\sigma_3 + \sigma_{ss} + 1) \\ & \times \log_{10}(\sigma_3 + 1) \end{aligned} \quad (10)$$

Eqn. (9) makes use of the spalling limit and Eqn. (10) uses the spalling/shearing transition limit. In the 3-D stress analysis program Map3D, implementation is similar except a sign function can be used instead of log10.

3 VALIDATION CASE

3.1 AECL-URL Mine-By Experiment

The Mine-by Experiment (MBE) tunnel at the AECL Underground Research Laboratory in Pinawa, Manitoba, Canada, provides a pioneering case study on the progressive failure and spalling of brittle rock. The MBE was carried out at a depth of 420 m in massive, sparsely fractured granite (Martin, 1997). The 3.5 m-diameter circular tunnel was excavated in 50 increments over its 46 m length using perimeter drilling and hydraulic rock splitters to break out the rock. Sixteen triaxial accelerometers were installed around the MBE tunnel to record crack initiation via microseismic events (Read & Martin, 1996). Figure 2a shows the V-shaped notch that formed by stress-induced extensional fracturing at the tangentially compressed but laterally low-confined zones in the roof and floor of the tunnel.

Figure 2b shows the progressive development of the notch as the tunnel face was advanced. The data showed that the microseismicity belonging to each advance of the face did not extend further than 2 times the tunnel diameter behind the tunnel face (Read & Martin, 1996). Thus, any spalling that occurred farther than several meters behind the face (e.g., the difference between profiles 3 and 5 in Figure 2b) might be related to either time-dependent fracturing or stress change caused by time-dependent formation of the V-shaped notch. As such, profile 3 was used for the validation exercise.

Figure 2c and d show the calculated stress paths by Read & Martin (1996) for a point in the tunnel

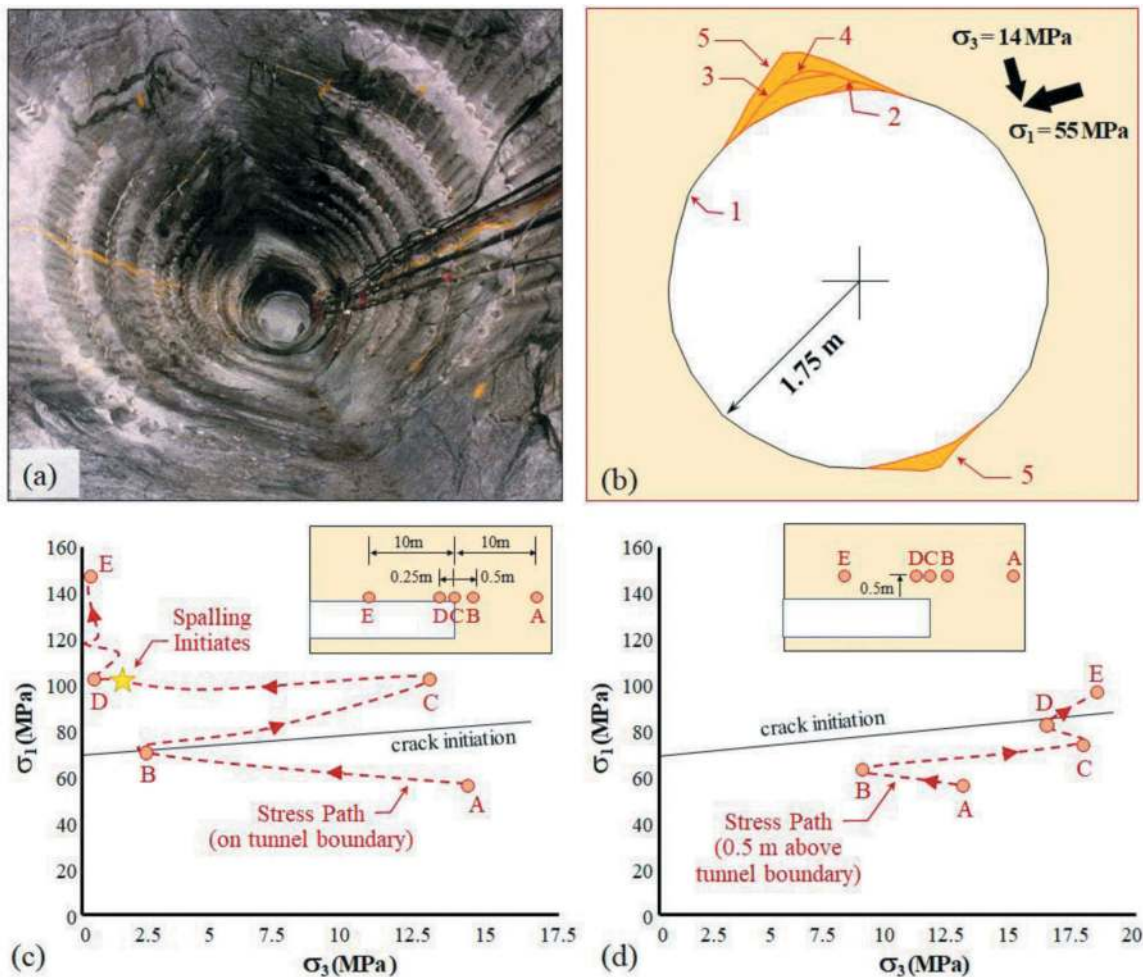

Figure 2. (a) MBE tunnel showing the final shape of the spalling breakout in the crown and invert of the tunnel. (b) Sequence of the progressive development of the spalling geometry. Profiles 1 to 4 were the surveyed boundaries when the face was 0.24 m, 0.5 m, 3.5 m and 10 m ahead of the section, respectively. Profile 5 represents the long-term depth of spalling after several months when the tunnel excavation was completed and the section was 24 m behind the tunnel face. (c) Stress path for a point located just above the tunnel boundary at the maximum compressive stress concentration in the roof. The first visual signs of spalling failure are observed just past point D, 0.5 m behind the tunnel face. (d) Stress path for a point located 0.5 m above the tunnel roof, showing the influence of increased confinement on suppressing the development of crack initiation and spalling. After Read & Martin, 1996).

roof at 0 and 0.5 m above the tunnel boundary, respectively. These show that the stress path exceeds the crack initiation stress just ahead of the tunnel face, with visible spalling initiating and developing 0.5 m behind the face (Figure 2c). Deeper within the rock mass above the tunnel boundary (Figure 2d), the crack-initiation stress is exceeded after the tunnel face is well beyond the surveyed section, but confinement acts to suppress and stop the depth of spalling.

Thus, the validation exercise for the confinement-dependent spalling criterion developed incorporates three targets: (i) the distance from the face where spalling initiates (0.5 m); (ii) the depth of spalling (0.25 m for profile 3; see Figure 2b); and (iii) the lateral extent of spalling around the perimeter (as shown in Figure 2b).

3.2 Model parameterization

The 3-D in-situ stress input was assigned as reported by Read & Martin (1996): $\sigma_1 = 55$ MPa, $\sigma_2 = 48$ MPa and $\sigma_3 = 14$ MPa, with σ_1 rotated 19 degrees from horizontal (see Figure 2b). The properties of the LdB pink granite were reported as having a σ_c of 213 MPa and Hoek-Brown properties of $m = 30.8$ and $s = 1$. Figure 3a shows the predicted distance from the face, depth and extent of spalling if using the assessed Hoek-Brown properties for the MBE. These show that spalling would not be expected if peak strength values are used. It has been well established that peak strength values are not appropriate for brittle failure and spalling analyses as the failure process initiates well below this at the crack initiation stress (Martin, 1997). Figure 3b shows the results of using only the crack initiation criterion in

Figure 3. 3-D stress and spalling analysis results assuming: (a) Hoek-Brown peak strength values for LdB pink granite, and (b) Hoek-Brown crack initiation values ($m=0$, $s=0.11$). Shown are the predicted extent and depth of spalling (strength factor < 1) in the tunnel roof along a longitudinal plane and those in a cross-sectional plane 6 m from the tunnel face. The cross-sectional plane corresponds with the advance from profile 3 to 4 (see Figure 2b), and shows the measured extent and depth of spalling outlined in red.

Eqn. (1). Without a spalling limit (or a spalling/shearing transition limit) to account for the suppressing influence of confinement, the results overpredict the distance from the face where spalling begins, indicating spalling at the face, as well as the extent and depth of spalling.

Proceeding with the parameterization of the confinement-dependent spalling criterion implemented using Eqns. (9) and (10), four input parameters are required: σ_{ci} , N_{ci} , N_{sp} and σ_{ss} . Eberhardt et al. (1998) determined a σ_{ci} of 0.4 to 0.5 σ_c from acoustic emission and strain measurements performed on LdB pink granite. Hoek & Martin (2014) more generally report a range of 0.4 to 0.6 σ_c , for a range of brittle rock types. A value of 0.5 σ_c was used for σ_{ci} in this study. The crack initiation gradient, N_{ci} , generally ranges from 1 to 1.5 where lower values are associated with more brittle rock dominated by crack opening (i.e., low friction) and higher values correspond to conditions with more bulking where friction develops between the spalled pieces. It can be calculated based on the Mohr-Coulomb relationship:

$$N_{ci} = (1 + \sin \phi) / (1 - \sin \phi) \quad (11)$$

where ϕ is the internal friction angle. The value of $N_{ci} = 1$ is used here for the case of the MBE as the spalling observed did not result in significant dilation and bulking. The spalling gradient, N_{sp} , ranges from 10 to 15 as per Diederichs (2002) and Diederichs et al. (2004). A value of 13 was used in this study, but it was found to be non-sensitive relative to the spalling to shear transition stress, σ_{ss} . The value for

σ_{ss} was determined from triaxial test data for LdB pink granite by analysing the peak strength, volumetric dilation (i.e., crack damage threshold), and plastic volumetric dilation, also referred to as the crack volumetric strain by Martin (1997). Figure 4a shows that the values derived have increasing trends with increasing confinement but reach a plateau beyond a σ_3 of 15 MPa (Figure 4b). As such, σ_{ss} was set at 15 MPa (see Rahjoo, 2019 for the full procedure).

4 SPALLING ANALYSIS RESULTS

Figures 5-7 present the results of the 3-D stress and spalling analysis using the confinement-dependent spalling criterion, implemented using Eqn. (10). Figure 5 shows the results in perspective view, highlighting the depth of spalling along a longitudinal profile. This shows the notch starting to develop 0.5 m behind the tunnel face, matching the visual observations by Read & Martin (1996). Figure 6 shows why the notch does not form right at the tunnel face, as the σ_3 confinement is higher at the face where the stresses rotate around the edges of the tunnel boundary. The importance of 3-D stress rotation with respect to spalling as a tunnel face advances is discussed in Eberhardt (2001). Thus, the results in Figures 5 and 6 confirm that the confinement-dependent spalling criteria correctly predicts the first validation check involving the distance from the face where spalling initiates (i.e., 0.5 m).

Figure 7 confirms that the confinement-dependent spalling criteria predict the other two validation

Figure 4. (a) Strength of LdB Pink Granite at peak strength (peak - red), volumetric dilation (VD - green) and plastic volumetric dilation (PVD - blue) under confining stresses ranging from 0 to 60 MPa. The data is derived from Lau & Gorski (1991). (b) Determination of the spalling to shearing transition using the ratio of σ_1/σ_1^{peak} , calculated here as $\sigma_3 = 15$ MPa for LdB pink granite. See Rahjoo (2019) for the full procedure.

Figure 5. 3-D stress and spalling analysis results applying the confinement-dependent spalling criterion, implemented via Eqn. (10) with inputs: $\sigma_{ci} = 106.5$ MPa, $N_{ci} = 1$, $N_{sp} = 13$ and $\sigma_{ss} = 15$ MPa. The locations where spalling is modelled as developing are indicated by the coloured areas. The extent of spalling on the tunnel boundary is in light brown to green. In dark red is the depth of spalling as projected on a longitudinal plane along the tunnel roof, as well as a cross-sectional plane 6 m from the tunnel face, corresponding with the advance from profile 3 to 4 (see Figure 2b). The results for these two projection planes, outlined in bright red, are provided in Figures 6 and 7, respectively.

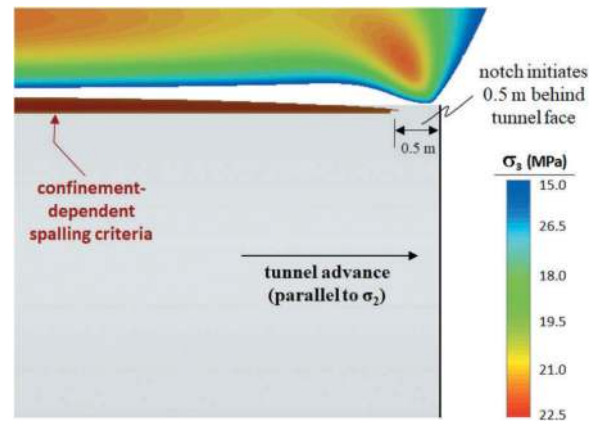

Figure 6. 3-D stress and spalling analysis results plotted on a longitudinal profile showing the distance from the tunnel face where spalling initiates (at 0.5 m). The model-predicted spalling is shown in dark red and is plotted together with the σ_3 confinement contours.

checks: that the depth of spalling several meters behind the tunnel face, beyond its influence on the redistributed stresses, is 0.25 m (agreeing with profile 3 in Figure 2b as reported by Read & Martin, 1996); and the lateral extent of spalling around the perimeter at the same location matches the measured tunnel profile (again, agreeing with that shown in Figure 2b). As shown by the σ_3 contours in Figure 7, the depth of spalling is limited by the confinement levels when they reach the spalling to shearing transition stress of 15 MPa. It is worth noting that using Eqn. (9), a similar result is obtained but with a slightly shallower depth for the notch.

Figure 7. 3-D stress and spalling analysis results plotted on a cross-sectional plane coinciding with “Profile 3” from Read & Martin (1996), including the measured tunnel profile outlined in bright red (see also Figure 2b). Plotted is the model-predicted extent and depth of spalling in dark red together with the σ_3 confinement contours.

5 CONCLUSIONS

Determining the depth of stress fracturing and spalling is essential for designing a deep tunnel in massive brittle rock. However, doing so requires numerical tools and rock strength criteria developed for brittle failure. Commonly used rock strength criteria, such as Mohr-Coulomb and Hoek-Brown, were developed based on experiences and observations dominated by shear failure and need to be revised for robust prediction and design where spalling is encountered. Missing is the recognition that brittle failure develops under high compressive stresses, for example, those tangential to the tunnel boundary, and is sensitive to confinement, exhibiting extensional fracturing under low confinement (near the tunnel boundary) and being limited by higher confinements (deeper into the rock mass) that suppress the spalling process.

A formulation was presented applying crack initiation and spalling limit principles in the form of a confinement-dependent spalling criterion developed for brittle rock failure. The criterion can easily be implemented into any numerical modelling software that allows user-defined criteria. When properly parameterized, it can provide the potential location, depth and lateral extent of spalling as required for excavation and ground support design, and pillar dimensioning. This was demonstrated using a 3-D boundary-element stress analysis against the measured location and depth of spalling failure observed during the advance of the MBE tunnel at the AECL-URL.

The validation exercise demonstrated that the criterion could correctly predict the distance from

the face where spalling was initiated, the depth of spalling, and the lateral extent of spalling around the tunnel perimeter. Results were compared against the use of the Hoek-Brown criterion using peak strength values and brittle fracture strength parameters. These were found to significantly under- and over-predict the observed spalling, respectively. Our findings thus demonstrate that the consideration of the role of confinement on extensional fracturing is critical for evaluating the location and depth of spalling around a tunnel in highly stressed brittle rock.

Practical considerations of shale swelling impact on underground structures liner design for Ontario Line transit project in Toronto, Canada

Masoud Rahjoo*

AECOM, Burnaby, British Columbia, Canada

Verya Nasri

AECOM, New York, New York, USA

ABSTRACT: The swelling-prone Georgian Bay Shale in the Greater Toronto Area, Canada, will host several underground transit projects. Swelling may apply excessive pressure on the support system of the underground structures. Investigating the short-term and long-term swelling impacts on the initial and final liners, respectively, is critical for a successful design. Driven by osmosis and diffusion processes, swelling in shale initiates only when all the prerequisites are available; namely, the outward salinity difference exists, the water is accessible, and the 3D confining stresses applied to a volume of shale are below the suppression stress threshold. This paper reviews the fundamental swelling behaviour characteristics, explains the numerical modelling approach, and discusses the practical considerations of swelling impacts on liner design.

Keywords: Swelling, Time-dependent Behaviour, Suppression Stress, 3D confinement, PLAXIS, RS2

1 INTRODUCTION

Several underground transit projects are being designed and constructed in the Greater Toronto Area, Canada. The host rock is the Georgian Bay Shale, which has swelling characteristics. Swelling, also known as Time-Dependent Deformation (TDD), may apply excessive pressure on the support system of the underground structures. Therefore, it is critical to investigate swelling impacts on the initial and final liners. This paper reviews the fundamental swelling behaviour characteristics, explains the numerical modelling approach selected for the Ontario Line South (OLS) project, and discusses the practical considerations of swelling impacts on liner design.

2 SWELLING CHARACTERISTICS OF GEORGIAN BAY SHALE

The swelling phenomenon in the Georgian Bay Shale is driven by osmosis and diffusion processes (Lee and Lo, 1993). Swelling initiates if all three prerequisites are available, including the existence of outward salinity difference, accessibility of water, and lack of 3D confinement. Rahjoo et al. (2023) provided a comprehensive summary of these

prerequisites and the scenarios for swelling initiation and suppression, as shown in Figure 1.

Figure 1. Prerequisites for swelling initiation in shaly rocks in southern Ontario, Canada (Rahjoo et al., 2023).

In Figure 1, the Swelling condition is noted by S, and the three No-Swelling (NS) Conditions are

*Corresponding author: masoud.rahjoo@aecom.com

noted by NS Salinity (NS S), NS Water (NS W), and NS Confinement (NS C). No-Swelling Type Salinity (NS S) is when there is no or negligible outward salinity difference between the pore and ambient fluids. So, even with a reduction of 3D confinement and extra access to water, the swelling would not initiate. As soon as an outward salinity difference is introduced, swelling will occur. No-Swelling Type Water (NS W) is when there is limited access to water. So, even with the reduction of 3D confinement and the potential existence of an outward salinity gradient, swelling would not initiate. As soon as water is accessible, swelling may occur. No-Swelling Type Confinement (NS C) is when the 3D stress state confines the shale. So, even with extra access to fresh water, the swelling would not initiate. As soon as stress is relieved, swelling will occur. The stress relief should happen in a 3D sense, and swelling would not arise unless the 3D confining stresses applied to a volume of shale drop below a suppression stress threshold.

Swelling behaviour, upon its initiation, has two aspects of time-dependency and confinement-dependency, as will be discussed next. Before getting to them, we should remember that shales are bedded and exhibit anisotropy (commonly transverse isotropy). The anisotropy is an inherent characteristic of the time-dependency and confinement-dependency of shales.

2.1 Time-dependency

As shown in Figure 2, swelling strain increases linearly over the logarithm of time. The swelling strain and its rate are higher perpendicular to the bedding (black curve) compared to tangential (parallel) to the bedding (red curve). This effect is the direct consequence of the inherent transverse isotropy of shales. The swelling rate decreases over time, and the maximum is expected to occur in the early days and months after swelling initiation rather than in years. Still, swelling strain can increase to several times the 1-year swelling strain over the lifetime of the tunnelling projects.

There are some constraints on swelling from chemical and mechanical perspectives. From a chemical perspective, the driving force behind swelling is the salinity gradient. So, the process naturally stops when there is no salinity difference between the water in the pores and the ambient water. The salinity difference is mainly affected by the shale composite and accessibility to fresh water over time. From a mechanical perspective, swelling results in the elongation of the sample. So, the shale sample eventually cracks (most probably tangential to the beddings) after reaching a specific extensional strain. The chemical and mechanical constraints point to an upper-bound swelling strain over time despite the high swelling rates at the early stages of swelling initiation.

Figure 2. A linear increase of swelling strain over logarithm of time. the example belongs to a free swell test. (Rahjoo et al., 2023). note the higher swelling strain and swelling rate perpendicular to the bedding (black curve) compared to tangential to the bedding (red curve).

2.2 3D confinement-dependency

Swelling strain decreases linearly over the logarithm of confinement. Confinement, whether the stress is applied perpendicular or tangential to the bedding, suppresses swelling, i.e., suppression is a multi-directional phenomenon. Again, this is the direct consequence of the inherent transverse isotropy of shales and the fact that swelling is a volumetric increase of pores size.

The multi-directional suppression effect of confinement is critical from a practical perspective: the rock around the underground excavation experiences radial unconfinement but tangential compression/tension. The radial stress reaches the original in-situ stress within a specific distance from the excavation perimeter. The potential swelling is limited to the rock surrounding the excavation. The induced tangential compression, however, acts to suppress swelling. Therefore, the swelling would only initiate in the laterally deconfined rock surrounding the excavation if the rock is sufficiently confined tangentially. The swelling is more expressed in the rock that is unconfined both radially and tangentially, especially considering the ease of access to fresh water via the opened fractures. Please recall that swelling would not occur even in the tension zones if water accessibility and salinity gradient prerequisites are not met.

2.3 Design considerations

The possibility of the scenarios that could initiate swelling should be carefully assessed in the early stages of the design of new excavations. The success of the swelling mitigation strategy is directly associated with suppressing the prerequisites, i.e., eliminating or diminishing any of the outward salinity gradient, 3D unconfinement, or water accessibility. The interaction between the in-situ conditions and construction sequences should be assessed to determine how the three swelling mitigation means can be used effectively and successfully. The cost-benefit evaluation of swelling suppression methods may lead to the allowance of a controlled swelling stage during construction as

a mitigation strategy, which is very cost-effective in many projects. It is only after the exhaustion of all possible means of mitigation strategies that the designer moves to control swelling by enhancing the support system's structural performance.

3 NUMERICAL MODELLING OF SWELLING BEHAVIOUR

3.1 Swelling model selection

For the OLS project, we decided to use PLAXIS2D to investigate swelling and its impacts on lining design. Among the swelling models available in PLAXIS2D, we selected the Anagnostou model (1993), as it considers the 3D confinement-dependency of swelling behaviour. A similar model exists in RS2. The time-dependency and confinement-dependency of this model are as follows:

$$(\epsilon)_p = (\epsilon_\sigma^\infty)_p (1 - e^{-A_0 t}) \quad (1)$$

$$(\epsilon)_t = (\epsilon_\sigma^\infty)_t (1 - e^{-A_0 t}) \quad (2)$$

$$(\epsilon_\sigma^\infty)_p = -k_{qp} \log(f(\sigma)/f(\sigma_{sup})) \quad (3)$$

$$(\epsilon_\sigma^\infty)_t = -k_{qt} \log(f(\sigma)/f(\sigma_{sup})) \quad (4)$$

$$f(\sigma) = \sigma_p k_{pt} + (\sigma_{t1} + \sigma_{t2}) \quad (5)$$

$$f(\sigma_{sup}) = \sigma_{q0p} k_{pt} + 2\sigma_{q0t} \quad (6)$$

$$k_{pt} = k_{qp}/k_{qt} \quad (7)$$

In which, $(\epsilon_\sigma^\infty)_p$, A_0 , k_{qp} , k_{qt} , σ_{q0p} and σ_{q0t} are the input parameters. σ_p , σ_{t1} , and σ_{t2} are the magnitudes of stress perpendicular and tangential to the bedding. Equation (6) enforces an implication to the Anagnostou model that a relation exists between $\sigma_p^{\mu-sup}$ and $\sigma_t^{\mu-sup}$ (the values of the uniaxial stress that suppresses swelling perpendicular and tangential to bedding, respectively) as:

$$\sigma_p^{\mu-sup} k_{pt} = \sigma_t^{\mu-sup} = \sigma_{q0p} k_{pt} + 2\sigma_{q0t} \quad (8)$$

In Anagnostou model, the ratio k_{pt} defines the ratio of $(\epsilon)_p/(\epsilon)_t$, $(\epsilon_\sigma^\infty)_p/(\epsilon_\sigma^\infty)_t$, and $\sigma_p^{\mu-sup}/\sigma_t^{\mu-sup}$.

3.2 Swelling model restrictions

The Anagnostou model comes with a few restrictions. The first restriction is that σ_{q0p} and σ_{q0t} can take any value if they satisfy Equation (8). For the sake of simplicity, we select $\sigma_{q0t} = 0$, so that Equation (8) reduces to:

$$\sigma_p^{\mu-sup} k_{pt} = \sigma_t^{\mu-sup} = \sigma_{q0p} k_{pt} \quad (9)$$

Therefore:

$$\sigma_{q0p} = \sigma_p^{\mu-sup} = \sigma_t^{\mu-sup} / k_{pt} \quad (10)$$

The second restriction is that the model uses an exponential function for time-dependency per Equations (1) and (2). The exponential functions come

with upper bound values of $(\epsilon_\sigma^\infty)_p$ and $(\epsilon_\sigma^\infty)_t$. More importantly, the strain rate of the exponential function is quite different from the observed logarithmic trend of swelling (see Figure 2).

The abovementioned three restrictions are carefully considered during model calibration. The first restriction concerning an upper bound value for swelling strain $(\epsilon_\sigma^\infty)_p$ is addressed by using a new logarithmic function to find the upper bound value for the project's lifetime. The new logarithmic function is defined as (Rahjoo et al. 2023):

$$\epsilon = m_1 \log(m_2 t + 1) \quad (11)$$

$$m_1 = SP_\sigma / \log(100 - \bar{t}) - 1 \quad (12)$$

$$m_2 = (90 - \bar{t}) / 10\bar{t} \quad (13)$$

SP_σ is the Swelling Potential defined as the difference between strains measured 100 and 10 days after initiation:

$$SP_\sigma = \epsilon_{100} - \epsilon_{10} \quad (14)$$

$\bar{t} > 0$ is the time at which we have $\epsilon = SP_\sigma$, and has an upper bound of $\bar{t} < 90$.

100-120 years is a typical lifetime for ordinary tunnelling projects in North America. This lifetime gives an upper bound for swelling strain $(\epsilon_\sigma^\infty)_p$ that should be considered in numerical modelling.

The second restriction concerning the strain rate of the exponential function is addressed by dividing the modelling timeframe to two periods, one for short-term swelling and one for long-term swelling, each section having its own A_0 and $(\epsilon_\sigma^\infty)_p$. For a given ϵ_σ^∞ , A_0 controls the slope of the swelling curve (i.e., swelling strain versus time) as we have $\partial \epsilon / \partial t = \epsilon_\sigma^\infty A_0$. Also, A_0 controls the time at which 0.95% of ϵ_σ^∞ is reached, i.e., time at $0.95 \epsilon_\sigma^\infty \approx 3/A_0$. The swelling rate is essential for the first period as it has its highest rate right after initiation. Construction sequencing and the lag between excavation and support installation are critical factors for the selection of an appropriate end date for the first modelling period. Therefore, the input parameters for this two-period model should be selected according to the construction specifications of each project. In other words, for a similar host rock, the input parameters used for an SEM cavern could differ from those used for a TBM tunnel due to the difference in their construction specifications. As a result, knowledge of construction specifications is a prerequisite for model calibration.

4 NUMERICAL INVESTIGATION FOR OLS PROJECT

The Ontario Line Southern Civil, Stations and Tunnel project is a design-build-finance contract for the southern portion of the Ontario Line, from Exhibition/Ontario Place to the Don Yard portal. The OLS project includes seven stations (one above-ground and six underground) and a six-kilometre tunnel from Exhibition to Don Yard portal. The project layout is shown in Figure 3.

Figure 3. Ontario Line Southern Civil, Stations & Tunnel Project.

4.1 Model geometry and excavation sequencing

The geometry and stratigraphy of an SEM cavern model for the OLS Project is shown in Figure 4. The phases defined in the model are listed in Table 1. The model is symmetric, and the snapshot is cropped in Figure 4. Note that the geometry and design presented here belong to the tender design and will be updated for construction design stage.

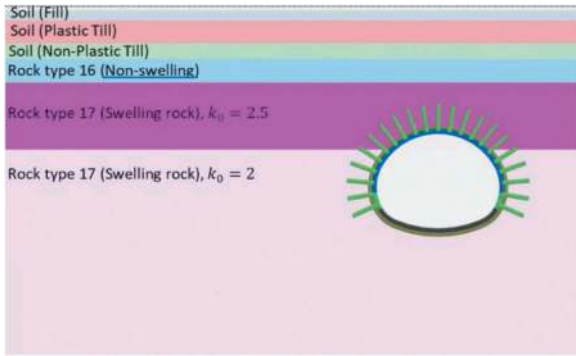

Figure 4. Geometry and stratigraphy of the SEM cavern model.

4.2 Swelling model calibration

The calibrated input parameters are listed in Table 2. Remember that $\sigma_{q0t} = 0$, and $k_{pt} = k_{qp}/k_{qt} = 3$. The calibrated time-dependent behaviour is shown in Figure 5.

4.3 Swelling initiation in numerical model

Above a certain depth, the in-situ stress level sits below the suppression stress criterion given as (Equations (5) and (6)):

$$f(\sigma) = f(\sigma_{sup}) \quad (15)$$

To differentiate and eliminate the swelling that had already happened in geological time in the naturally low-confined over-burden, a historic swelling phase is considered in the numerical model (see Table 1), after which displacements are set to zero

Table 1. Modelling Phases in PLAXIS2D.

Phase	Relaxation/ TTD
In-situ Stress State Initialization	-
Historic Swelling Initialization	TDD for 100 Days
Excavation of the Top Heading, Shotcrete and bolts	Top Heading: 60% Top Heading: 100%
Short-term TDD	TDD for 30 Days
Excavation of the Top Bench Shotcrete and bolts	Top Bench: 70% Top Bench: 100%
Short-term TDD	TDD for 30 Days
Excavation of the Bottom Bench Shotcrete and bolts	Bottom Bench: 80% Bottom Bench: 100%
Short-term TDD	TDD for 30 Days
Excavation of the Invert Shotcrete	Invert: 100% -
Short-term TDD	TDD for 10 Days
Long-term TDD	TDD for 80 Days
Installation of Final Lining	
Long-term TDD	TDD for 120 Days
Long-term TDD Until 120 Years	TDD for 43700 Days

Table 2. Calibrated input parameters for PLAXIS2D model.

TDD Period	k_{qp}	k_{qt}	σ_{q0p}	A_0	$(\epsilon_{\sigma}^{\infty})_p$
1st Period (Day 0 to 100)	0.01071	0.00357	800	0.06	0.018
2nd Period (Day 100 to 44000)	0.02142	0.00714	800	0.001	0.036

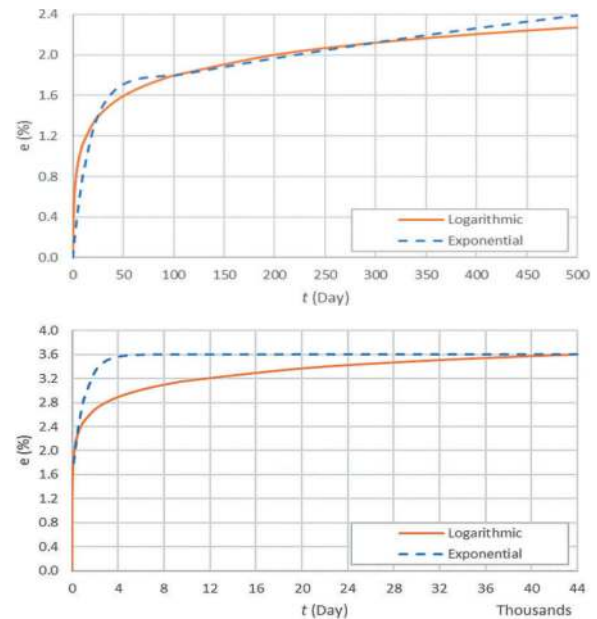

Figure 5. The modelled exponential vs lab-based logarithmic time-dependency of swelling strain perpendicular to bedding.

before the excavation phases. As a result, the naturally low-confined zone consumes a portion of its swelling potential in this historic swelling phase.

4.4 Lining specifications

Based on the load requirements of the permanent lining, the lining thickness increases from 40 cm at the crown to 80 cm at the invert. In the model, three lining sections are considered with 40cm, 60cm, and 80 cm thicknesses. The permanent lining properties are listed in Table 3.

Table 3. Properties of the permanent lining.

Support Element	Properties	
Lining (Cast-in-place)	PLAXIS Element	Plate, elastic
	Drainage type	Non-porous
	Young's modulus E	33 E+06 kN/m ²
	Poisson's ratio ν	0.2
	density	25 kN/m ³
Top Section	thickness	0.4 m
Middle Section	thickness	0.6 m
Bottom Section	thickness	0.8 m

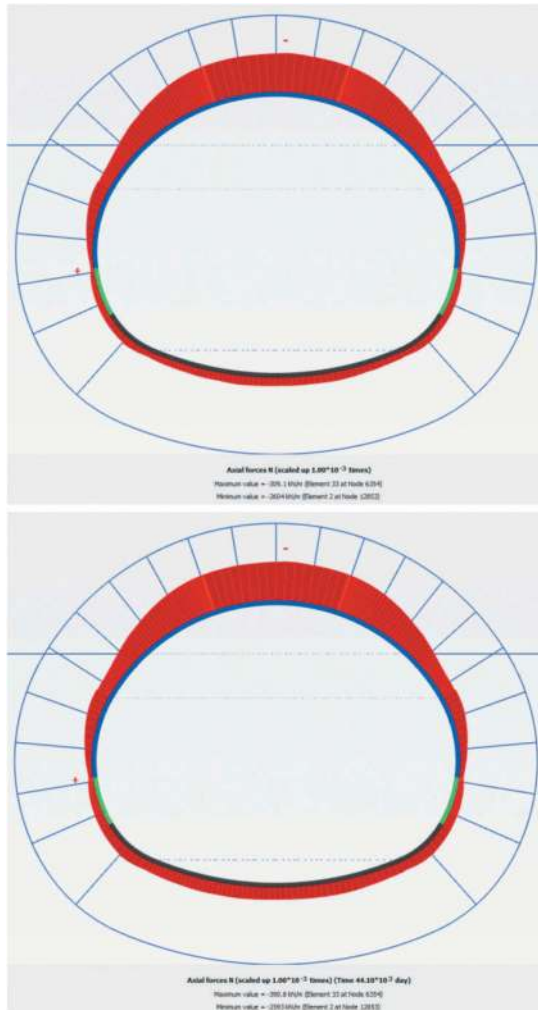

Figure 6. Axial force in the sem cavern model liner over time. top) after installation of permanent liner, after TDD for 180 days, Bottom) after TDD for 44000 days.

4.5 Results and discussion

The numerical analysis shows that the magnitudes of total displacements at the springlines and invert are more significant than at the crown. Every excavation sequence is followed by a short-term TDD, which quickly vanishes. Liner responses to long-term TDD show increases in the maximum value of axial and shear forces, as well as bending moment, as seen in Figures 6 to 8.

Ground response to long-term TDD shows increase in the magnitude of total displacement, as shown in Figure 9. An increase in the magnitude of displacement in the invert over time (TDD-induced) is noticeable, although it is very small. The long-term TDD is only observed in the invert with a magnitude of 2.5mm over the course of 4000 days (approximately from day 300 to day 4300), which vanishes afterwards. Similar observations are made investigating the displacement of the liner.

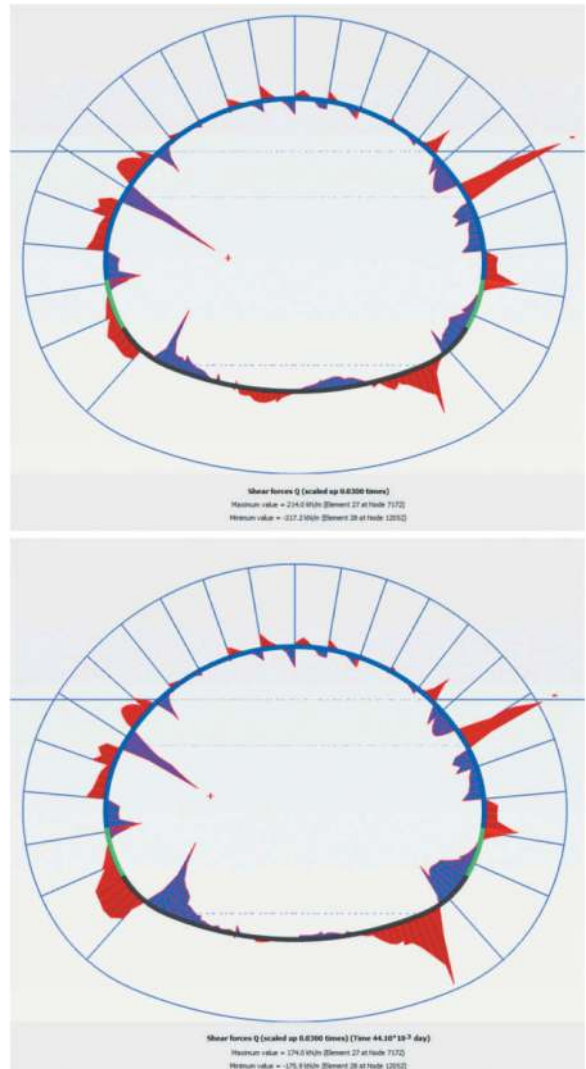

Figure 7. Shear force in the sem cavern model liner over time. top) after installation of permanent liner, after TDD for 180 days, Bottom) after TDD for 44000 days.

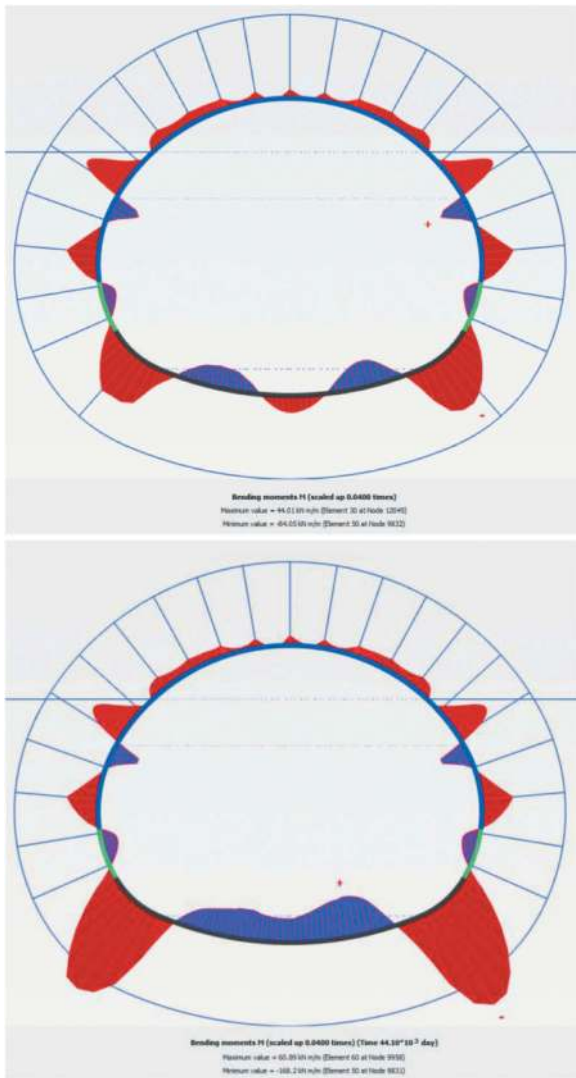

Figure 8. Bending moment in the sem cavern model liner over time. top) after installation of permanent liner, after TDD for 180 days, bottom) after TDD for 44000 days.

Figure 9. Total displacement contour in the sem cavern model over time. left) after installation of permanent liner, after TDD for 180 days, right) after TDD for 44000 days.

Figure 10. Axial force-shear force diagrams for the sem cavern lining. data is plotted for the 40cm, 60cm, and 80cm lining sections. data after 44000 days is used.

The demand vs capacity of the lining is investigated using the interaction diagrams for each lining section (40cm, 60cm, and 80 cm sections, as shown in Figures 10 and 11. Demand data falls below the acceptable limits of the capacity of the designed lining. Overall, the time-dependent displacements are found to be suppressed by the 3D confinement around the excavations, and in cases where a small amount of swelling mobilizes, it vanishes over the course of 2000 days.

Figure 11. Axial force- moment diagrams for the sem cavern lining. data is plotted for the 40cm, 60cm, and 80cm lining sections. data after 44000 days is used.

5 CONCLUSION

Swelling in shale initiates only when all the pre-requisites are available and may apply excessive pressure on the support system of the underground structures. Upon initiation, the swelling has the highest strain rate right at the beginning. Hence, the primary mitigation strategy against the potential swelling impacts is giving the ground enough relaxation time after excavation and before installation of the permanent lining.

In this paper, we present the results of our investigation of swelling for an SEM cavern of the OLS Project that will be developed in the swelling-prone Georgian Bay Shale in the Greater Toronto Area, Canada. The numerical modelling results show that the alterations in the swelling-induced deformation and load/ bending moment of the lining over the project's lifetime are negligible. Our interpretation of the results is that the induced tangential compressive stresses around the excavation and the increase of radial compressive stresses in the rock due to lining-rock interaction over time contribute to the suppression of swelling.

How to consider the effects of longitudinal joint imperfections on internal forces in segmental tunnel linings

Fabian Rauch* & Oliver Fischer

Chair of Concrete Structures, Technical University of Munich, Munich, Germany

ABSTRACT: Small geometrical imperfections are inevitable when assembling concrete segments to a circular segmental tunnel lining. As a result, small translational and rotational contact imperfections occur in the longitudinal joints between the segments. As these imperfections sum up, they can significantly influence the internal forces in the lining. While the normal forces are not very sensitive to imperfections, the bending moments and, consequently, the stresses in the lining can be significantly increased. In structural design, imperfections are typically taken into account in local analyses (e.g. stress distribution at joints). In the overall calculation of internal reactions, however, imperfections are mostly neglected or considered with approaches that strongly simplify the structural behavior. A more accurate and realistic investigation of this influence is achievable with numerical models that explicitly include the longitudinal joints and potential imperfections with contact formulations. Therefore, first, a suitable modeling strategy was developed. However, these calculations are time-consuming if many combinations have to be considered and only supported by limited available calculation programs. Therefore, it is shown and verified how imperfections can be considered in a simplified way with one-dimensional bedded beam models and rotational springs. The simplified approach's results approximate well the numerical model's results with discrete joints and contact formulations.

Keywords: FEM, structural design, imperfections, assembly, tolerances, TBM

1 INTRODUCTION

Mechanized tunneling by placing curved reinforced or steel fiber concrete segments to form a circular segmented lining is nowadays a state-of-the-art tunnel construction technique that is widely used (Fischer et al., 2014).

One essential construction step of this method is the assembly of about five to 13 (Grübl, 2012) segments into a ring within the cover of the TBM shield, after which the segments are connected through several joints (Figure 1).

The number of joints with one surface axis in the longitudinal direction (“longitudinal joints”) equals the number of segments. Two further joints connect the neighboring rings (“circumferential joints”). The joint surfaces can be of different shapes. Flat shapes are nowadays state-of-the-art for longitudinal joints, while several options exist for circumferential joints (DAUB, 2013) (DAUB, 2023).

Figure 1. Segmental structure and nomenclature.

*Corresponding author: fabian.rauch@tum.de

For ring assembly, experienced TBM operators usually bring the segments into their foreseen position with the help of visual control and simple auxiliary means. Sometimes built-in components that assist the operators during assembly (e.g. guiding rods, tongue/groove) are used. These methods ensure satisfactory assembly quality, and watertightness is commonly achieved.

However, a completely accurate assembly of these large segments is not possible. Small irregularities and geometrical imperfections in the longitudinal and circumferential joints are inevitable (OEVB, 2009). Although they do usually not adversely affect functions like watertightness, they can cause incomplete contact between two joint surfaces. Both translational and rotational imperfections are possible (Figure 2).

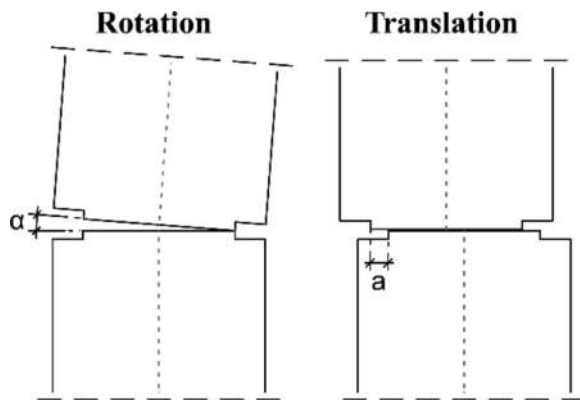

Figure 2. Rotational and translational imperfections.

Such imperfections, which were all within the permissible tolerances, were measured in a recent structural monitoring project of the authors (Rauch and Fischer, 2022), which was the starting point for investigations on the influence of geometrical joint imperfections on the internal forces in a segmental tunnel lining. The imperfections in this study are those caused by assembly inaccuracies. Although some mechanisms overlap, imperfections due to production tolerances are not considered here, as they are generally kept as low as possible.

Imperfections in circumferential joints can lead to local stress peaks due to inaccurate longitudinal supports. They can cause damage to the concrete segments during TBM advance when the longitudinal jacking forces act on the lining. This was already discussed e.g. in (Behnen et al., 2016), and is therefore not further studied.

The general, qualitative mechanisms regarding the influence of longitudinal joint imperfections on the internal forces become visible by analyzing the

situation in Figure 2. Both rotational and translational imperfections cause an incomplete contact of the two joint surfaces. Their center lines do not match, and an initial eccentricity is already included in the structure before loading. When normal forces develop in the lining, these initial eccentricities cause additional bending moments.

Former investigations regarded the local resistance of longitudinal joints with geometric imperfections (Cavalero et al., 2011) and the general influence of joint imperfections on the linings' structural behavior (Schotte, 2016). To the authors' best knowledge, a systematic analysis of the effects of longitudinal joint imperfections on the stresses and internal forces along the linings' circumference compared to a perfectly assembled ring has yet to be carried out. This is necessary to assess their significance for structural design.

Due to the large number of possible combinations and the resulting great effort, experimental studies are not feasible for this analysis. Numerical investigations are the better-suited approach.

Therefore, a modeling strategy had to be developed as a first step to reproduce the influence of longitudinal joint imperfections on segmented linings realistically and accurately in a numerical model. Further requirements of the modeling strategy were a short calculation time and eligibility for parametric studies. An advanced and a simplified modeling strategy were established and can be used depending on software availability and available calculation time.

The model development, the established strategies, and the (validating) results of the first calculations are presented in this paper.

2 LONGITUDINAL JOINT IMPERFECTIONS

Longitudinal joint imperfections can appear in the forms shown in Figure 2. Theoretically, as a third form, it is also possible that the two surfaces of a joint have no contact. This is possible if the segments of neighboring rings interact and stabilize each other via friction. However, the corresponding mechanisms differ from those in Figure 2; therefore, this third case is not considered in this study. Except for some special cases, it is almost always necessary to combine rotational and translational imperfections in an imperfect ring assembly (Figure 3) for geometrical compatibility.

To cause longitudinal joint imperfections, the segments have to be rotated and translated. These movements also cause "global" deformations; consequently, the form of the segmented lining differs from a perfect circle. This is called "initial ovalization" and was e.g. described in (Baumann, 1992) (Figure 3).

Figure 3. Left: combined rotation and translation, right: initial ovalization (OEVBB, 2009).

2.1 Imperfections in structural design

In structural design, when dimensioning the longitudinal joints for partial (concentrated) compression stresses and tensile splitting forces (Schmidt-Thrö et al. 2019), the negative influence of imperfections on stresses and internal forces can be considered by an extra eccentricity due to assembly inaccuracies (ITA, 2019). This value has to be set project-specific, but it should generally be around ± 10 mm (e.g. (DB Netz AG, 2002)).

Regarding the effects of longitudinal joint imperfections on internal force development, to the best knowledge of the authors, no explicit recommendations are available. Performing calculations on an elliptical-shaped ring is a thinkable way to consider initial ovalizations, but this does not reproduce well the real situation. Generally, it is indirectly tried to keep the influence of longitudinal joint imperfections low through other recommendations (e.g. small tolerances).

2.2 Limit values

To consider a realistic parameter range for translational and rotational imperfections as well as for initial ovalizations in the study, limit values are set according to guidelines and literature. There is no direct, generally valid relation between the three values. Therefore, one limit for each must be set and checked separately for any model input parameter combination. The modeling strategy presented in this paper was developed and tested for and within these limit values.

Relevant guidelines on segmental tunnel linings (e.g. (ITA, 2019), (DAUB, 2013), (DAUB, 2023), (OEVBB, 2009), (DB Netz AG, 2002), (BMDV, 2022)) do provide limit values for assembly misalignments (translational imperfections). A realistic range should be of ± 10 mm. Due to geometrical compatibility, this value indirectly also narrows down rotational imperfections and ovalizations. However, separate limit values are set.

(Cavalaro et al., 2011) assumed possible segment rotations of up to 0.4° . (Schotte, 2016) reported measured values of up to about 0.1° . (OEVBB, 2009)

considers values below 0.225° as feasible. The limit is set to $\pm 0.3^\circ$ to consider the possible range.

The third limit value regarding the initial ovalization is set to 0.5% of the inner diameter, according to (DAUB, 2013) (DAUB, 2023).

3 ADVANCED MODELING STRATEGY

The FEM software ABAQUS/CAE 2017 (Dassault Systemes, 2016) is used for the “advanced” model. In this advanced model, the different mechanisms relevant to this study are included in a more realistic and detailed way. Some of the corresponding modeling strategies were developed during investigations for a Master’s Thesis (Dreier, 2023) that the authors of this paper supervised.

3.1 General model configuration

The focus of the study is on the influence of joint imperfections. Therefore, the model detailing is increased around this aspect. Other model components that are usually important for tunnel structures are not relevant to this study, e.g. soil parameters or groundwater. Therefore, the model basis is a bedded beam model ((Behnen et al. 2012), (Behnen et al., 2015)) (Figure 4). In this model, the soil-(tunnel)structure-interaction (SSI) is considered in a simplified way by springs. The radial spring stiffness is determined according to (Duddeck, 1980). The tangential spring stiffness, simulating the tangential SSI, is set to 2.5 % of the radial spring stiffness to increase numerical stability but is not expected to occur in reality (DAUB, 2013) (DAUB, 2023). Because a shallow tunnel is modeled in this case, a 90-degree area around the tunnel crown remains unbedded.

In bedded beam models, the concrete segments are typically modeled as one-dimensional straight beam chains to approximate the circular form. In the studied case of this paper, 96 beams formed the ring. The longitudinal joints are modeled in a simplified way with hinges that connect these beams. Rotational springs are applied to these hinges to account for the rotational stiffness of the longitudinal joints. The corresponding moment-rotation-relation was established by (Janßen, 1983), adapting the findings of (Leonhardt and Reimann, 1965) for tunnel linings. The earth and water pressure are applied to the tunnel explicitly through active loads.

However, because of the simplified approach with hinges and rotational springs, one-dimensional models do not include the actual longitudinal joint geometry. Therefore, explicit modeling of longitudinal joint imperfections is not possible. At least a two-dimensional model is required. That is why, in this study, two- and three-dimensional beam models are used to model longitudinal joints and their imperfections realistically, as presented in the next section.

The concrete segments are modeled with an elastic material model. A more accurate elastic-plastic

concrete material model (Sargin, 1971) leads to no significant changes in the results. Reinforcement bars were not considered in this model.

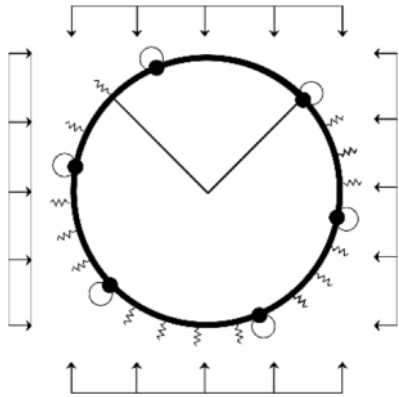

Figure 4. Bedded beam model.

3.2 Longitudinal joint modeling

The joint area is modeled with its actual geometry. The only geometrical simplification regards the transition area from joint surfaces to segment body. These are considered rectangular, although, in reality, they are sometimes inclined. This had no significant effect on the results. Bolts and gaskets were not included as they were not expected to significantly influence the studied mechanisms.

The interaction of two joint surfaces is modeled with surface-based contact in ABAQUS/Standard. The normal and the tangential behavior of two interacting surfaces in contact must be defined. The various options and settings for contact simulation can significantly impact the results and must be selected carefully.

The parameters and settings for numerical longitudinal joint simulations of (Schmidt-Thrö, 2019) are used to ensure a realistic behavior perpendicular to the joint surface. These values were calibrated on an extensive experimental study. The normal contact behavior is defined by the pressure-overclosure relationship of “hard contact.” This minimizes penetration of two surfaces and does not allow for tensile stress transmission across them (ABAQUS Documentation, 2006, 30.1.2). The penalty constraint enforcement method was used with a stiffness scale factor of 300 (Schmidt-Thrö 2019).

The tangential behavior is simulated by a penalty friction formulation (ABAQUS Documentation, 2006, 30.1.5). The friction coefficient for the Coulomb friction model is set to 0.4. This is slightly below the range of 0.5-0.7 proposed for concrete-concrete friction in (fib, 2013) because the concrete surface of lining segments is expected to be exceptionally smooth and regular due to the high production tolerances and the normally used steel formworks.

To model longitudinal joint imperfections, the segments are rotated and arranged with an offset (translated) according to predefined values. These values

are within the limit values of section 2.2 and ensure that overlapping of the joint surfaces is avoided (geometrical compatibility).

3.3 Test results and model selection

The presented modeling strategy is applied to an example case of a recently built shallow segmented tunnel (Rauch and Fischer, 2022) to test the strategy and investigate the influence of longitudinal joint imperfections on the internal forces of the lining. The modeling parameters of the example case are listed in Table 1. The models’ geometry and the loading situation are presented in Figure 5, as well as the geometric details of the longitudinal joints.

A two-dimensional and a three-dimensional model are created. The mesh size is set following a sensitivity analysis, and the model is meshed regularly and evenly distributed. The CPE4R element type is used for 2D calculations, and the C3D8R element type is used for 3D calculations.

Table 1. Model parameters and values.

Parameter	Value
Oedometric modulus (soil)	45 MPa
Concrete elastic modulus	36,000 MPa
Concrete strength	C 45/55
Concrete density	2,500 kg/m ³
Segment length	1.2 m
Segment thickness	45 cm

Figure 5. Example case, upper: model geometry and loads., lower: longitudinal joint detail.

3.3.1 2D vs. 3D model

The results of the two-dimensional (2D) and the three-dimensional (3D) model are compared in Figure 6.

The model dimensionality has no significant influence on the linings' normal forces. However, they do have a small effect on the bending moments. While the qualitative trends are similar, there are some differences regarding the quantitative values. The maximum bending moment magnitude is 14 % higher in 3D than in 2D. Except for a slight influence of the general differences between 2D and 3D models, this is ascribed to the fact that the longitudinal joints show a slightly stiffer behavior in 3D than in 2D (Schmidt-Thrö, 2019).

However, both models deliver adequate results to reproduce the structural behavior and can be used to study the influence of longitudinal joint imperfections. The 2D approach is used for further calculations and analyses to reduce modeling and computation time.

Figure 6. Effect of model dimensionality on internal forces with explicit longitudinal joint modeling.

3.3.2 Perfect vs. imperfect assembly

To illustrate the mechanisms, the results of the example case with one full-ring configuration of imperfections are presented. The applied imperfections are shown in Table 2. A positive value

corresponds to a clockwise rotation. Translational imperfections were added within the limit values to ensure the required geometric compatibility.

The internal forces get disturbed when applying this configuration to the example case (Figure 7). The effect of imperfections is much smaller on normal forces than on bending moments. The difference in normal force magnitude is about 4.5 %. Although some minor qualitative changes occur, the overall trend and the magnitude remain similar to the normal forces in perfectly assembled segments.

Table 2. Rotational imperfections.

Segment	Rotation in [°]
A	-0.04
B	-0.06
C	0.09
D	-0.11
E	0.11
K	0.01

This is not the case for bending moments. The bending moments change strongly both qualitatively and quantitatively. E.g., although almost no bending moments resulted in the tunnel invert of a perfectly assembled model, significant bending moments have now developed. The bending moments differ almost everywhere along the circumference, also in their sign.

Generally, in this and other analyzed examples, the bending moments are increased due to the longitudinal joint imperfections. The peak bending moments almost triple. Since the normal forces remain pretty similar, this results in significantly higher stresses in the segmented lining, which is not desirable.

Of course, it is also possible that different configurations of imperfections have no influence or even reduce stresses in segments. However, since the actual assembly imperfections can neither be predicted in advance nor steered accurately, it should generally be tried to avoid them by ensuring an accurate segment assembly and considering auxiliary means to keep (additional) lining stresses low.

4 SIMPLIFIED APPROACH

With the strategy presented in section 3, it is possible to simulate the influence of longitudinal joint imperfections on the linings' internal forces. However, this strategy is costly and requires advanced numerical modeling software. A simplified approach would be beneficial to perform more calculations in a shorter time and consequentially enable more extensive systematic parametric studies – and to allow for potential applications in engineering practice. As an essential requirement, a simplified approach must

Figure 7. Influence of longitudinal joint imperfections on internal forces.

also reproduce the influence of longitudinal joint imperfections similar to the advanced strategy with satisfying accuracy.

Such a simplified approach is presented and compared to the results of section 3.

4.1 Simplified modeling and simulation strategy

In the simplified approach, the dimensionality of the model is again reduced to one (1D). Because of the one-dimensionality, the longitudinal joints cannot be modeled explicitly anymore. Still, as mentioned, their stiffness can be considered with rotational springs and the moment-rotation-relation proposed by (Janßen, 1983) (Figure 8). The rest, e.g. loads, radial springs, etc., is modeled similarly to section 3. Since no surface contact is required anymore, this approach is feasible with almost any software. Here, the software SOFiSTiK (Sofistik, 2018) is used for the calculations with the simplified approach.

The original formulation of (Janßen, 1983) applies to perfectly assembled rings and complete contact between two flat joint surfaces before loading. When loading starts, the angle α between two neighboring joint surfaces is $\alpha_0 = 0$. Then, the formulation induces the formation of bending moments that develop due to the rotational stiffness of the

joints when opening and closing (which means α gets smaller or greater than one ($\alpha \lessgtr 0$)). It defines a relation between moments and rotations and is reversible in both directions.

Figure 8. Original and modified moment-rotation-relation.

Now, to account for longitudinal joint imperfections, the moment-rotation-relation is modified. When loading starts, the joints are not closed but opened by an angle $\alpha_0 \neq 0$ (Figure 3). This angle is the difference between the rotational imperfections of two adjoining segments. Because the original formulation by (Janßen, 1983) is reversible, $\alpha_0 \neq 0$ equals $\alpha \lessgtr 0$. Graphically, this means the vertical axis in Figure 8 is moved horizontally. Consequently, additional bending moments develop in the lining due to the initial eccentricities caused by the imperfections when a normal force is applied to the longitudinal joint.

4.2 Comparison and validation

To validate the simplified approach, it is applied to the same example case of section 3, and the results are compared to the results of the advanced two-dimensional model with explicit joints. The model configuration can again be found in Table 1, Table 2, and Figure 5.

The results are shown in Figure 9. When considering imperfections, the normal forces resulting from the simplified approach correspond well to the normal forces of the two-dimensional contact model both qualitatively and quantitatively. Once again, it can be seen that the quantitative effect of

longitudinal joint imperfections on normal forces is also small when using the simplified approach.

The bending moments for imperfect assemblies calculated by the two approaches do not agree to the same extent, but similarities can be observed in the two lines. First, with both models, the bending moments are increased significantly compared to the assembly without imperfections. Also, the general qualitative trends are the same in both models. Second, the agreement of the four peak values – important for further studies – is quite satisfactory, especially if put in relation to the peak values of the perfectly assembled model. The observations in different examples were similar.

Figure 9. Comparison of simplified (1D) and advanced (2D) approach.

However, the comparison also shows some disagreements. Although the four peak values have similar magnitudes, they still do not equal each other. Also, the bending moment distribution is slightly shifted to the right in Figure 9, which means it is rotated clockwise on the lining circumference.

Two reasons are found that contribute to these deviations. First, the general model configuration of the two approaches is not exactly the same, even if no imperfections are modeled. Also, although the basic idea is the same, the interaction of two joint surfaces through contact and the simplified

consideration with a rotational spring are not equal. Second, as shown e.g. in Figure 3, modeling the imperfect linings with real geometries requires to include some translations into the model due to geometrical compatibility. This is not possible with one-dimensional beams and rotational springs. This reason should influence the results and could be the leading cause for the observed differences.

Altogether, the simplified approach yields results that reproduce the structural behavior of a segmented lining under the influence of longitudinal joint imperfections in a realistic way. Although there are some disagreements with the results of the two-dimensional model with explicitly modeled longitudinal joints, the results of the simplified approach are satisfying, especially if put in relation to magnitudes of internal forces in perfectly assembled linings. Especially qualitative trends are reproduced accurately. The simplified approach's advantages, which are mainly quicker and easier-to-get results, have to be considered for model selection. By applying either the simplified approach or the two-dimensional model, one gets a good impression of the influence of longitudinal joint imperfections and the resulting trends. Both models can be used for further studies e.g. for systematic investigations on how sensitive the internal forces of models with different parameters react to longitudinal joint imperfections.

5 CONCLUSIONS AND OUTLOOK

A modeling strategy was established to consider the effects of longitudinal joint imperfections on the internal forces in segmental tunnel linings. First, an advanced model was presented. It consists of a two- and a three-dimensional bedded beam configuration that includes longitudinal joints explicitly with their actual geometry. The interaction of two adjoining joint surfaces is considered with a calibrated contact formulation. It was found that the dimensionality has no significant influence on the results.

Then, a simplified approach was presented. The corresponding model consists of a one-dimensional bedded beam. The longitudinal joints are modeled with hinges and rotational springs whose behavior has been described by means of a widely used moment-rotation-relation. To consider longitudinal joint imperfections, this relation was modified.

Both approaches were applied to an example case. Although there were some differences in the results of the two models, they both reproduced the basic mechanisms accurately. They gave the same general trends: while longitudinal joint imperfections have a low influence on the linings' normal forces, they strongly disturb the bending moments, which can increase significantly. As a consequence, the stresses increase, which is not desirable. Because of that, longitudinal joint imperfections should generally be minimized.

The approaches were tested on several example configurations, and the results of one of them were

presented. As a next step, a more systematic study is carried out to analyze the influence of longitudinal joint imperfections on the internal forces under different boundary conditions.

Athens metro “Piraeus” station: Numerical analysis versus observational method

Konstantinos Sampsakis-Bakopoulos* & Nikos Gerolymos

IPP Design & Construction of Underground Works, National Technical University of Athens, Athens, Greece

ABSTRACT: Piraeus, Europe's busiest passenger port and primary gateway to the Greek islands, required a vital metro connection to address the significant tourist influx and resulting traffic congestion during the summer. The inclusion of Piraeus in the Line 3 extension project not only met this demand but also served as a compelling case study for exemplary infrastructure development. The station's underground location, just 40 meters from the sea and 2 meters from the historic ISAP terminal, presented intricate challenges. These challenges involved managing surface traffic diversion and adhering to regulatory guidelines for settlements due to the station's proximity to the ISAP terminal. To overcome the complex hydrogeological conditions and limited surface area, the construction employed the cut-and-cover method with diaphragm walls and prestressed steel struts as temporary support. This approach ensured stability and structural integrity while providing an opportunity for an in-depth case study on implementing the cut-and-cover method in challenging hydrogeological conditions. An array of geotechnical monitoring instruments was meticulously installed, which played a pivotal role in measuring the displacements of the diaphragm walls and nearby structures, variations in groundwater levels due to dewatering processes and settlements arising from the construction activities. By exploiting geological and geotechnical data, finite element analyses were performed to compute the displacements of all monitored points. The focus was on comparing the measured with the computed response in terms of the wall's displacements. The results derived from the aforementioned analysis were in satisfactory agreement with the measured values, affirming the reliability and accuracy of the applied methodologies.

1 INTRODUCTION

The growing tourist influx and the traffic congestion in the area, especially during the summer months made it indispensable for Piraeus to be connected via metro to the centre of Athens and the airport. Thus, Piraeus became one of the 6 stations of the Line 3 extension and was inaugurated in October of 2022 after numerous delays and challenges that arose during the construction of the station.

2 RETAINING STRUCTURE

The Piraeus station is situated adjacent to the terminal of line 1 within the Piraeus port area and is part of the most recent extension of the Athens Metro Line 3. The station is positioned in close proximity, approximately 2 meters, to the ISAP station on its eastern side, while on its western side lies the sea at a distance of 40 meters.

Figure 1. Top view of the Piraeus station outline.

Numerous challenges arose during the construction of the Piraeus station, encompassing various aspects. Firstly, the proximity of the station to the aged and historically significant ISAP terminal building posed a distinct challenge. Additionally, the station's proximity to the Piraeus port led to prevailing hydrogeological conditions, resulting in a water table that reached surface level.

*Corresponding author: sampsakiskostas@gmail.com

This circumstance gave rise to several complications due to the additional pressure exerted by water on the station's diaphragm walls, necessitating careful consideration of the additional load. Moreover, the excavation process induced water due to the head difference. This water flow led to increased pore water pressures beneath the excavation level and subsequent reduction of effective stresses, thereby creating potential risks of uplift. To address these challenges, the construction implemented 80cm thick diaphragm walls, that were constructed in 240cm panels, reaching a depth of 38m, with the reinforced concrete portion spanning up to 29.5m depth.

Figure 2. Side view of the retaining structure.

Figure 3. Retaining structure with emphasis in the struts during the construction phase.

To reinforce the diaphragm walls, a system of five rows of prestressed struts was installed. These struts were progressively added as the excavation deepened, allowing for minimal movements and deformations to prevent an active state. Specifically, the Piraeus station incorporated a total of five rows of prestressed metal supports within its primary trench. The horizontal spacing between the struts was equal to 5.4m, although slight variations in distance occurred in certain areas, especially the corner sections of the station. A visual representation depicting the arrangement of the struts relative to the station trench, both vertically and horizontally, can be observed in Figure 2 and Figure 3.

3 GEOLOGICAL CONDITIONS AND DESIGN PARAMETERS

3.1 Geological conditions

Based on the findings of the geotechnical investigations, which involved sampling and pressure borings, the geological formations encountered within the construction vicinity of the Piraeus station primarily consist of recent Quaternary sediments. Furthermore, in certain deep positions, the presence of the *Marl of Piraeus* formations has been identified. The stratigraphic succession of these units (also seen in Table 1), arranged according to their depth, is as follows:

- [AL] Artificial/Alluvial Deposits
- [SW] “Alipidon” Marsh Deposits
- [PT] Coastal Deposits
 - [PT-CN] Conglomerate-breccia-microconglomerate, exhibiting varying degrees of cementation from light to strong
 - [PT-SD] Sands, silty Sands, silty Sandstones
 - [PT-SM] Silts, sandy Silts, sandy Siltstones
- [NM] Marl of Piraeus
 - [NM-CN] Conglomerate-breccia- microconglomerate, occasionally featuring sandstone horizons or layers of calcite silt in specific locations.

3.2 Idealized geotechnical profile

The design of the GDP-2 section (Table 1), developed utilizing stratigraphy within the study area and encompasses a wide spectrum of anticipated geotechnical conditions. Upon this section, geotechnical calculations were conducted to facilitate the design process for the excavation, temporary support systems, and permanent construction of the Piraeus Station. Specifically, in the construction of the GDP-2 section a unification of the fractional relatives approach was employed between the geotechnical formations sands-sandstones and silts-siltstones. This procedure was also used for the slightly and strongly bound cobblestones of the coastal deposits but also of the cobblestones of the *Marl of Piraeus*.

Figure 4. Stratigraphic representation of the idealized geotechnical profile GDP-2.

The area that was simulated in Plaxis was the section A-A' (as shown in Figure 1) of the deep excavation, while the subsequent calculations and simulations that took place were based on the stratigraphy of the ideal design section GDP-2, the elements of which are presented in the following table:

Table 1. Stratigraphic Succession in GDP-2.

Idealized Geotechnical Profile GDP-2	
Layer I	Level from +2 to +0.20m (Artificial/Alluvial Deposits)
Layer II	Level from +0.20 to -2.60m ("Alipedon" Marsh Deposits)
Layer III	Level from -2.60 to -4.80 m (Conglomerate-breccia)
Layer IV	Level from -4.80 to -17.30 m (Silty Sands, Sandstones)
Layer V	Level > -17,30 m (Sandy Silts, Siltstones)

Table 2. Geotechnical design parameters.

Layer Parameters	Layer I	Layer II	Layer III	Layer IV	Layer V	Units

Permeability, k	10^{-5}	$3 \cdot 10^{-6}$	$8 \cdot 10^{-6}$	$5 \cdot 10^{-6}$	$4 \cdot 10^{-8}$	m/s

3.3 Geotechnical design parameters

The geotechnical design parameters utilized in this study were established in accordance with the guidelines outlined in paragraph 2.4.5.2 of Eurocode 7, specifically the Geotechnical Design Part 1: General Rules. These parameters were estimated by considering the outcomes and derived values from laboratory tests, as well as the findings from field tests. This comprehensive approach ensured the incorporation of reliable and relevant data to accurately determine the geotechnical design parameters for the project.

All the values of the geotechnical design parameters that will be implemented in this thesis are summarized in Table 2.

4 MONITORING SYSTEM

Given the extensive nature of projects of such magnitude, continuous monitoring is imperative throughout both the construction phase and after its completion. In line with this requirement, the Piraeus Station implemented a comprehensive array of monitoring instruments to track movements, settlements, and potential deformations that may arise.

Consequently, the Automated Monitoring System (AMS) program was implemented, encompassing the measurement and recording of various data points, including:

- Vertical and horizontal movements of buildings and structures, facilitated by a volumetric measurement system and a 3D movement measurement system (BNOS0282 & BNOS0285).
- Monitoring the level and water pore pressures of groundwater through the utilization of piezometers (BNHC07 & BNHC08, BBNP0050 & BP244).
- Tracking horizontal movements of the diaphragm walls of the trench via the installation of inclinometers (BNDF06).

This study incorporated data obtained from the previously mentioned piezometers, inclinometers, and the 3D movement measurement system to enhance the accuracy of simulating the authentic conditions that prevailed during the construction of the project. By leveraging the measurements

Figure 5. Monitoring instruments and their position in the studied analysis.

obtained from these monitoring instruments, a more robust and realistic representation of the project's construction environment is expected to be achieved.

5 NUMERICAL ANALYSIS AND COMPARISON BETWEEN FINITE ELEMENT CALCULATIONS AND MONITORED DATA

5.1 Parametric investigation

Analyses were performed with the finite element code PLAXIS for plane strain conditions, in terms of effective stresses, and for fully coupled flow deformation properties of the soil.

A parametric investigation was carried out with the aim of matching the calculated movements with those measured by the inclinometers and the geodetic targets. A total of 6 scenarios were considered regarding the estimated geotechnical and hydraulic conditions (strength and deformability parameters of the soil, excavation levels, groundwater level, water pumping inside the trench etc). By pursuing this approach, the study aimed to ascertain the closest possible

approximation of shared conditions, thereby facilitating the final comparison of data from the instruments employed by the GDP organs. The main features of the scenarios that were examined are summarized in Table 3.

In Figure 6 the deformed meshes of the finite elements at the final stage of the construction stage is presented as calculated by Plaxis for the 1st, 2nd, 4th and 6th scenario.

Figure 6. Deformed meshes of the different scenarios (Upper Left: 1st scenario, Upper Right: 2nd scenario, Lower Left: 4th scenario, Lower Right: 6th scenario).

5.2 Results from finite element calculations

The maximum values of the calculated displacements in the retaining wall and on the ground surface near the station are presented in Table 4.

5.2.1 Horizontal displacements of diaphragm wall and inclinometer

The best comparison between calculated and measured displacements from the monitoring data in the retaining wall is achieved with scenarios 3, 4 and 6. The distributions of said movements are shown graphically in Figure 7.

The smallest deviation for the maximum horizontal movement of the wall results for the 6th scenario and is approximately 20%. On the contrary, the horizontal movements which have resulted from the analyses

Table 3. Parametric Investigation with the altered parameters.

	West	9.3	16	21.2	12	14.3	9.8

Figure 7. Horizontal displacement of the diaphragm wall compared with readings from inclinometer BDNF06.

that used the excavation levels obtained by the monitoring data are slightly increased, but without exceeding the action limit or alarm limit. Therefore, both scenarios of the parametric investigation regarding the regulations set by Attiko Metro are considered safe.

5.2.2 Vertical displacements and geodetic targets

During the construction of the station, the settlements were the most important monitoring size, due to the proximity of the ISAP building to the eastern side of the station trench. The strict limits for the settlements that had to be taken under consideration posed formidable challenges to the project's execution. Specifically, the settlement action limit was 22mm, while the alarm limit was 33mm.

The calculated maximum ground surface settlement based on the initial analysis model exceeded not only the caution limit, but also the alarm limit. As a result, the set of assumptions/considerations regarding the geotechnical and hydraulic conditions is judged as

Figure 8. Settlement curves in the east bank of the excavation in comparison with readings from the 3D movement measurement system.

unrealistic. In Figure 8 the calculated distributions of surface settlements from the 6 scenarios are shown and compared to those measured by the prismatic targets BNOS0282 and BNOS0285. It is observed that the measured behaviour is more favourable even than the forecasts of the most optimistic scenario.

5.2.3 Water pressure, groundwater level and piezometers

Without a doubt, the measurements provided by the vibrating wire piezometers and the standpipe piezometers were of paramount importance in terms of comparison, aiming to achieve a more precise simulation through the analyses.

Figure 9 shows the estimated water table level (scenarios 2, 3 and 4) in comparison with the readings from the piezometers BP244 and BNP0049. It is observed that the measured groundwater level is identical to the initial one (before start of construction activities) at distances from the wall longer than 15 m.

Figure 9. Groundwater level during its depression.

Figure 10 shows the calculated time series of the pore pressure at the upper (-37.6 m) and lower (-39.6 m) positions of the BHNC08 piezometer and are compared with the corresponding measured ones. The comparison of scenarios 2, 4 and 6 is very satisfactory, in contrast to the predictions based on the original analysis model, which show a huge

deviation from the measured behaviour. This justifies to a significant extent the errors as well the large movements based on the original analysis model.

Figure 10. Pore water pressure at the Upper and Lower positions within the vibrating wire piezometers.

6 CONCLUSIONS

Two-dimensional numerical analyses of the excavation and temporary retaining structure were examined, the aim which was the matching of the

calculated with the measured displacements in the retaining wall and on the ground surface. The effect of crucial factors in the behaviour of the temporary support system of the station was investigated parametrically, such as: the stiffness of characteristic soil layers, the pumping conditions and groundwater level, the numerical method used (coupled mechanics - hydraulic analysis or undrained behaviour - consolidation). From the results of the analyses, it was found that the factors with the dominant role are the pumping conditions and groundwater level as well as the excavation step in combination with the depth of the struts placement.

ABSTRACT: The geometry and geology at the southern end of Karanga-a-Hape Station combine to create a challenging set of constraints for design and construction. These were effectively negotiated through the design phase via a collaborative approach between the construction and design teams. Challenges included: development of the overall sequence in order to develop an efficient geometry for the installation of pre-support over the junction in the area; managing the design in response to discovery of a large, fractured fold hinge traversing the junction; refinement of the design through collaboration with the construction-team to manage the risks associated with the junction breakthroughs.

Keywords: Fold, canopy tube

1 INTRODUCTION

The City Rail Link (CRL) Project includes the design and construction of two underground rail stations; a redevelopment of an existing surface rail station; two new rail tunnels; and connections to the existing North Auckland Line (NAL). The twin tunnels connecting the stations extend from Albert Street to Newton where they bifurcate through a grade separated interchange with terminations at Mt Eden Station and between Mt Eden Road and Normanby Road bridges. Connections to the NAL are via east and west grade separated connections.

The twin tunnels were driven northwards from Mt Eden towards the CBD via TBM drives (using a single TBM, first along MC30, then MC20). Karang-a-Hape Station is aligned roughly north-south along Pitt Street, with the intersection with Karang-a-Hape Road over the approximate mid-point of the station. The station layout comprises two station shafts, one at Mercury Lane in the south, and one at Beresford Square in the north, two platform caverns and five connection adits. The two platform tunnels

Figure 1. Overall scheme layout.

(MC20 and MC30) and adits have been mined using roadheaders. Sub-zone MC21 encompasses the junction between a ventilation adit at the southern end of the station, and the MC20 platform tunnel (Figure 2).

The MC21 Junction geometry is influenced by the need to connect ventilation rooms in the Mercury Lane shaft with the southern end of both platform tunnels via MC20 and the adit linking the end of each platform cavern. Four ducts are routed through MC21 totalling 16 sqm. providing tunnel ventilation supply and over track exhaust connections for both platform caverns link the over-track exhausts. The

*Corresponding author: Arun.Sarathchandran@aecom.com

solution results in an oversized platform cavern through the MC21 junction, and a local trench into the adjoining ventilation adit (see Figure 3).

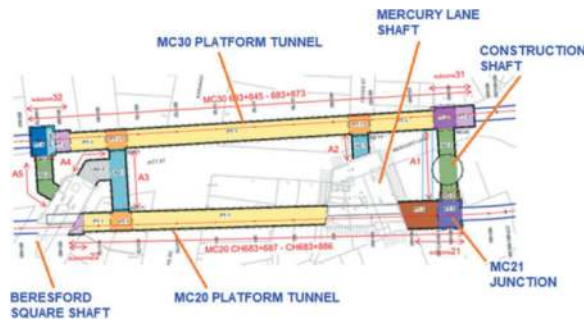

Figure 2. Karang-a-Hape Station layout.

Figure 3. Karang-a-Hape Station – Geometry at south end.

The mined tunnels are designed with a two-pass lining system, an initial, temporary primary support shell, within which cast insitu concrete linings are installed. The platform caverns are approximately 15m span, and 11-14 m high. The ventilation adit is approximately 9m span, and 7-9m high. The mined station caverns and adits are designed as drained structures, with a groundwater pressure relief system.

2 GROUND CONDITIONS

2.1 Geological profile

The geological profile in the vicinity of MC21 consists of fill and alluvium over the sedimentary rocks of the East Coast Bays Formation (ECBF). The ECBF was formed during the Early Miocene, and consists of the following major units in the vicinity of MC21:

- Predominantly interbedded very weak, sandstone and siltstone (EU2). Typical unconfined compressive strength (UCS) values for un-weathered EU2 is 1-5MPa.
- Well cemented volcanoclastic, polymitic sandstones and conglomerates (EU3), typically weak to moderately strong and more massive than EU2.

- Channelised Sandstone (EU3cs) - around Karang-a-Hape Road there is a very specific sequence of conglomeratic sandstone (2-3m thick) grading up into fine sandstone (c.8m thick).

The topography, and rockhead levels, drop away rapidly to the south, such that cover over the crown on MC21 narrows to less than 1m. An inferred geological section along the southern end of the MC20 platform cavern is shown in Figure 4.

Figure 4. MC21 geological long section.

2.2 Geological structure

A normal fault zone was identified during the site investigations, and subsequently mapped during excavation of the tunnels running through the MC21 junction and the Mercury Lane Shaft, Adit 1 and MC30 tunnel (Figure 5). Zones of brecciated rock were encountered within the fault zone, particularly in areas where shear zones intersected. Either side of the fault, zones of blocky rock mass were observed, this graded laterally into massive sandstone (Figure 6). The fault zone varied between 6 to 12m in width and displayed up to 5m vertical offset of the EU2 unit below the Channelised Sandstone. A number of discrete shear zones were observed within the fault zone, these were infilled with 30 to 50mm of highly plastic clay gouge. Defects within the massive rock mass comprised very widely spaced (5 to 10m) orthogonal joint sets.

2.3 Groundwater

The Karang-a-Hape Station area is located in the upper reaches of the ridge line that runs northwards, towards the Waitemata Harbour area. Within this zone the groundwater regime is relatively complex, with four to five levels of perched groundwater systems identified, and a suspected fault-bounded groundwater network, where perched tables are gradually under-drained in cells towards the underlying regional groundwater level. The mined station caverns and adits are designed as drained structures, with a groundwater pressure relief system.

Figure 5. Mapped shear zone associated with normal faulting.

Figure 6. Typical rock classes in the Channelised Sandstone. Zones of broken brecciated rock occurs where shear zones intersect. A zone of blocky rock occurs sub-horizontal defects adjacent to the fault intersect the sub-vertical orthogonal joint sets. Sketch courtesy of A Thorpe.

3 DEVELOPMENT OF MC21 SEQUENCE AND GEOMETRY

3.1 Geometry

The geometry and sequence for the MC21 junction was developed as a close cooperation between the design and construction teams, acknowledging the proposed general arrangement, the expected ground conditions, interfaces with adjacent structures, and construction programme. The platform caverns at

the southern end of the station were accessed via a temporary construction shaft from surface (Figure 2), with the caverns to be constructed prior to TBM transit. The southern station entrance and plant building, the Mercury Lane Shaft, was constructed top-down, lagging behind tunnel construction.

Options for advancing MC21 access from the direction of the ventilation adit were considered, with a phased construction of the arch profile over the top of the junction under spiles rejected in favour of an approach from the north from the direction of the Mercury Lane Shaft. This offered the following advantages:

- Enabled the use of canopy tubes in the area of non-existent to limited rock cover over the junction of the adit.
- Allowed for break-in from the direction of the adit under mature sprayed concrete ($f'c > 20\text{MPa}$) installed in MC21.

Approach from the north was achieved via a construction adit driven through the base of the partially excavated Mercury Lane Shaft (see Figure 7).

Figure 7. Construction access for MC21.

The geometry local to the junction was developed in response to inferred rockhead levels extending south from the Mercury Lane Shaft consisted of (from south to north, see Figure 9):

- Skewed headwall and entry to MC21 under 4m long rock-bolts and shotcrete. The profile here widened as it exited the Mercury Lane Shaft footprint, and transitioned from the narrow construction adit span to a split top-heading for the platform cavern (Figure 10).
- Expansion of the profile (maintaining the split top-heading) under spiles, shotcrete and lattice girders in an area of reducing rock head cover, in order to create sufficient space for the installation of canopy tubes southwards.
- Continuation of the split top-heading southwards under the canopy tubes through the area of the junction with the adit, with the primary support consisting of lattice girders and shotcrete.

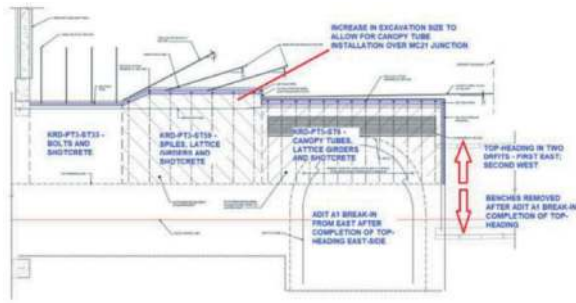

Figure 8. MC21 Arrangement of primary support types.

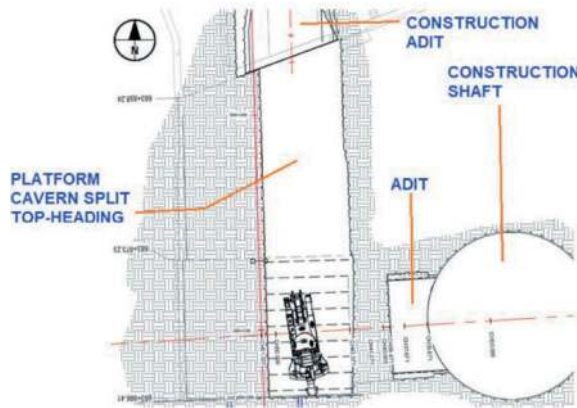

Figure 9. Platform cavern split top-heading layout.

The adit enters MC21 from the east, with the crown level of the adit approximately 2m below that of the platform cavern. This allows break-in of the adit below the level of the canopy tubes over MC21, inside collar reinforcement installed in MC21 prior to the break-through.

Figure 10. Section along the ventilation adit.

3.2 Construction sequence

The base-line construction sequence for excavation and primary support was developed in response to the geometry and ground conditions described above, and involves the following steps:

- A. Break-out from the construction shaft to east and west. The drive to the west terminates short of MC21 (Figure 9).
- B. Access into the northern section of MC21 via a construction adit driven through the unexcavated base of the Mercury Lane Shaft. This enables excavation of MC21 whilst top-down construction of the shaft proceeds (Figure 8).
- C. Split top heading down the eastern side of MC21.
- D. Break-in of the adit top-heading into the completed eastern side drift in MC21 (Figure 11).
- E. Top-heading completed by drift down the western side of MC21. The walls of the Mercury Lane Shaft in the southwest corner require a pillar of rock to be maintained for support. The pillar to be safely removed after the structure at the B2 Level constructed (Figure 12).
- F. Removal of the rock pillar adjacent to Mercury Lane Shaft, and completion of the top-heading, after construction of the shaft B2 level structure.
- G. Closure of access through the construction access through the Mercury Lane Shaft, and backfill of the adit, allowing shaft construction to continue.
- H. Excavation of benches from the direction of the construction shaft and ventilation adit.

Figure 11. MC21 adit break-through.

4 PRIMARY SUPPORT DESIGNS

4.1 Ground model for MC21

The design of the MC21 Zone, which encompasses the junction with Adit A1 and interfaces with the Mercury Lane shaft to the north, relies predominantly on numerical analyses conducted using the 3D Plaxis software. Figure 13 presents an illustration of the 3D Plaxis model. To assess the reliability of the design, the following two distinct ground models were developed.

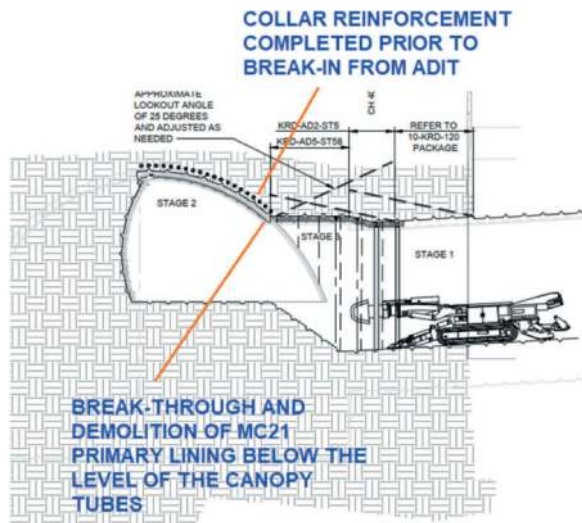

Figure 13. Long section of the modelled geometry with broken zone intersection the tunnel at ventilation adit MC20 cavern junction.

4.1.1 Characteristic-Case (Model #1)

This model is constructed based on inferred geological data from boreholes and face mapping. It comprises a fractured and folded zone, roughly 10 meters wide, with a prevailing orientation of approximately NE-SW and a dip to the SE. The geological strata affected by this zone include the beds of EU3 and the overlying and underlying layer of EU2, which extends up to 3 meters below the base of the EU3. The rock-mass strength parameters for this zone are derived from a Geological Strength Index (GSI) of 40, in accordance with a characteristic, observation-based condition.

4.1.2 Lower-bound ground model (Model #2)

This model maintains the same geometric characteristics as the characteristic-case model but incorporates rock-mass strength parameters corresponding to a lower-bound condition. The rock-mass strength parameters for this zone are based on a GSI of 25. Additionally, the fractured zone in this model extends to a greater depth compared to the characteristic-case.

4.2 Geotechnical parameters

To model the stiffer unload/reload behaviour compared to the initial loading modulus, hardening soil constitutive model was adopted for the design. However for EU3 rock unit, geotechnical data suggests no substantial difference between loading and unloading modulus hence loading/unloading modulus was kept the same for EU3 rock. Parameters adopted for numerical modelling are shown in Table 1 below.

Table 1. Parameters adopted for numerical modelling.

Unit	γ (kN/m^3)	ϕ' ($^\circ$)	c' (kPa)	E_{50} (MPa)	E_{ur} (MPa)
Fe2	19	28	8	20	60
ER	18	30	7	20	60
EW	19	35	25	100	300
EU2	20	40	100	400	1000
EU ₃	21	45	400	2500	6500
EU _{g3}	21	45	400		3500
Fault Zone (FZ)					
EU2 (FZ) GSI 55	20	40	25	200	500
EU ₃ (FZ) GSI 40	21	40	60	400	1000
EU _{g3} (FZ) GSI 40	21	40	60		600

4.3 Numerical modelling

The presence of a broken rock zone as shown in Figure 5, coupled with reducing rock cover towards the southern end, combined with the complex geometry of the tunnel makes the analysis a three-dimensional problem. Consequently, a detailed three-dimensional numerical modelling of the cavern intersection was undertaken using Plaxis 3D software with geological surfaces imported from a Leapfrog model to generate a more accurate representation of the geological conditions of the area. Moreover, the 3D model also facilitated an evaluation of how the broken zone influenced the surrounding rock mass. Figure 13 shows a long section of the modelled geometry in Plaxis 3D.

Outline details of the support types developed for application in the MC21 Zone are listed in Table 2. To mitigate tunnel face stability concerns, a split heading approach was adopted through the area of the junction. Canopy tubes were positioned in a nearly horizontal orientation in order to maximise cover.

Figure 14 shows the excavation sequence adopted in Plaxis 3D with partial drifts with top-heading tunnel advances varying from 1.8m for rock bolted support to 1m for tunnel advance under canopy tubes.

Table 2. Summary of primary support types.

Cavern – Zone	Primary support	Sequence
MC21 – North of the junction with Adit A1	150-200 thk. fibre-reinforced shotcrete. 4m long rock-bolts.	Top-heading and bench
MC21 – North of the junction with Adit A1 – Area of reducing cover	Profile expands to facilitate installation of canopy tubes to the south. 150-300 thk. fibre-reinforced shotcrete. Spiles in the crown, 4m long rock-bolts on sidewalls and bench.	Top-heading and bench
MC21 – Junction with Adit A1	Single round of canopy tubes across the intersection and over the southern headwall of the platform cavern. 150-350 thk. fibre-reinforced shotcrete. Lattice girders at 1m centres. 4m long rock-bolts on sidewalls and bench.	Split top-heading and bench
Adit A1	Spiles from east and west over break-through. 300 thk. fibre-reinforced shotcrete. Lattice girders at 1m centres. 4m long rock-bolts on sidewalls and bench.	Top-heading and bench

Figure 14. Mining sequence adopted A). East Side drift under rock bolts B). Spile support with elevated crown to enable canopy tube installation at intersection zone C). Complete side drift under canopy tube D). Adit excavation and break-in.

4.4 Analysis results

4.4.1 Tunnel deformations

Figure 15 shows a contour plot of ground convergence deformations on the primary tunnel liner. Maximum deformation occurs above the intersection zone and coincides with the location of the fractured zone. The total displacement at the tunnel crown was estimated to be in the order of 20 to 30mm.

4.4.2 Surface settlement

The surface settlement was estimated to be approximately 20mm. Maximum settlement is expected directly above the MC20-Adit junction, coinciding with the location of the fault or broken zone modelled. Figure 16 illustrates the projected contours of ground settlement upon completion of tunnel mining operations.

Figure 15. Predicted ground convergence at tunnel crown.

Figure 16. Maximum predicted surface settlement at MC21 junction.

5 DESIGN REFINEMENTS

5.1 Refinements in response to observed conditions

Following the commencement of construction, and subsequent to additional ground investigations, the design was further refined. The significant observations and ground investigation data were assessed, and the following conclusions drawn:

- Higher rockhead extending further south, enabling an active support design to be extended southwards (Figure 17).
- Better than previously adopted characteristic strength parameters for the broken-EU3 zone inferred to affect the eastern side of the MC21 junction.

- Observations from the MC30 excavations suggesting that at least locally, that the broken-EU3 was unstable/meta-stable when exposed in the face, with sliding of blocks on sub-vertical joints noted during excavation.
- Observations of persistent inflows from probe-holes drilled into the MC21 junction zone from the direction of Adit A1.

The subsequent design refinements allowed for the following changes:

- Extension of the section under bolts and shotcrete southwards (Figure 17).
- Adoption of full width top headings south from the shaft to the end of MC21, and increase in height of the top heading. These refinements supported by a requirement for mandated ring cut and buttress and face dowels in the area under the canopy tubes; rock bolts in the areas below the canopy tubes.
- Elimination of lattice girders in the primary support linings north of the area of the adit junction.
- Elimination of the need to retain the rock pillar adjacent to the Mercury Lane Shaft, allowing for opening up of the full top-heading face to the south of the shaft. This required the opening up of a panel of the top-heading in stages adjacent to the shaft wall (Figure 18).
- Development of additional mitigations to deal with the potential for poor ground at the face, or at the locations of the primary support elephants feet.

Figure 17. MC21 refinements.

5.2 Numerical model refinements

5.2.1 Full face top heading

Following the commencement of tunnelling, improved geological parameters and an updated geological model with higher rock-cover extending further south were developed. This enabled extension of the bolted solutions further south, and exploration of the potential to move to a full width top-heading advance. The 3D numerical model was updated to a full-face model to

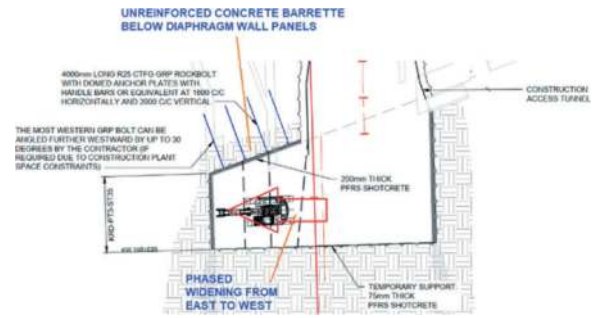

Figure 18. Initial widening of MC21 profile south of the Mercury Lane Shaft.

test whether a full-face advance through the area of the junction could be supported. Modelling results showed with improved geological parameters that a full-face advance was feasible with ground movements and shotcrete lining loads within acceptable limits. Bending moments within the canopy tubes were also within acceptable limits for the full face heading as shown in Figure 19. A further sensitivity check conducted with more unfavourable ground conditions showed the requirement of a widened elephant footing at the top heading invert level, a detail subsequently added to the design as a mitigation measure.

Figure 19. Canopy tube bending moment envelop after the end of tunnelling.

A series of 2D models were also modelled for different sections and lining capacities were compared with the 3D modelling results, both were comparable and within capacity limits except at the intersection zone where the 3D model captured the force redistribution of the intersection area more realistically. Subsequently a reinforced section around the break-in area was designed to account for tensile stresses at the breakout zone (see Figure 20).

5.2.2 Elimination of lattice girder for spile support

In the original design, lattice girders were assumed to act as reinforcing elements especially for early

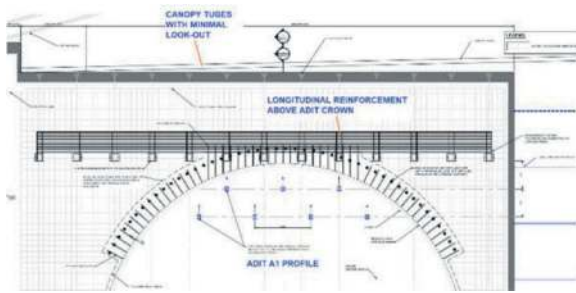

Figure 20. Junction reinforcement detail.

age shotcrete to provide sufficient flexural capacity to accommodate additional loading transferred from spiles. A series of numerical modelling checks were conducted by assuming spile loads acting on the shotcrete shell as eccentric loads as well as a uniformly distributed load acting on the entire spiled cross section. The loading on the shotcrete lining was conservatively assumed as a wedge load acting on the lining in addition to ground load. Early age shotcrete strength was defined as 8MPa and the results showed that combined ground loads acting on shotcrete are within the capacity limits, hence allowing for the elimination of lattice girders from the sections under spiles immediately north of the junction with Adit A1.

6 CONCLUSIONS

The primary support designs for the Karanga-a-Hape Station MC21 Junction excavation were developed and refined through close collaboration between the construction, geotechnical and tunnel design teams,

with feedback leading to improved designs leading to enhanced cost and schedule outcomes. Ground conditions were challenging, as the junction location corresponds to an area of low cover, and a normal fault zone. The initial designs and sequences were developed to enable opening up of the junction from the north, allowing for the installation of canopy tubes tight to the cavern profile through the area of low cover. This in turn allows the break-in from the east of the ventilation adit beneath a mature cavern arch with a reinforced collar zone. The designs were further refined as construction proceeded to respond to local higher than expected rock cover, and better than originally predicted fault zone parameters. This paper has outlined the core principles behind the primary support design, the design challenges for the cavern excavation as well as the strategies employed to enhance the design and construction schedule. The successful completion of this project highlights the collaborative efforts between the design and construction teams, ultimately resulting in a highly favourable outcome.

Design of temporary cofferdam and deep excavation for cofferdam tunnel of Shenzhen-Zhongshan Link

Zheng Shi, Chun Ning He*, Long Yu & Qiao Wang Xia

Shanghai Tunnel Engineering & Rail Transit Design and Research Institute, Shang Hai, China

ABSTRACT: Considering the layout of the interchange ramp on the East Artificial Island of Shenzhen-Zhongshan Link, the width and construction difficulty of the immersed tube tunnel, as well as the influence of Fuyong Wharf and other factors, a temporary cofferdam is built in the sea on Shenzhen side as the water retaining structure, then the open excavation and the structure of the cut and cover tunnel with widened and diverging section is implemented within the cofferdam, to ensure the construction feasibility of the tunnel with variable cross-section and large-span and the adaptability of the curved and widened tunnel elements. The engineering geology of the Pearl River estuary is complicated, and the soil layers are variable and unevenly distributed. The cofferdam and island are built on soft silt layer with the maximum thickness of 15m in the sea. The elevation of the formed land area is 5-7.5m lower than the sea level. The maximum depth of excavation is up to 23m below the sea level, and the excavation width is up to 70.7m at the widest. The construction safety of the cofferdam and excavation must be ensured, which poses great challenges to the engineering construction. This paper provides a detailed introduction to the engineering scope and structural form of the cofferdam, design scheme and calculation method of the cofferdam and retaining structure, serving as references for similar projects in the future.

Keywords: cofferdam tunnel, double-row steel sheet pile cofferdam, marine environment, complicated geological conditions, extra-wide excavation

1 PREFACE

Shenzhen-zhongshan Link is located in the core of Guangdong-Hong Kong-Macao Greater Bay Area, which directly connects Shenzhen Special Economic Zone and Zhongshan City. As a sea-crossing link integrating “tunnel, artificial island, bridge and underground interchange”, the project connects with the Jihe Expressway in the east, passing through the south side of Shenzhen Airport and the Pearl River estuary, and finally reaches the Zhongshan Xinlong Interchange in the west, where it connects with Zhongkai Expressway. The project is 24km long in total with eight lanes in both directions. The project is designed in highway standards with a design speed of 100km/h. The sea section is an immersed tube tunnel, the standard element of which is 46m wide.

According to the function and traffic organization of the project, the East Artificial Island is built on the side of Shenzhen, which connects with the existing Guangzhou-Shenzhen Coastal Expressway through an underwater interchange. According to the overall arrangement, the Ramp F and G respectively merge into the immersed tube tunnel. The element width in the merging

area gradually increases from a standard width of 46m to 70.7m; and then the Ramp F and G are separated from the immersed tube tunnel and connect to the island interchange. See Figure 1.

Figure 1. Location relationship between cofferdam tunnel and tunnel under east artificial island.

*Corresponding author: he.chunning@stedi.com.cn

In order to reduce the total length and the width of the widened immersed tube section, to minimize the risk of the tunnel element construction, and to ensure the construction feasibility of tunnel structure with variable cross-section and large-span, it is considered to build a cofferdam tunnel on the west side of the East Artificial Island, without affecting the interconnection arrangement. This means to construct a temporary cofferdam in the estuary, and to implement the excavation and structure of the cut and cover tunnel with widened and diverging sections within the cofferdam. Upon completion of the main structure, the temporary cofferdam will be removed after the backfill and coverage, and restored to the original seabed surface.

2 DIFFICULTIES IN CONSTRUCTION OF COFFERDAM TUNNEL

2.1 *Complicated environmental conditions*

The tidal current in the estuary is of irregular semi diurnal type, in reciprocating motion. The average tidal range is 0.85-1.70m and 2.30-3.20m at the maximum.

The region is in the subtropical marine monsoon climate zone. Affected by the alternating influence of Eurasia and tropical oceans, the weather and climate are complex and changeable, and it is vulnerable to the gale and rainstorm brought by tropical cyclones from June to October every year.

The engineering geological conditions in the Pearl River estuary are complicated and changeable. The soil layers include silt, clay, mucky clay, residual soil, completely weathered granite, and strongly weathered granite from top to bottom, and are in extremely uneven distribution. The maximum thickness of the surface silt in the area where the cofferdam constructed is up to 15m.

2.2 *Constraints from existing wharf*

The north side of the cofferdam tunnel is adjacent to the Fuyong Airport Wharf. The minimum clear plane distance from the temporary cofferdam to the wharf is only approximately 49m. During cofferdam tunnel construction, the normal operation and safety of the wharf shall be guaranteed.

2.3 *Challenges in construction of cofferdam and extra-wide excavation*

During island backfilling and land-forming construction in the silt layer, the following requirements shall be fully considered including the ground bearing capacity, flexural and shear bearing capacity, anti-erosion and anti-seepage, and stability requirements of cofferdam structure. As a temporary work, the cofferdam's economy and ease of demolition shall also be considered.

Different from the traditional excavation, after forming the land, the land elevation is 5~7.5m lower than the sea level, the deepest excavation of the tunnel is 23m below the sea level, the widest is 70.7m, and the excavation is close to the temporary cofferdam. The excavation design shall consider the influences of backfill load of cofferdam, and the water level fluctuation as well.

Considering the site conditions and according to the construction organization plan, it is required to build a trestle in the middle of the excavation. The trestle is 14m wide, running longitudinally and serving as a heavy load passage during the construction.

In view of the above complex construction environment and load conditions, the safety of cofferdam and excavation must be ensured in the such an extra-wide excavation for the cofferdam tunnel, which brings strict requirements for design and construction.

See Figure 2~4 for site photos of the temporary cofferdam and tunnel excavation.

Figure 2. Bird's-eye view of cofferdam.

Figure 3. Bird's-eye view of excavation in cofferdam.

Figure 4. Excavation and support arrangement in cofferdam.

3 DESIGN OF TEMPORARY COFFERDAM

3.1 Determination of temporary cofferdam scope

The scope of cofferdam shall be determined by comprehensively considering the layout of interchange ramps, width and construction difficulty of tunnel elements, impacts on adjacent Fuyong Wharf, feasibility of constructing tunnel structure with variable sections and large-span and other factors.

Considering that the tunnel axis on Shenzhen side is located on a horizontal curve, and some of the tunnel elements are curved, two schemes as long cofferdam and short cofferdam are proposed to minimize the total length and the width of the widened immersed section as possible or to make all the tunnel elements straight.

3.1.1 Long cofferdam scheme

As the straight element will be more convenient for prefabricating, towing, sinking, and installation, the western end of the cofferdam in the long cofferdam scheme follows the principle as all the tunnel elements are straight. That is, all the widened and curved tunnel section need to be cast-in-situ in the cofferdam. According to the layout of the route, the tunnel section starts at mileage K7+672.6 as the straight section with standard width; the end mileage of the cofferdam is at K7+730. The starting mileage of the cofferdam at K6+513 is determined based on the mileage of Eastern Artificial Island wall at K6+560. So the long cofferdam scheme is approximately 1217m long along the tunnel axis, and the formed land area is approximately 249,000m². As the cofferdam encroaches into the Dachan Waterway and Airport Branch Waterway, the construction of the long cofferdam scheme is planned in two phases and three sections to minimize the impact on the waterways, as shown in Figures 5 and 6. However, in the construction of Phase I, temporary diversion measures are still required for the Dachan Waterway and Airport Branch Waterway. The length of the route need to be diverted and dredged will be 6.1km, and the dredging volume will be 1,776,600 m³.

The Section I on the west side (K7+270~K7+730) and Section II on the east side (K6+513~K6+958) of Phase I will be constructed firstly; after the cofferdam is completed, the cut and cover tunnel sections between K7+330~K7+665 and K6+550~K6+885 respectively in the cofferdam will be constructed simultaneously.

Figure 5. Layout of long cofferdam scheme (phase I).

Figure 6. Layout of long cofferdam scheme (phase II).

The cofferdam Phase II is between the mileages of K6+824 and K7+391. Upon completion, the cut and cover tunnel sections will be constructed between the mileages of K6+885 and K7+330 in the cofferdam. The two phases construction of cofferdam and the corresponding tunnel structure will take about 63 months.

3.1.2 Short cofferdam scheme

As the long cofferdam scheme has a longer distance into the sea area and encroaches both of the Dachan Waterway and Airport Branch Waterway, a short cofferdam scheme is proposed to ensure the smooth operation of elements towing and sinking. This scheme may also minimize the impact on the wharf during the construction, minimize the impact on the Pearl River flood control and avoid construction risks. The western end mileage of the cofferdam changes to be at K7+072, and the starting mileage of the cofferdam to be as same as the long cofferdam scheme at K6+513. So the cofferdam is approximately 559m long along the tunnel axis and the formed land area is approximately 80,000m². See Figure 7.

The short cofferdam will be completed in one stroke. Upon completion, the construction of cut and cover tunnel sections between K6+550~K7+030 in the cofferdam will begin. The total construction period will be approximate 25 months.

Figure 7. Layout of short cofferdam scheme.

3.1.3 Comprehensive comparison of temporary cofferdam scope

For the short cofferdam scheme, six tunnel elements still remain in the curved section. The width of these elements varies in the range of 46~55.46m. To facilitate the selection of construction equipment, cost control and reduce construction difficulty, the length of curved and widened elements shall be considered based on the principle of equivalent drainage volume to standard elements during floating transportation.

Considering the safe operation of underwater interchange, difficulty in construction of tunnel element, construction period and cost, impact on water conservancy, flood control, navigation channels and other factors, the short cofferdam scheme is recommended.

3.2 Selection of cofferdam structure

According to the practical cases of cofferdam tunnel construction, the main types of cofferdam include: steel pipe pile cofferdam, steel sheet pile cofferdam,

Table 1. Comparison of temporary cofferdam structure types.

Cofferdam type	Applicable conditions	Features
Double-row steel sheet pile cofferdam	Suitable for soft ground areas with strong adaptability to ground	(1)Low soil usage, strong erosion resistance. (2)Small settlement. (3)The overall stiffness is relatively high, bringing good safety and stability of the cofferdam. (4)The steel sheet piles can be leased and recycled after completion. (5)The construction process is relatively complex.
Double-row wooden pile cofferdam	Suitable for soft ground areas with strong adaptability to ground	(1)Low soil usage, strong erosion resistance. (2)Small settlement. (3)Good safety and stability of the cofferdam. (4)The wooden piles may be more economical. (5)The construction process is relatively complex.
Membrane bag sand cofferdam	Suitable for areas with high soil and rock content, with moderate adaptability to ground	(1)Large amount of sand and soil. (2)The settlement may be relatively high. (3)Higher requirement for the bearing capacity of the ground. (4)The cross-section is large and has a significant impact on the marine environment. (5)The construction process is relatively simple.

wood pile cofferdam, membrane bag sand cofferdam and the others.

The selection of cofferdam structure type and materials shall be based on the requirements of water depth, flow velocity, geological conditions, tunnel structure type and other considerations. The selection shall not only consider the applicable conditions, advantages and disadvantages of different types of cofferdams, but also consider the characteristics of the project. Due to high cost, the steel pipe pile cofferdam is not considered. Table 1 shows the comparison of different types of cofferdams. From the comparison table and the characteristics of the project, the double-row steel sheet pile cofferdam is adopted thanks to its features of fast construction speed, convenient demolition, and high cost-effectiveness.

3.3 Cofferdam structure design

3.3.1 Standard and principle of design

- (1) The lifetime of the cofferdam shall be 2-3 years, and according to *Design Specifications for Cofferdam in Water Resources and Hydropower Engineering* (SL 645) and *Classification and Flood Standards for Water Resources and Hydropower Engineering* (SL 252), the cofferdam level shall be Level 4.
- (2) The designed flood recurrence period shall be 5-10 years, with a 10-year high water level of 2.85m and a 10-year low water level of -1.28m taken as the design standard. Wave forces shall be considered based on a 10-year recurrence period. The designed normal water level shall be +0.52m, and the maximum designed water retaining height shall be 8m.
- (3) The cofferdam must undergo verification calculations such as anti-sliding, anti-overturning, depth of penetration, anti-seepage, and overall stability of the cofferdam; the bearing capacity of the structural components of the cofferdam must be verified according to the most unfavourable load combination during in use.

3.3.2 Cofferdam structure design

The scope of the cofferdam is determined between the mileage K6+511.5 and mileage K7+072. The length of the cofferdam along the tunnel axis is 560.5m, and the perimeter of cofferdam is about 1393.4m. The cofferdam is designed to be constructed in one stroke. The width of the cofferdam is about 206m on the east side and 116m on the west side. See Figure 8.

The width of double-row steel sheet pile cofferdam is 10m, and the top elevation of the cofferdam is +3.00m. The top elevation of the outer row steel sheet pile is +6.00m. The pile length is 30-33m. The top elevation of the inner row steel sheet piles is +3.00m, and the pile length is 27-30m, driven into the fully weathered layers. The cross-section of the steel sheet pile is 750 × 225 × 14.5mm, and the

material is Q390BZ. Steel tie rods with a diameter of 60mm are used to connect the inner and outer rows of steel sheet piles at a spacing of 1.5m. The elevation of the steel tie rods is +1.5m.

To effectively resist the power of wave currents and typhoons, a L-shaped buttress retaining wall is installed along the cofferdam. The thickness of the retaining wall is 200mm, and the height is 2m. The buttresses are set every 1.5m, with a thickness of 150mm and a height of 1.5m.

Figure 8. Schematic diagram of cofferdam tunnel.

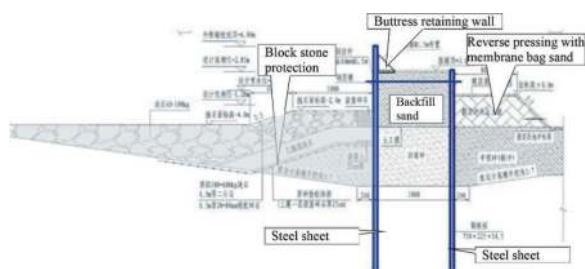

Figure 9. Typical cross-section of cofferdam.

To avoid erosion of the outer slope bottom of the cofferdam, multiple layers of different specifications of block stones are set on the slope surface for dumping and filling. Reverse pressing with membrane bag sand is set on the inner side of the cofferdam, and the slope surface is protected by membrane bag concrete. See Figure 9.

The engineering geological condition is complex and soil layers are unevenly distributed. The surface layer is composed of Holocene marine sediment, with a thickness of 5.2-15.0m, presenting poor engineering properties, high water content, high compressibility, rheological properties, and thixotropy. The differential weathering of the bedrock is significant, and the rock layers are with large fluctuations and uneven thickness of the weathered layer. To ensure the stability of the cofferdam, the surface silt is removed in layers within a range of 8m below the seabed surface and replaced with medium to coarse sand before the construction of the cofferdam. After the cofferdam is constructed, the remaining silt between the double row steel sheet piles is reinforced with rotary jet grouting piles.

3.3.3 Cofferdam structure calculation

A 2D load structure model is established for calculation. The stratum is simulated by loads and springs, the beam elements are used for the steel sheet pile and cable elements for steel tie rods. Only vertical restraint is applied to the bottom of the steel sheet piles, and all horizontal springs simulating lateral constraints as compress-only springs only (without tension). The spring ultimate bearing capacity considered the relationship with passive soil pressure. Different values of spring stiffness are specified based on specific positions and action forms. See Figure 10.

In the design, typical sections are taken and calculated based on different construction conditions and assumptions of high and low water levels. All of the normal stress and shearing stress of steel sheet piles and steel walings, and normal stress of steel tie rods meet the design requirements. In the calculation, a soil model is also used to conduct numerical simulation analysis and parallel verification of the double-row steel sheet pile cofferdam according to the construction processes (see 4.2 Support and retaining structure design for details).

Figure 10. Assumptions of calculation constraint conditions.

Table 2. List of stability calculations and safety factors of cofferdam.

Serial number	Stability calculation	Safety factor
1	Anti-sliding stability	1.1
2	Anti-overturning stability	1.35
3	Overall stability	1.35
4	Depth in soil	1.25
5	Anti-seepage stability of steel sheet piles	1.5
6	Anti-piping stability of cofferdam body	2.0

Note: The stability calculations are based on the combination of high and low water levels + 10-year recurrence period and wave forces of 10-year recurrence period.

Various stability calculations are conducted on the steel sheet pile cofferdam according to relevant specifications. All of the calculation results meet the design requirements.

3.3.4 Sub-cofferdam design

During construction, in order to provide the conditions for the connection of tunnel element as early as possible, a sub-cofferdam is added on the west side of the cofferdam.

Figure 11. Layout plan of sub-cofferdam.

The sub-cofferdam is at mileage K6+925, where the double row steel pipe pile cofferdam is used between the tunnel structure and the original cofferdam, and the buttress retaining wall is used on the top of the tunnel structure.

The width of the double row steel pipe pile cofferdam is 10.5m; the top elevation of the cofferdam is +3.00m; the top elevation of the outer row of steel pipe pile is +6.00m; the top elevation of the inner row of steel pipe pile is +3.0m; and the bottom elevation of the steel pipe piles is -24m. The outer diameter of the steel pipe pile is $\Phi 820$, and the thickness is 16mm, and its material is Q355B. The steel pipe piles are connected by locking buckles. The full length of the gap inside the locking buckles is sealed by grouting. The inner and outer steel pipe piles are supported by the HW200×200×8×12 steel support at a spacing of 2.0m, and the center elevation is +2.5m. See Figure 11.

The top elevation of the buttress retaining wall is +6.0m, and the thickness of the wall is 600mm. The 400mm thick buttresses are set at a horizontal spacing of 4.7~5.6m cross the tunnel. The inner and outer sides of the retaining wall are respectively protected by bag sand and membrane bag sand backfilling.

The overall construction process of the cofferdam tunnel with additional sub-cofferdam is adjusted as shown in Figure 12:

Process 1: After dewatering within the cofferdam, level the site and carry out the retaining structure construction. First implement the main tunnel excavation ① on the west side and then carry out the excavation of Ramp F and Ramp G on the east side. In the construction process, it shall ensure that the tunnel excavation ① as soon as possible to form the conditions for tunnel element connection.

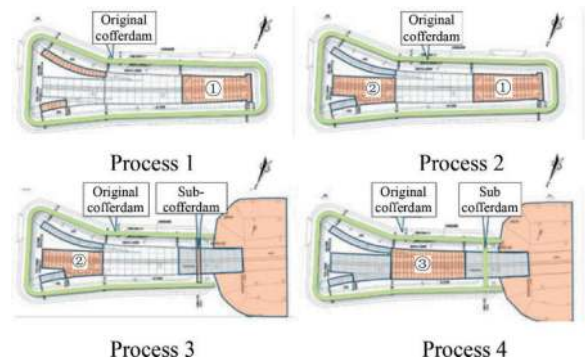

Figure 12. Overall construction process of cofferdam with additional sub-cofferdam.

Process 2: After the completion of the excavation of Ramp F and G on the east side, implement the main tunnel excavation ② in sequence.

Process 3: After the completion the main tunnel excavation ①, construct the sub-cofferdam at mileage K6+925. Upon the connection of the sub-cofferdam with the original cofferdam, ingress water into the west side of the sub-cofferdam and dismantle the original cofferdam on the west side. The corresponding work will be prepared for tunnel element immersing and installation.

Process 4: Construction the main tunnel excavation ③.

4 SUPPORT AND RETAINING STRUCTURE DESIGN

4.1 Standard and principle of design

- (1) Determine the safety level of the excavation works based on the surrounding environmental conditions, excavation depth, support and retaining structure and other considerations.
- (2) Select a reasonable support and retaining structure based on the safety level, excavation depth, and engineering geological conditions.
- (3) The support and retaining structure must be verified by strength, deformation and stability check.
- (4) When determining the depth of the retaining structure, it must be verified by anti-sliding, anti-overturning, overall stability, anti-uplift and anti-

Table 3. Control standard for excavation deformation.

Safety level of excavation	Maximum horizontal displacement on top of the retaining structure	Maximum horizontal displacement of the retaining structure	Maximum settlement of the earth surface
First level	min(0.2% H,30mm)	0.3%H	0.25%H

Note: H presents the excavation depth.

pipng stability. For these weak soil areas, vertical bearing capacity, deformation, and stability calculation must also be carried out, and reasonable measures such as ground improvement should be taken into account.

4.2 Support and retaining structure design

The design mileage of the tunnel in the cofferdam is K6+550~K7+030. The tunnel is 480m long with 26 structural segments. The support and retaining structure is made of a 1m thick diaphragm wall + concrete support + steel support. See Figure 13.

Table 4. List of tunnel support and retaining structures.

Scope	Depth of excavation	Form of support and retaining structure
K6+550~K6+918 Main tunnel	13.21~16.60m	Two concrete supports and one $\Phi 80$ cm steel support
K6+91~K7+030 Main tunnel	16.60~17.96m	Two concrete supports and two $\Phi 80$ cm steel supports
FK1 +268~FK1 +329.198 RampF	12.38~13.84m	One concrete support and two $\Phi 80$ cm steel supports
GK0 +485~K0 +330.355 RampG	9.79~14.04m	One concrete support and two $\Phi 80$ cm steel supports

Different from these traditional land excavations, the tunnel excavation is close to the cofferdam, which is only about 8m between the excavation and the membrane bag sand of the cofferdam, and the water level fluctuates greatly outside the cofferdam. So the design of the excavation shall consider both the impact of the stacking load of the cofferdam, and the impact of water level fluctuations.

In addition to using the conventional elastic foundation rod system finite element method for calculation and analysis, a 2D soil structure interaction model is

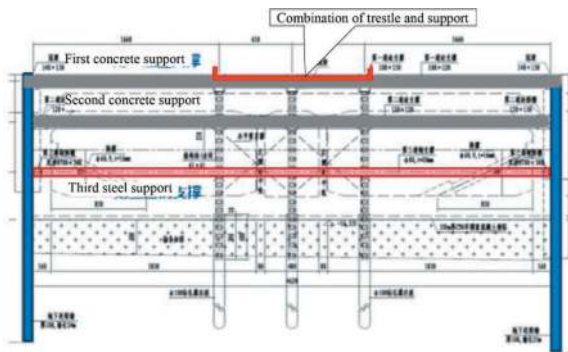

Figure 13. Typical cross-section of support and retaining structure for the cofferdam tunnel.

Figure 14. Computational model and grids.

(a) Horizontal displacement

(b) Vertical displacement

Figure 15. Cloud diagram of deformation of double-row steel sheet pile cofferdam after backfilling to elevation +3.0m.

(b) Vertical displacement

Figure 16. Cloud diagram of deformation of double-row steel sheet pile cofferdam during excavation.

established for typical cross-section to carry out re-checks according to the overall construction process of

the cofferdam and excavation. The 2D physical element is used for the soil, and the HS model is used for the constitutive models of soft soil and sand; steel sheet piles are simulated using plate elements, and steel tie rods are simulated using point-to-point anchor elements, both of which are calculated using linear elastic models.

The interaction between steel sheet piles and the surrounding soil is simulated by the software's built-in interface element. The support and retaining structure is designed based on the calculation results of the elastic foundation rod system finite element method in combination with verification results of the soil model, so as to ensure the engineering safety. See Figure 14~16.

4.3 Trestle design

Considering the constraints of site conditions as well as the construction organization plan, a trestle is required in the middle of the tunnel excavation. The trestle goes longitudinally and has a width of 14m, it is impossible to avoid the support system in both plane and vertical profiles. Therefore, the trestle is designed with the first concrete support system to ensure the safety of the excavation and trestle while saving engineering investment.

As the trestle serves as a heavy load traffic passage for the excavation in construction, to ensure the safety, an overall calculation of the excavation support and trestle is carried out based on a 3D finite element model. The first support, together its tie rods, and

Figure 17. Schematic diagram of 3D model of trestle and support structure.

Figure 18. Schematic diagram of bending moment of the first support and longitudinal beam of trestle.

lattice columns are strengthened in the design according to the calculation results. See Figures 17, 18.

5 ANALYSIS OF THE IMPACT OF COFFERDAM TUNNEL CONSTRUCTION ON FUYONG WHARF

The Fuyong Wharf of Shenzhen Airport is close to the cofferdam. The filling material for the wharf is basically block stone. The minimum clear distance between the wharf and the temporary cofferdam is about 49m, where the tunnel is at the mileage of K6+857. The tunnel excavation depth is 16.4m, and the excavation width is 65.50m.

To accurately reflect the additional deformation impact on wharf caused by the construction of temporary cofferdam, tunnel excavation, the plane elastic-plastic finite element analysis is adopted to simulate the construction process.

The calculation results show that: during the whole construction, the maximum additional vertical displacement of the wharf is about 28mm (settlement), and the maximum additional horizontal displacement is about 27.6mm, less than the control requirement of 30mm. See Figure 19. The actual displacement measured during construction is within 10mm.

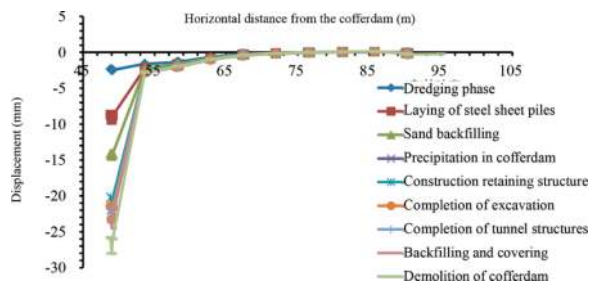

Figure 19. Settlement curve of wharf.

6 CONCLUSION

The construction of double row steel sheet piles for the temporary cofferdam started in May 2018, and the tunnel structure was completed in January 2022. During the construction, it has experienced severe weather impacts such as typhoons and rainstorm many times.

Following the principles of economic rationality, safety and reliability, and relying on practical engineering experiences, targeted design schemes and treatment measures have been adopted for the temporary cofferdam and excavation support and retaining structures according to the characteristics of the project to ensure the smooth construction of the tunnel in the cofferdam, and good economic, social, and technical benefits have been achieved. It also provides a reference and an experience for the future construction of tunnels in the cofferdams in complex marine environmental conditions.

Comparative effects of twin-stacked tunnel excavation on adjacent structure using different simulation models

ABSTRACT: The increase in transportation in urban areas has made it inevitable to excavate the twin-stacked tunnels and consequently affect adjacent structures. Therefore, an appropriate evaluation of the impact of tunnel excavation on the nearby building has been necessary to prevent the damage that may occur to the structure. In current engineering practice, there are various methods with different degrees of complexity to assess the impact on the building. This study presents a comparison of the effect caused by twin-stacked tunnel excavation on adjacent pile-supported structures by using three different simplified analysis methods. The results reveal that each method gives different results and the distance between the tunnels and the nearest pile affects the computed results. This study indicated that the tunneling analysis with the loaded pile method (FEM-LP) is more appropriate and conservative for the building impact assessment of the piled supported structures. The tunneling in green field (FEM-GF) conditions is proven to not be the conservative method.

Keywords: Tunneling, Interaction, Finite element, Pile supported structure

1 INTRODUCTION

The execution of tunnel construction projects within densely populated urban zones induces soil displacement, unavoidably posing a potential hazard to nearby building structures (Sirivachiraporn and Phienwej, 2012; Duangsano et al., 2023). A comprehensive impact assessment becomes imperative for mitigating risks and preventing resulting damages. Past research (Boscardin and Cording, 1989) has commonly utilized building movements, such as settlement, horizontal displacement of the building at diverse column positions, and distortional angularity, as practical measures to evaluate and classify potential risks of structural damage. A predominant assumption in practical applications is that column settlement equates to soil surface settlement at the same

position due to tunneling in the absence of buildings, resulting in a conservative evaluation. Empirical solutions, such as Gaussian equations or normal probability curves (Loganathan and Poulos, 1998), are often employed for preliminary assessments to estimate soil settlement.

The Finite Element (FE) method stands out as another widely adopted technique for appraising soil movement resulting from tunnel construction, enabling the simulation of more realistic tunnel-soil-structural interactions, particularly in twin tunneling scenarios. However, achieving highly accurate results demands a complete FE modeling, involving a detailed analysis of the entire structure. To streamline this complexity, a simpler simulation method entails selecting representative portions of the structure for settlement analysis. Two prevailing approaches for impact assessment

*Corresponding author: pornkasem.jon@kmutt.ac.th

thus involve: 1) estimating soil movement values through the analysis of tunnel construction simulations only (Greenfield condition: without the presence of buildings), as exemplified by Bilotta et al.'s research (Bilotta et al., 2017), and 2) simplifying the model of nearby structures by analyzing only specific representative parts, such as applying force to thin plate elements to estimate the impact of the structure's weight on evaluation (Mirhabibi and Soroush, 2012).

In regions with soft soil where structures rely on pile foundations, similar concepts have been applied for impact assessment. Considering the connection between columns and piles, the representative components in this context are the piles. However, the interaction among tunneling, soil, and piles becomes intricate depending on the relative position of the pile tip and the tunnel (Jongpradist et al., 2013; Heama et al., 2021). The assumption conventionally employed in impact assessments may no longer be valid. This study aims to assess soil and pile settlements derived from FE simulations of twin-stacked tunnel excavation using models with varying complexities. The calculated settlements and the corresponding buildings impact assessment (BIA) on piled-supported are compared and discussed.

2 ANALYSIS CONCEPTS FOR BIA

2.1 Simulation models

In this study, to indicate the different effects of different types of modeling assumptions on nearby existing piles due to twin-stacked tunneling, a total of three types with different degrees of complexity in FE modeling was considered. The complexity involves the existence of the structural parts (i.e., different types of modeling of the existing pile structure) in each modeling assumption which provides a significant dissimilarity of impact on the obtained FE results. Referring to the study of Mirhabibi and Soroush (2013), it is revealed that the type of structure has an important effect on the structural behavior. However, the above-mentioned study considered solely the structures beyond the soil surface without considering the piling support. Therefore, the pile-supported structure is the main focus of this study. The FE analyses with differences in pile-supported structure assumptions including (1) FE modeling of tunneling under the greenfield condition (FEM-GF), (2) FE modeling of tunneling incorporated with pile existence (FEM-P), and (3) FE modeling of tunneling incorporated with loaded pile existence (FEM-LP) are considered. Detailed components involved in FE modeling of each considered case can be illustrated in Figure 1.

Figure 1. Schematic diagram of considered twin-stacked tunneling adjacent pile structures.

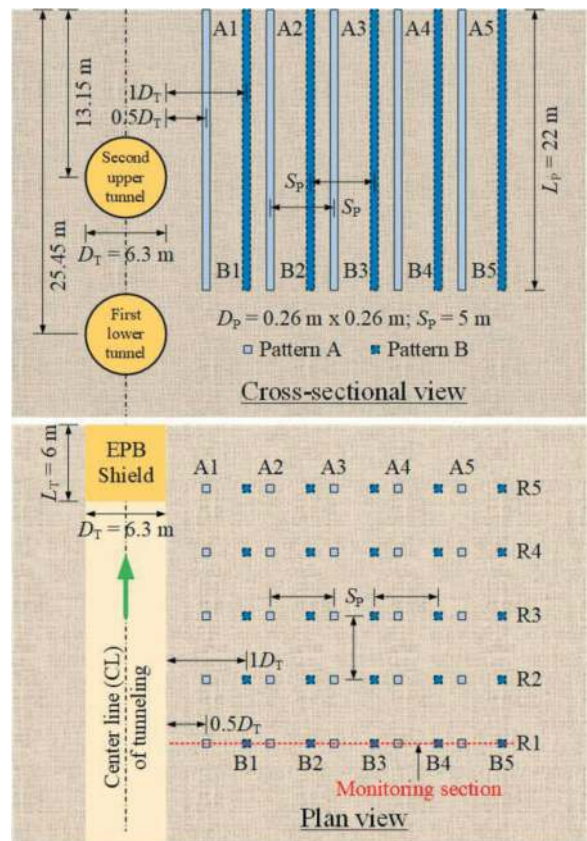

Figure 2. Cross-sectional and plan views of considered problems.

In addition, to take into account the effect of the relative position of the pile tip to the tunnel on the behavior of the existing pile in the evaluation, two patterns of pile arrangement (i.e., Pattern A and Pattern B) as presented in Figure 2 were adopted. Pattern A represents the pile position in which the tips of the nearest pile row are located in the influencing zone of tunneling as proposed by Jongpradist et al.

(2013). In contrast, the pile arrangement used for Pattern B is designed for the case in which the tips of the closet pile row are located out of the influencing zone.

Figure 3. FE mesh for 3D numerical modeling of considered problems.

2.2 Considered problem in the study

For the current study, a history case of twin-stacked tunnel excavation was chosen from section CS-4C of the Chaloe M Ratchamongkhon Line, Bangkok MRTA project in Thailand. The subsolo profile of the selected twin-stacked tunnel analyzed in this study is shown in Figure 3 which consisted of a 1.5-m-thick made ground (MG) layer followed by a 9.5-m thick Bangkok soft clay (BSC) layer and a 2-m-thick medium clay (MC) layer. These above-stated layers were placed on a 10-m-thick stiff clay (SC) and 5-m-thick dense sand (DS) layer which was situated on the hard clay (HC) layer with a thickness of 32 m. This selected section composed an excavation of the twin-stacked tunnel (i.e., lower southbound and upper northbound tunnels) with a vertical clearance of 6 m as also depicted in Figure 3. The outer diameter (D_T) of both tunnels was 6.3 m and the concrete lining was 0.3 m thick and 1.2 m wide. The lower and upper tunnels were respectively excavated at the depth of -25.45 m and -13.15 m below the ground surface by a mechanized method using the earth pressure balance (EPB) shield with a shield length (L_T) of 6 m. For the existing pile structures, a 5×5 pile group of a single pile with a spacing of 5 m located aside from the twin-stacked tunnel was considered. The pile with a square cross-sectional area of 0.26×0.26 m² and a length of 22 m was considered for both pile arrangement patterns. For Pattern A, a clearance between the nearest pile row and tunnel equals to 3.15 m ($0.5D_T$) while for Pattern B, the distance of 6.3 m ($1D_T$) was considered.

3 FINITE ELEMENT ANALYSIS

The FE software PLAXIS 3D was adopted in this study to investigate the tunnel-pile-soil interaction for assessing the impact of twin-stacked tunneling on the response of an adjacent existing piled structure. The obtained responses of the adjacent existing structure owing to the tunnel construction computed by several modeling assumptions were discussed and compared to highlight the influence of using different conditions in the analysis.

Figure 4. 3D FE mesh.

3.1 FE modeling details and material properties

Figure 4 presents an example of FE mesh in the case of a twin-stacked tunnel adjacent to an existing loaded pile (considered as FEM-LP for this study). The bottom boundary of the FE mesh was assigned at a depth of 60 m below the ground surface. The other FE mesh dimensions were 120 m in the transverse direction and 210 m in the longitudinal direction. The above-stated FE modeling dimensions were considered for all cases of this study and can provide satisfactory FE results without any boundary effects (Phutthananon et al., 2023). For the displacement boundary, a fixed constraint was applied only for the FE modeling bottom while for the four side boundaries, the movement was restrained only in the horizontal direction. In terms of drainage boundary conditions, all boundaries are set to be impermeable surfaces, except for the top surface of FE modeling (freely drained boundary). The soil was modeled with the 10-noded tetrahedral elements while the modeling of tunnel lining was simulated by the 6-noded triangular plate elements. For simulating the soil characteristics, the Hardening Soil (HS) constitutive model was used for all layers. The required input soil parameters for HS model used in this study (see Table 1 and 2) are adopted from the study of Likitlersuang et al. (2014) which were completely calibrated through drain triaxial and oedometer testing results of collected soil samples at the project site. The information related to the calibration results can be found in the previous study (Surarak et al., 2012). The tunnel lining was modeled as a linear elastic behavior using plate elements. The required properties of tunnel

lining and pile utilized in this study were followed from the past study (Lueprasert et al., 2017a; 2017b; Phutthananon et al., 2023): Young's modulus of 31 GPa, Poisson's ratio of 0.2, and unit weight of 24 kN/m³. The pile was modeled using embedded beam elements with 3-noded line elements. The concrete pile material with a unit weight of 24 kN/m³ is assumed to be a linear elastic behavior with Young's modulus of 31 GPa and Poisson's ratio of 0.2.

3.2 FE analysis procedures

The FE modeling procedure of the considered problem can be divided into two main phases. As for the first phase, the initial stress state of the subsoil was simulated using the combination of the coefficient of earth pressure at rest and soil unit weight. Then, a set of single concrete-driven piles was simulated based on the wished-in-place method prior to the tunnel excavation. After finishing the pile installation, only for the FEM-LP case, the application of axial loading was then applied. The allowable load of the single pile was set to be equal to the ratio of the ultimate capacity of the single pile over the safety factor of 2.5

(Phutthananon et al., 2023). In the second phase, tunnel excavation was simulated following the "step-by-step" approach (Do and Dias, 2022) together with the "AG-shell" method (Lueprasert et al., 2017b) in which the tunneling advancement rate of 1.2 m in each step (equivalent to tunnel lining width) was considered. The simulation of tunnel excavation as mentioned earlier can be partitioned into three minor steps. In the first minor step, the soil elements within the desired excavation area were deactivated simultaneously with the modeling of the application of face pressure. Then, the shell elements with the calibrated contraction ratio were activated to stand for the mechanized tunneling procedure. These aforementioned processes were iterated until the EPB shield advancement was achieved corresponding to the shield length of 6 m (equal to 5 rings). As for the second minor step, modeling of tail void grouting considering the liquid state of grouting was considered by simulating using the radial pressure. Finally, the hardening stage of tail void grouting was modeled by utilizing the solid elements, and the shell elements to represent the tunnel lining were activated. Note that the required properties of EPB shield and grouting material are adopted from the past work of Phutthananon et al. (2023). For more detailed information about EPB advancement modeling, it can be found in the previous studies (Lueprasert et al., 2017b, 2023; Phutthananon et al., 2023).

4 FE ANALYSIS RESULTS

4.1 Calibration of tunneling simulation

Figure 5 shows the suitable contraction ratios for tunneling simulation of the lower southbound and upper northbound tunnels were first determined by adjusting the contraction ratios to match with the field measurement. From the analyses, the contraction ratios of 0.6% and 1.3% were found suitable for the simulation to replicate the settlement patterns observed in the actual twin-stacked tunneling in this

study. These two values were used throughout all subsequent analyses.

4.2 Pile/soil settlements

The computed transverse settlement distribution along the transverse section R1 from different analysis modeling are compared in Figure 6 for Patterns A and B, respectively. The magnified figure of the results near the centerline of the tunnel is also included in the figure. Note that section R1 cuts through the piles. For the positions at which the piles are located, the pile settlements are presented.

Figure 6. Transverse settlement profile at section R1 of Pattern A.

For the FEM-GF case, the symmetry normal-distribution shape settlement profile is seen. The settlement trough from the excavation of the lower tunnel expands to the distance from the tunnel center (from center to point of inflection) of approximately 30 m ($\approx 5D_T$) while that from excavation from the upper tunnel induces the settlement increase to the distance of 20 m from tunnel centerline.

It is clearly seen that, compared to the greenfield (FEM-GF), the settlement distribution of the side with the piles (right side in the figure) differs significantly. The settlements from the FEM-P case are generally smaller than those of the FEM-GF case, except at pile A1 for lower tunnel excavation. This implies that the ground was reinforced by the embedded piles. The larger settlement at pile A1 from the excavation of the lower tunnel is due to the stability loss of the pile tip since pile A1 is considered to be in the influencing zone or the lower tunnel excavation as suggested by Jongpradit et al. (2013). The pile must settle to mobilize the shaft resistance along the pile and compensate for the end-bearing resistance. However, after the excavation of the upper tunnel, no significant settlement increase is seen from the position of pile A1.

Larger settlements are seen for the case of FEM-LP, compared to the FEM-P case. This indicates that the application of the loads on the pile head

significantly affects the computed results. Moreover, the larger settlement at pile A1 is more noticeable. The settlement increase due to the excavation of the upper tunnel is seen even for greater distance from the center line. Considering the BIA, the pile/soil settlements at the pile positions in section R1 from different analysis methods are plotted in Figure 7. It is clear that the used analysis assumption has a great impact on the computed settlements and their profile.

Figure 7. Pile settlement of Pattern A.

Figure 8 Shows the results of cases for pile settlement of Pattern B. Similar tendencies to those of Pattern A are seen. However, the settlement of the nearest pile (B1) is not much greater than the soil settlement at the same position of the FEM-GF case, particularly from the FEM-P case. This emphasizes the significance of the relative position between the pile and the tunnel.

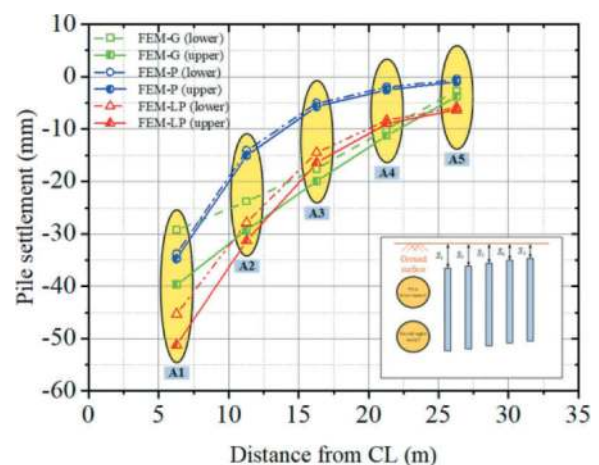

Figure 8. Transverse settlement profile at section R1 of Pattern B.

The pile/soil settlements at the pile positions in section R1 of Pattern B from different analysis methods are plotted in Figure 9. Compared to those

of Pattern B in Figure 7, the pile settlements computed from the FEM-P are the smallest. However, the results of the FEM-LP and FEM-GF become close. In terms of pile settlement prediction, the FEM-GF can be considered to be the conservative and yet simplest.

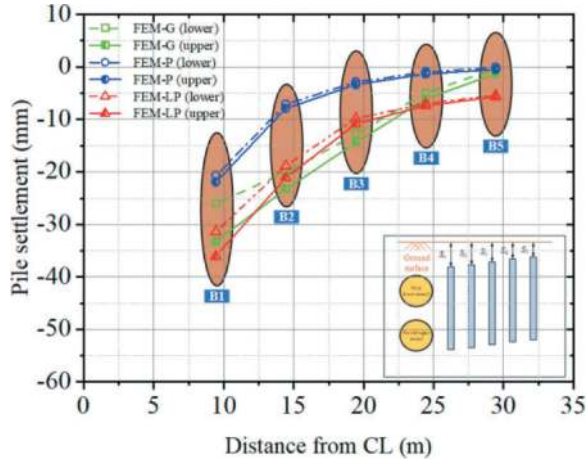

Figure 9. Pile settlement of Pattern B.

4.3 Differential settlement

The differential settlements (S_d) between two piles along section R1 are illustrated in Figures 10 and 11 for Patterns A and B, respectively.

For Pattern A, the computed S_d from FEM-GF becomes the smallest. As expected, the maximum S_d occurs at bay 1 which is closest to the tunnel. For the FEM-P case, since the settlements from Pile A1 to the farther side do not much change during the excavation of the upper tunnel, almost the same S_d for excavation of the lower and upper tunnels are thus seen. An increase in S_d from the excavation of the lower tunnel to that of the upper tunnel is noticed for the FEM-LP case. Among the three models, the FEM-LP case offers the largest computed S_d .

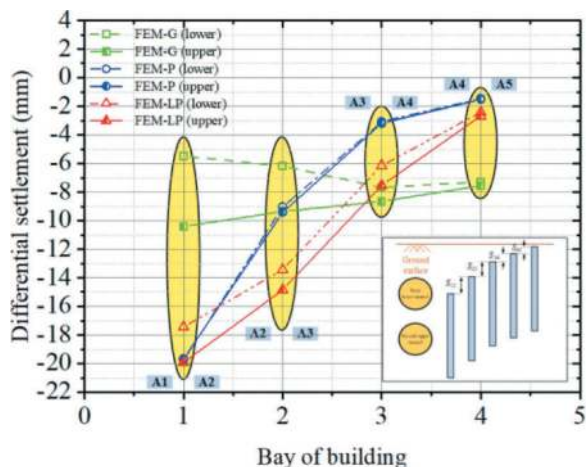

Figure 10. Differential settlement of Pattern A.

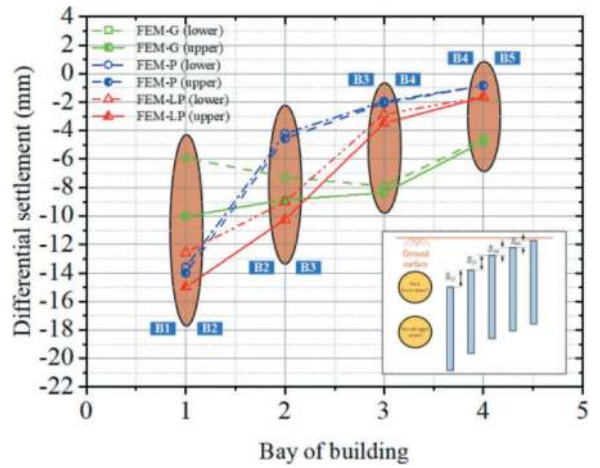

Figure 11. Differential settlement of Pattern B.

For Pattern B, a similar tendency to that of Pattern A is noticed. It seems that, in terms of differential settlement, the FEM-GF is not conservative and the FEM-LP gives the largest computed S_d .

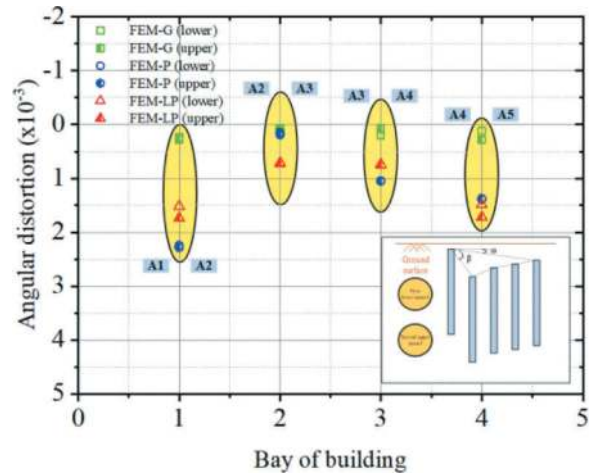

Figure 12. Angular distortion of Pattern A.

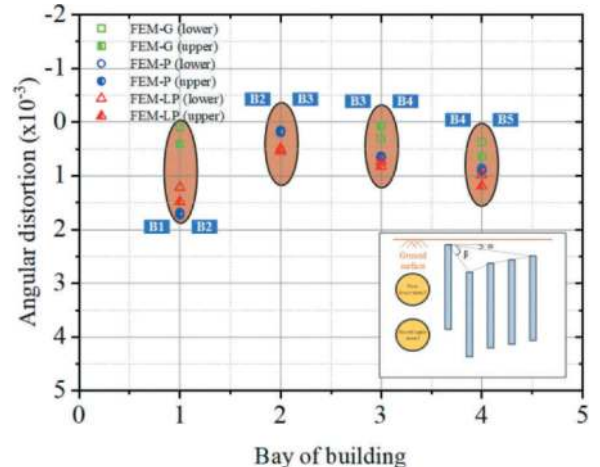

Figure 13. Angular distortion of Pattern B.

4.4 Angular distortion

Angular distortion (β) is defined as the ratio of the differential settlement between two piles to the tilting of the pile structure. Figures 12 and 13 depict the β of all bays of the building at section R1 for piles of both Patterns A and B, respectively. The magnitudes β of from Pattern A are larger due to a closer spacing to the tunnel. For both patterns, the largest β are from the FEM-P method. However, the results from the FEM-LP are not much different from those of the FEM-P.

5 CONCLUSIONS

The study compared the BIA of twin-stacked tunneling adjacent to nearby piled structures by employing simplified methods with different levels of complexity in the analysis. The conclusions drawn from the study are;

1. Different analysis methods provide different evaluations, yet, the relative position of the piles and the tunnel has a great impact on the evaluation.
2. It is evident that the green filed consideration which is believed to provide the conservative evaluation and commonly used in the practice, becomes unsuitable for the piled structures, particularly when the piles are situated in the influencing zone.
3. From the results presented in this study, it is postulated that the FEM-LP can be considered the simplified method providing the conservative evaluation of all considered items.

Key technology of submarine railway tunnel in complex environment and high-water pressure

Chaoye Song*, Weiguo He, Shuqing Lv & Yong Yu
China Railway Liuyuan Group Co. Ltd, Tianjin, China

ABSTRACT: A submarine tunnel is generally characterized by its large scale, a complex site environment with high water pressure, and a lack engineering experience. The success or failure of the project is directly tied to the design scheme. In current research and practice, the water pressure of shield tunnelling is approximately 0.8MPa. However, the Zhujiangkou Tunnel of the Shenzhen-Jiangmen Railway faces an extreme geological environment, with a water-rich sand layer and hard granite, and water pressure exceeding 1.0MPa. In this study, we analyzed the key technologies in the design of a long and large submarine railway tunnel design. This includes construction method selection, section design, waterproofing and drainage system design, complex geological response in the sea area, durability design, and evacuation. We employ methods such as geological analysis, engineering analogy, and comprehensive comparison based on the engineering background of the Zhujiangkou tunnel. A combination of the shield and mining methods is proposed to account for the diverse geological conditions in different sections. The drainage system in the mining section can be maintained by implementing advanced grouting to control displacement and ensure its effectiveness. Both the durability design of the tunnel structure and the limit of the bearing capacity are treated with equal emphasis. The conclusions drawn from this study provide technical support for decision-making on interval schemes and serve as a reference for similar projects.

Keywords: Railway tunnel, Submarine tunnel, Shield and mining combination method, Waterproofing and drainage, Durability

1 INTRODUCTION

With the rapid development of China's economic construction, railroad construction has entered a new period of high-speed development. At present, China's "four vertical and four horizontal" high-speed railway network has been completed ahead of schedule. Tunnels, as essential crossings over rivers and seas, offer inherent advantages over other engineering types like bridges. They prove superior in bad weather prevention, operation cost reduction, maintenance, and national defence strategy considerations in Zhang, 2021 and Zhou et al., 2019.

Railroad submarine tunnels are generally large, with a complex site environment and a lack of engineering experience. The success or failure of a project is directly related to the design program. At present, there is no completed undersea railroad tunnel in China, and there are limited design standards and technical studies on cross-harbour tunnels. Foreign developed countries initiated submarine tunnel constructions as early as the 1930s. Examples includes Japan's closed submarine railroad shield tunnel and the Netherlands' Rotterdam immersed tube tunnel. In 1988, Japan completed the world's longest strait railroad tunnel, the Aokikan

Tunnel, using the drilling and blasting method, with a total length of 54 km in Zhang et al., 2017. Representative projects of submarine tunnels constructed by the shield tunnel method include the Anglo-French Channel Tunnel (49.2 km) and the Danish Grand Channel Project (7.9 km), both are railroad tunnels with double-tube diameter of 8.5 m in circular section in Li & Mu, 2009 and Wang, 2014.

In China, the Liuyang River tunnel of the Wuhan-Guangzhou high-speed railway is the first underwater high-speed railway tunnel with a large span (14.8 m) and excavation section (170 m²), constructed using the mining method in Huang et al., 2011. The Lion's Bay Tunnel of the Guangzhou-Shenzhen-Hong Kong high-speed railway, at a length of 10.8 km, is the longest underwater high-speed railway tunnel in China, employing the shield tunnel technology of "tunneling toward each other, docking in the middle of the ground, and disintegration in the hole" in Li, 2010. Although research on submarine tunnel projects mainly focuses on feasibility analysis(Guo, 2022;Huang & Liu, 2006;Wang, 2008;Qu, 2009), program selection (Song, 2020;Tian et al., 2008;Zhang, 2013), and overall design(Tang et al., 2021;Wu, 2021;Han et al., 2021), there is limited systematic introduction to the key

*Corresponding author: scyesty@126.com

technology of designing submarine tunnels across the sea. This paper combines the specific project of the submarine tunnel in the Pearl River Estuary of the Shenzhen River Railway and introduces in detail the design key technology of the extra-long railroad submarine tunnel in the complex site environment. Figure 1 illustrates the alignment plan of the Pearl River Estuary tunnel. The aim is to provide important guidance for the safe and smooth construction of the project and offer reference material for similar projects.

Figure 1. Alignment plan of the Pearl River Estuary tunnel.

2 PROJECT OVERVIEW

2.1 Tunnel design overview

The Zhujiangkou Tunnel serves as the pivotal component of the new Shenjiang Railway, crossing the sea area of Zhujiangkou and linking Humen in Dongguan with Nansha in Guangzhou. Covering a total length of the tunnel is 13.69 km, with approximately 11 km crossing the sea, the tunnel adheres to the standard of a two-lane high-speed railroad. The line spacing is set at 4.6 m, and the design speed is targeted at 200 km/h. The tunnel is comprised of distinct sections, including a 5520 m mine tunnel, a 6520 m shield tunnel (3590 m on the Humen side and 2930 m on the Wanhaisha side), and a -1650 m cut-and-cover tunnel (including two working shafts), along with one inclined shaft.

2.2 Geological conditions and environment

2.2.1 Geological structure

The tunnel site is situated along the northwest-oriented Lion's Ocean Fracture Bundle and Baini-Shawan Fracture, and the survey revealed three sets of fracture zones, F1, F2, F3-1, F3-2, and seven secondary fracture zones, as shown in Figure 2.

Figure 2. Location map of the Pearl River Mouth tunnel fault zones.

2.2.2 Geological conditions

The site is in the downstream of the Pearl River waterway, characterized by a predominantly deltaic plain geomorphology. The maximum water depth of the sea section is approximately 18 meters. The geological conditions for tunneling through the stratigraphy are complex and variable. On both sides of the land section, the bedrock surface is low. The Cretaceous Baihetong terrestrial clastic rocks to gravelly sandstone dominate the Humen site, while the Nansha side features metamorphic rocks transitioning from Aurignacian metamorphic rocks to schist. The sea area in the middle exhibits a slightly weathered bedrock rock surface undulation, primarily based on Yanshan late intrusive rocks granite. The saturated compressive strength averages about 70 MPa for slightly weathered granite and schist, with potential maximum values exceeding 200 MPa, indicating significant strength variations.

Groundwater at the site encompasses are four main types: upper stagnant water, loose rock-like pore water, weathered bedrock pore fissure water, and bedrock fissure water. These are predominantly weakly water-rich, with locally moderate water richness. Projections estimate the maximum water influx in the main hole of the mine section to be 150,000 cubic meters per day, and that the maximum influx in the sloping shaft to be 10,000 cubic meters per day. The sea area is characterized as a marine chloride corrosion environment, with an environmental action level of L3 and a salt crystallization action level of Y2.

2.2.3 Environmental conditions

Environmental conditions along the planned fairways in the Pearl River Estuary Tunnel are detailed in Table 1 and Figure 3. The tunnel site traverses the sea area encompassing the Dongguan Yellow Lip Fish Nature Reserve. The land areas on both sides are densely populated and complex, featuring pipelines and notable sensitive sites such as the Weiyuan Island Battery, Museum of Naval Battles historical relics and monuments, Nansha Tin Hau Temple, as well as wetland parks. The areas carry high environmental protection requirements.

2.3 Design features and criteria

- The construction of a long cross-harbour railroad tunnel spanning 11 km across the sea poses significant construction risks and demands rigorous operational measures for disaster prevention and evacuation;
- The tunnel operates at considerable depth, exposed to substantial water pressure. The maximum water depth across the sea is 18 m, and the deepest point of the tunnel reaches 115 m;
- The main structure is designed with a service life of 100 years;
- The structural waterproof grade is designated as Grade II; and

Table 1. Planning channel grade table.

Channel Name	Planned channel class	Representative Ship Type	channel bottom elevation/m	Distance from the top of the tunnel/m
Taiping River Channel	River I	3000t class general cargo ship	-8.52	23.64
Humen River Channel	coastal waterway	100,000t class general cargo ship 225,000t cruise ship	-16.26	63.1
Nanbeitai River Channel	coastal waterway	10,000t class bulk carriers	-11.45	85.57
Zhenxiang River Channel	River I	3000t class general cargo ship	-5.03	66.11

17-3	Cracked and strongly weathered granodiorite	2.21	50	28	1.0	0.2	/	/
17-4	Medium-weathered granodiorite	2.58	70	30	0.1	/	/	50
17-5	Microweathered granodiorite	2.68	120	35	0.08	/	/	110

Figure 3. Location map of the Pearl River Mouth tunnel fault zone.

(e) The seismic intensity of the structure is assessed 7 degrees, and seismic structural measures are implemented in accordance with an 8-degree standard.

3 INTERVAL TUNNEL METHOD SELECTION AND DESIGN

The selection of a construction method for submarine tunnels is a critical determinant of project success. Commonly used methods include the mine method, shield tunnel method, and immersed tube method. The choice among these methods hinges on factors such as site geological conditions, adjacent structures, tunnel function, as well as project cost, duration, and risk. Given the specific conditions of the tunnel in question, the primary consideration is between the mine method and the shield tunnel method.

3.1 Full shield tunneling method scheme

The tunnel adopts a single-hole, two-lane design with a shield outer diameter of 12.8 m. The water shield section spans a total length of 11,940 m, divided into east and west sections of 6,950 m and 4,990 m, respectively. The east section uses two shields, initiating construction from both ends and meeting in the middle. Conversely, the west section employs a single shield, with the two ends of the banked section constructed using the open excavation method, totaling 1,650 m. The total construction period is about 52.5 months, with a project cost of 3.887 billion RMB shown in Figure 4.

3.2 Combination scheme of shield tunneling method and mine method

The scheme involves a single-hole, two-lane design, utilizing shield tunnel construction at both ends of the water section and the mine method in the hard rock section in the middle. The mine method section spans a total length of 5,520 m, with construction through the Nansha Island shore sloping shaft. The sloping shaft has a length of 1,160 m. The shield method section spans a total length of 6,520 m, divided into east and west sections of 3,590 m and 2,930 m, respectively. Two composite mud-water balanced shields are used, initiated from the two ends of the shield shafts towards the sea, with the shield method concluding in mines. The demarcation of disintegration is performed using the shield method. Cut-and-cover construction is applied at both ends of the shore section, totaling 1,650 m. The total construction period is approximately 56 months, with a project cost of 3.086 billion RMB shown in Figure 5.

For comparison between the two schemes,

Shield tunnel section at both ends: The full shield tunneling scheme has a relatively short upper soft and lower hard formation with low water pressure. In contrast, the combined scheme has a slightly higher water pressure, requiring high waterproofing standards.

Intermediate tunnel section: The combined scheme's mine tunnel passes through various faults, i.e. F2 fault and f1-f6 secondary faults, posing risks of sudden mud and water influx, with grouting challenges and high

costs. The shield tunnel in the full shield scheme traverses a long upper, soft and lower hard formation, incurring tool wear and frequent knife changes. Attention is need for the unknown risk of locally unproven hard rock intrusion which may affect the attitude and operating parameters of shield tunneling. The combined scheme anticipates a leakage of approximately 2600 m³ per day in the mine method section, resulting in higher operating costs. The construction cost of the full shield scheme is 805 million yuan higher than that of the combined scheme.

After comprehensive comparison, both the full shield method and the combination of the shield method and the mine method are technically feasible, with comparable construction periods. The combination scheme entails slightly higher construction risk at the shield tunnel ends. However, considering the synergies between the shield and mine methods and an overall cost reduction of 800 million yuan, the recommended implementation plan is to adopt the shield method and mine method.

4 TUNNEL CROSS-SECTION DESIGN

4.1 Shield method section

In adherence to the requirement for a minimum effective area of tunnel clearance (not less than 90 m²), the proposed inner diameter of the shield tunnel is 11.7 m. The effective clearance area above the tunnel rail surface is 74.05 m². The profile section layout is shown in Figure 6.

Considering factors such as tunnel depth, economy efficiency and shield segment joint forms, the concrete segment is designed with varying thickness of 600 mm and 550 mm, resulting in a ring width of 2.0 m. The lining comprises 9 rings with a universal wedge ring and a 40 mm double-sided wedge.

4.2 Mining method

The selection of mining method section is primarily based on the intended function and construction risk. To address the substantial groundwater pressure in the sea section, a composite lining structure is adopted.

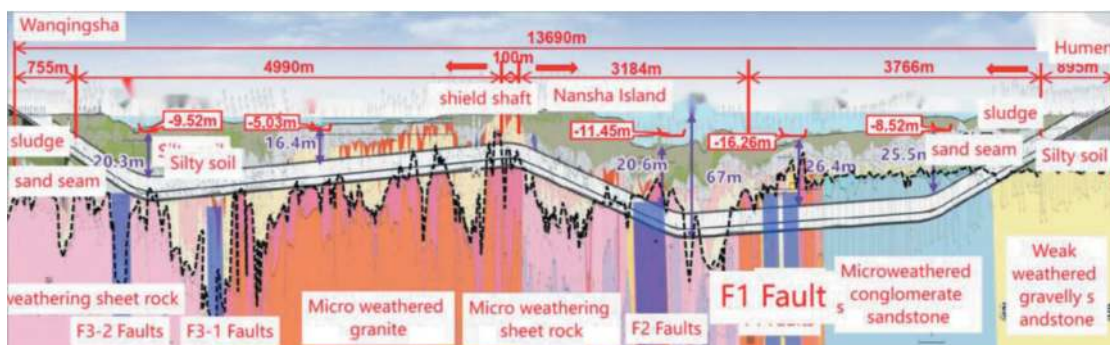

Figure 4. Vertical sectional drawing of shield mines combination tunnel.

Figure 5. Construction organization plan of shield mines combination tunnel.

Figure 6. Single hole double line shield section view.

The tunnel section takes on a horseshoe shape, featuring an inverted arch for added support. Either spray anchor or grid steel frame support is implemented, with the second lining constructed as a reinforced concrete structure. The effective internal clearance area above the double line section of the mine method is 81.37 m². The profile of the single-hole and double-line mine is shown in Figure 7.

Figure 7. Single hole double line mine profile.

5 WATERPROOF AND DRAINAGE DESIGN

The tunnel, characterized by a vast sea span and significant water seepage, presents a substantial challenge to drainage capacity during both construction and operation. The tunnel’s waterproof grade is designated as secondary, with a maximum hydrostatic pressure of approximately 1.15 MPa in the mine section and around 1.06 MPa in the shield section.

5.1 Mine method tunnel waterproof and drainage

To ensure the effective management of water ingress and drainage in the mine method tunnel, a comprehensive set of measures is implemented:

- Utilization of advanced geological forecasting system analysis to analyze and anticipate potential challenges related to water ingress and drainage;
- Improvement of the permeability coefficient of surrounding rock to control and manage permeability effectively;
- Implementation of drainage measure post-tunnel grouting to maintain controlled drainage rates: not exceeding 0.4 m³/dm in the mine section; not exceeding 0.2m³/dm in other sections;
- Integration of a maintainable drainage system into the tunnel, directing water towards a bottom drainage ditch;
- Establishment of longitudinal shafts at intervals of 100 m to facilitate later dredging and maintenance operations;
- Utilization of C50 and P12 waterproof concrete for the secondary lining, enhancing the tunnel’s waterproofing properties.

During the construction process, the water inflow and pressure test are conducted to assess and monitor conditions. Selection of different grouting schemes is based on advanced geological forecast results. For local fissure development, the scheme involving local section advanced pre-grouting + radial supplementary grouting in the sections with low water pressure. Implementation of surrounding curtain grouting + radial supplementary grouting where water pressure and water output are controlled. Adoption of the scheme involving full section grouting + radial supplementary grouting in

sections where surrounding rock is extensively broken, fault rock is seriously weathered, or fault mud is present.

5.2 Shield method tunnel waterproof design

The Zhujiankou shield tunnel is bifurcated into east and west sections, experiencing varying maximum water pressure. In the western section, the maximum water pressure is 0.88 MPa, and in the eastern section, it reaches 1.06 MPa, making it the highest in the world presently. The waterproof design of segment joints is very important for the later-stage operation safety of the tunnel.

For segment joint waterproofing design, a typical approach in domestic underwater shield tunnel involves using an elastic gasket on the outside with a water pressure of 0.8 MPa, along with a water expansion stop on the inside. Due to the limited durability of 0.8 MPa, the tunnel opts for two EPDM elastic gaskets on the outside to ensure tightness in the shield tunnel joints.

Adopting a segmented fine design concept, the joint of the shield segment in the shield tunnel poses a challenge in assembling segments under ultra-high water pressure. The accuracy of segment assembly becomes a crucial factor limiting the waterproof performance of the joints, as shown in Figure 8.

Figure 8. Double channel EPDM elastic gasket joint waterproof design.

6 DOCKING DESIGN FOR SEA AREA

In the sea area, two common methods for shield machines to dock on the seabed are civil docking and mechanical docking. To ensure smooth construction, the docking position of the shield and the mining method is selected in the microweathered granite layer with good rock integrity. The microweathered rock layer's coverage thickness in this section is greater than two times the hole diameter, with a longitudinal length of about 30 m. The receiving scheme is shown in Figure 9.

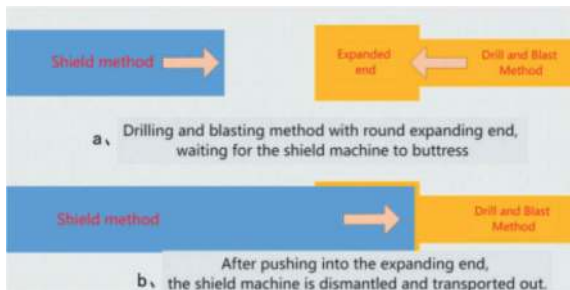

Figure 9. Design of Submarine Docking Enlargement Chambers.

Considering the potential adjustments to the theoretical docking mileage of the shield and the mine may during actual construction, the shield machine adopts the “double-shell” mode. This approach allows the shield machine to receive and synchronize in situ disassembly independently of the mine section's progress, facilitating a retreat from the whole body akin to a ‘golden shell’.

7 DURABILITY DESIGN

7.1 Design principles

Durability is a critical consideration in the design of the tunnel structure, with equal emphasis on both the durability and the limit design of bearing capacity. The design should meet the requirements of reparability and considered reserved reinforcement space to enhance the undersea tunnel's service life. Key components such as the reinforced concrete structure and drainage system, segment connecting components, and segment sealing material, collectively form a durability system. The failure of any of these components not only directly affects the normal use of the engineering but may also accelerate the deterioration of other parts, making the service life of the tunnel dependent on the weakest link of the durability system.

7.2 Durability design of mine method tunnel support structure

The mine method tunnel adopts a composite lining structure, where the secondary lining is designed for both bearing capacity and durability under the entire load. While the durability of the initial support lacks a quantitative implementation standard, it serves as an auxiliary measure to further improve the overall durability and structural safety of the project.

(a) Durability design measures for the initial support

In the mining tunnel, advanced curtain grouting is used to block the groundwater, thereby reducing soil permeability and the water pressure behind the lining. Grouting recommendations include the use of ordinary cement slurry, sulphaluminate slurate, and other grout materials with proven durability, controlling the amount of cement-water glass double slurry. For

sections with weak surrounding rock, the initial support incorporates an “8” bar grid steel frame, ensuring shotcrete impermeability not less than P6 through the application of the wet spray process. The net protective layer, both inside and outside the steel frame, is designed to be not less than 40 mm.

(b) Durability design for the secondary lining

Concrete strength and structural measures are reasonably selected based on environmental action grade considerations. The second lining adopts C50 and P12 reinforced concrete, with a specified crack width limit of 0.15 mm and a net protective layer thickness of 60 mm.

To control the hydration heat of molded concrete, the design opts for ordinary Portland cement with low hydration heat, maintaining a water-cement ratio within 0.36 and controlling the amount of cementing material within the range of 360 ~ 480 kg/m³. A significant proportion of high quality fly ash (20 ~ 30 % of the cementing material) is incorporated to enhance concrete properties. The curing time for concrete is not less than 14 days, followed by humidification curing until reaching 50 % of the standard strength at 28 days and lasting not less than 7 days. Additionally, polypropylene fiber is introduced with a dosage of 0.9 kg/m³ to further enhance the crack and seepage resistance of concrete.

(c) Durability design of the waterproof and drainage control system

Evaluation of the seawater resistance of the 2 mm thick ECB waterproof coil and water stop involves soaking in a 10 % NaCl solution and 23°C for 168 hours. The tensile strength retention rate should not be less than 80 %, and the pull elongation rate should not be less than 90 %.

7.3 Durability design for shield tunnel structure

The durability design of the shield tunnel focuses primarily on the segment structure, joint sealing material, and connecting bolts. Past projects have shown that corrosion resistance protection was not adequately emphasized. Taking Shenzhen Qianwan cable tunnel, completed in 2005, concrete test results in February 2014 were satisfactory without the need for repair. However, corrosion rates averaged 80 %, with bolts experiencing an average corrosion rate of 92.3 %, and bolt gaskets facing an average corrosion rate of 99.5 %, leading to loosening and water leakage in some severely corroded bolts.

1) Shield segment durability design measures

The Zhujiangkou Tunnel, enduring a marine corrosive environment for extended period, requires additional anti-corrosion measures to meet its 100-year design life. Traditional methods involve applying epoxy resin waterproof material to the outer structure surface. However, in shield tunneling, this material is susceptible to damage from the shield tail

brush, affecting anticorrosion performance. To address this, the project adopts silane impregnated anticorrosion design, allowing hydrophobic material to attach to the concrete structure’s air holes without blocking pores. The epoxy resin coating, with a thickness of up to 3.5 mm, poses challenges in meeting the assembly accuracy requirements for the pipe piece, particularly concerning the ring and longitudinal seam gap deviation (≤ 2 mm). To address this issue, the shield segment of the project adopts a silane impregnated anticorrosion design, as shown in Figure 10.

Figure 10. Silane impregnation anticorrosion design of segment.

Silane impregnation leverages its permeability to penetrate the concrete structure to a certain depth, allowing hydrophobic material to attach to the air holes without blocking the pores. Through this treatment, it prevents the entry of corrosive mediums while enabling water vapor to permeate freely. This ensures the permeability of the segment structure, ultimately achieving an effective anti-corrosion effect. This technology resolves interference concerns caused by epoxy resin and other processes on segment assembly accuracy. Additionally, it proves effective in avoiding the impact of shield tail brush scraping, meeting the stringent anti-corrosion requirements of shield tunnels.

The segments adopt C55 and P12 reinforced concrete, with a crack width limit of 0.15 mm and a net protective layer thickness of 50 mm. Durability indexes, including concrete cement ratio, dosage of cement material, and chloride ion diffusion coefficient, are strictly controlled. Admixtures such as polycarboxylic acid high-performance water reducer, steel rust inhibitor, fly ash, and polypropylene fiber are utilized. Proper temperature and time during steam curing and pool maintenance are ensured.

2) Durability design measures of bolt and joint sealing material

(a) At present, shield bolts usually use coating for anticorrosion, constrained by coating thickness limitations and insufficient protection life. The project adopts for 316L stainless steel bolts with chlorine salt corrosion resistance and passivated surfaces.

(b) Micro-expansion cement mortar is used to seal the bolt hand hole.

(c) Materials such as sealing ket, water stop, and others at the joint are selected for seawater resistance, with consideration for embedding inside the segment.

8 CONCLUSIONS AND SUGGESTIONS

The Zhujiangkou Tunnel, a pivotal project for the Shenzhen-Jiangmen Railway, stands as China's deepest and most water pressure-intensive mine and shield tunnel combination submarine tunnel. With increasing depth and pressure, new technical challenges emerge. This paper employs geological analysis, engineering analogy, and comprehensive comparison to scrutinize key technical aspects in the intersection design across the sea:

- (1) It is proposed that a combination of shield and mine methods tailored to the geological conditions of different sections is adopted. The layout design employs a single hole and double-line configuration.
- (2) The drainage control should be emphasized, ensuring the maintenance of the drainage system. Use of a double ternary ethylene propylene elastic gasket layout for large-diameter, ultra-high water pressure shield tunnels is recommended to enhance assembly accuracy and achieve effective sealing and waterproofing.
- (3) The durability design of the tunnel structure and the limit design of bearing capacity should be treated equally. Silane impregnation anticorrosion technology is introduced to safeguard against external damage, such as shield tail brush scraping, meeting the anti-corrosion requirements for shield tunnel.
- (4) A combined submarine docking technology that is independent of project progress is introduced. Through the "double shell" mode, the shield machine can autonomously receive and synchronize in-situ disassembly.

The enormity of undersea tunnel construction necessitates high standards, promoting the advancement and innovation of tunnel construction technology in China. Although construction has commenced, challenges persist, including limited experience and elevated safety risks. The design technology issues discussed in this paper will require further exploration, accumulation, and summarization in the future practice endeavors.

ABSTRACT: The design method of tunnel support system is an important way to ensure the safety of tunnel support structure construction, help tunnel construction efficiently and achieve the goal of green and low-carbon construction. This paper systematically reviews the development history of railway tunnel support system design in China from three dimensions of tunnel support system design concept, support type and design method, and points out the characteristics of the development of design concept from emphasizing the support to emphasizing the surrounding rock, support type from passive support to active support, and design method from empirical method to quantitative analysis method. This paper also expounds the innovative achievements in the design of advanced support of the face and anchorage support of the tunnel body in the analytical method, summarizes the problems still faced in the design of tunnel support system at the present stage, and puts forward that the whole-process intelligent dynamic design method based on the multi-information data of the construction period and the intelligent algorithm as the core is an important direction for the future development. The key technologies involved in intelligent dynamic design, such as sample database construction, intelligent algorithm model and safety evaluation method of supporting structure, are introduced.

Keywords: Railway tunnel, Supporting system, Design method, Empirical design method, Quantitative analysis method, Intelligent dynamic design method

1 INTRODUCTION

The tunnel support system is an important measure to maintain the clearance of the tunnel cross-section, prevent the deterioration of tunnel surrounding rock quality, withstand various external loads of the tunnel, and ensure the safety of tunnel construction. Therefore, scientifically designing the tunnel support system, selecting reasonable support types and parameters, is of great significance for the safe, economic, and efficient construction of the tunnel, and achieving the goal of green and low-carbon construction of the tunnel.

Since the establishment of the People's Republic of China, Chinese railway tunnels have been developing for more than 70 years, especially in the past 40 years. During this period, China's railway tunnel support system design has been based on the

continuous reference, digestion and absorption of foreign advanced concepts and experiences, fully combined with the actual conditions and characteristics of railway tunnel construction in China, and through a large number of engineering practices and summaries. Continuous innovation and breakthroughs have been made in the support design theory and method, and the level and quality of China's railway tunnel support design have been continuously improved, demonstrating the international influence of China's railway tunnel construction (Tian et al., 2021).

This article reviews the development process of China's railway tunnel support system design, summarizes the main innovative achievements of China's railway tunnel support system design, and proposes development directions and prospects based on the current technical difficulties and challenges faced by

*Corresponding author: tsmd@163.com

railway tunnel engineering. This has positive significance for further improving the design level of China's railway tunnel support system.

2 DEVELOPMENT OF DESIGN METHODS FOR RAILWAY TUNNEL SUPPORT SYSTEMS IN CHINA

For tunnel engineering, a complete support system consists of two parts: surrounding rock and support structure (Guan, 2011). Therefore, how to understand the position and role of surrounding rock and support structure in the design of tunnel support system is the core and key of tunnel support system design.

It should be pointed out that the understanding of surrounding rock and support structure in tunnel support design is not achieved overnight, but gradually deepens with the continuous development of tunnel support technology and construction technology. The design concept of support system varies depending on the understanding during different periods. Throughout the development process and characteristics of China's railway tunnel support system design, it can be roughly divided into three stages.

2.1 *Stage 1: Before the 1980s*

At this stage, China's railway tunnels continue to use the traditional mining method construction concept, and the support technology mainly adopts simple wooden support + integral lining. The support construction is mainly manual. Due to the low efficiency and poor timeliness of support, it is often difficult to ensure the stability control of the surrounding rock. To ensure the reliability of the support design, the surrounding rock load is considered as a relaxation (collapse) load, and the lining structure is considered as the main bearing unit, assuming that the lining structure bears all the load. The design method is generally based on empirical methods, and a formula for calculating the relaxation load of surrounding rock has also been studied and proposed, starting to apply the load structure method to support design. The surrounding rock load considered in this stage of support design is the most unfavourable working condition, and the bearing unit is single, so the safety redundancy of support parameters is often too high.

2.2 *Stage 2: From the 1980s to the end of the 20th century*

At this stage, the construction concept of the New Austrian Tunnelling Method (NATM) was gradually applied and promoted in Chinese railway tunnels, and the support technology was transformed into a composite lining structure system of "primary support + secondary lining". The primary support components were mainly sprayed concrete and mortar anchor rods, and special sections were supplemented with steel support. The support construction method gradually developed into small-scale mechanized or single-process

large-scale mechanized construction. Due to the fact that anchor-spray support can effectively control the deformation and stability of the surrounding rock, the design of support during this period gradually emphasizes the study of deformation loads on the surrounding rock, and both the primary support and secondary lining are considered as load-bearing units. It is believed that the two work together to bear all the loads. The design method is mainly based on empirical methods for primary support, while the load structure method is mainly used for secondary lining. At the same time, the surrounding rock structure method, which can consider the synergistic effect of the two, has also begun to be applied in design. Although the quality of support design in this stage has been significantly improved compared to the first stage, there are still some deficiencies in the self-bearing effect of the surrounding rock in the design.

2.3 *Stage 3: Since the beginning of the 21st century*

At this stage, China's railway tunnels have been continuously developed and influenced by new materials, construction equipment, artificial intelligence and other technological fields. Support technology has gradually introduced new support components such as early high-strength sprayed concrete and prestressed anchor rods (cables). Support construction has gradually evolved into a large-scale mechanized or even intelligent construction mode throughout the entire process, further improving the timeliness and quality of support construction. The active control effect of support on the stability of surrounding rock is becoming more prominent, and the design concept of active support is becoming increasingly mature, emphasizing the main role of rock anchor support system in bearing, and using secondary lining as a safety reserve. The design method focuses more on the synergistic bearing capacity of surrounding rock and support structure and the spatiotemporal effects of their support effects, and the level of support design has also been continuously improved.

3 MAIN ACHIEVEMENTS OF DESIGN METHODS FOR RAILWAY TUNNEL SUPPORT SYSTEMS IN CHINA

In recent years, Chinese scholars have gradually formed a new method for designing tunnel support systems with active support control of surrounding rock deformation as the core, based on the characteristics of railway tunnel construction in China and through continuous exploration, practice, and summary.

3.1 *Design method for deformation control of tunnel surrounding rock*

In response to the problem of controlling the deformation of surrounding rock in tunnels, a design method for controlling the deformation of surrounding rock in

railway tunnels is proposed (Zhao, 2019). The core idea of this method is to take the stability of the surrounding rock as the premise, control the deformation of the entire process of the surrounding rock as the goal, and use scientific support measures as the means to achieve the synergistic effect between the support structure and the tunnel surrounding rock, in order to fully utilize the self-bearing capacity of the surrounding rock and achieve a safe, economic, fast, and durable tunnel stability structural system.

This method assumes that the surrounding rock is composed of a combination of shallow and deep layers. Shallow surrounding rock refers to the loose zone surrounding rock that is disturbed and unstable around the tunnel, and the load generated by this part of the surrounding rock needs to be fully borne by the support structure; Deep surrounding rock refers to the surrounding rock outside the loose zone that is in a stable or temporarily stable state. This part of the surrounding rock is composed of a structural layer and a load layer, and the load generated is mainly deformation load. The magnitude of the load mainly depends on the control level and force transmission effect of the structural layer. Based on the load transfer effect of the composite surrounding rock, the final force of the support structure can be analysed, and then the design of the support structure can be carried out.

Based on the composite surrounding rock load effect, the calculation model shown in Figure 1 can be used to analyse the support reaction force. r_c is the thickness of the deep surrounding rock structure layer; r_b is the thickness of the shallow surrounding rock; r_a is the excavation size of the tunnel.

Figure 1. Calculation model of composite surrounding rock load.

Take a group of structural layers for analysis, with a focus on supporting radial loads. Assuming the support reaction force is p_a , the contact reaction force between the structural layer and the shallow

surrounding rock interface is p_b , and the load applied to the structural layer by the load layer is p_c .

The support load p_a comes from the self-weight load p_1 of the shallow surrounding rock and the deformation load p_2 of the structural layer, respectively.

$$p_a = p_1 + p_2 \quad (1)$$

The self-weight load p_1 directly acts on the support, and the structural layer deformation load p_2 is transferred to the support structure through the shallow surrounding rock. The self-weight load of shallow surrounding rock is:

$$p_1 = \gamma_1 h_1 \quad (2)$$

Where, γ_1 is the weight of shallow surrounding rock; h_1 is the thickness of the shallow surrounding rock.

If the deformation load of the structural layer is related to the pressure of the load layer and its own parameters, it can be expressed as:

$$p_2 = \alpha p_c + \beta \mu_i \quad (3)$$

Where, α is the pressure transfer coefficient of the load layer; β is the deformation load transfer coefficient of the structural layer, both of which are related to the geometric and material parameters of the analysis problem; μ_i is the deformation amount of the structural layer.

Therefore, the focus of support load calculation is shifted to the determination of deformation load transfer parameters α and β for the structural layer and shallow surrounding rock. Reference (Zhao, 2019) specifies the parameter determination of α and β .

3.2 Tunnel mechanized large section design method

Based on the characteristics of mechanized large-section construction in tunnels, a design method for mechanized large-section support in railway tunnels has been proposed, which mainly includes two aspects: advance support design and tunnel body system support design (Wang, 2018).

In terms of advanced support design, the mechanical mechanism of various advanced support measures such as advanced pipe roof, tunnel face bolt, and advanced pre-grouting were systematically analysed. Based on the analysis of the ultimate mechanical balance of the tunnel face surrounding rock, a calculation and analysis model for advanced support was constructed, which can achieve the quantitative design of various advanced support parameters.

As shown in Figure 2, the height and width of the tunnel face is D and B , respectively; the length of the unsupported span is L_e . According to the force analysis of the tunnel face, the equations for the stability coefficient of the tunnel face is derived based on the limit equilibrium method as follows:

Figure 2. Calculation Model for Advance Support of Tunnel Face.

$$K = \frac{P_1 + \beta_1 F_c}{\beta_2 (F_w + \alpha_1 F_q)} + \beta_3 \geq [K] \quad (4)$$

$$F_c = \frac{cBD}{\sin \theta_0} + 2D^2 \cot \theta_0 \left[c + \lambda \left(\frac{2}{3} q + \frac{D\gamma}{3} \right) \tan \varphi \right] \quad (5)$$

$$F_w = \frac{D^2 B \gamma \cot \theta_0}{2} \quad (6)$$

$$F_q = qB(D \cot \theta_0 + L_e) \quad (7)$$

$$\beta_1 = \frac{1}{\sin \theta_0 \tan \varphi + \cos \theta_0} \quad (8)$$

$$\beta_2 = \frac{\sin \theta_0}{\sin \theta_0 \tan \varphi + \cos \theta_0} \quad (9)$$

$$\beta_3 = \frac{\cos \theta_0 \tan \varphi}{\sin \theta_0} \quad (10)$$

$$\theta_0 = \frac{\pi}{4} + \frac{\varphi}{2} \quad (11)$$

Where, K is the face stability coefficient; $[K]$ is the design stability coefficient of tunnel face, with the value of 1.15; F_c is the shear force on the failure surface; F_w is the weight of tunnel face; F_q is the vertical force exerted by the underlying ground; c is the cohesion of the ground; q is the earth pressure; γ is the bulk density of the ground; θ_0 is the failure angle of tunnel face; λ is the lateral pressure coefficient; β_1 , β_2 and β_3 are the coefficients related to φ ; P_1 is the support force of face bolt; α_1 is the load transfer coefficient of pipe roof.

In terms of support design for the tunnel system, a calculation formula for the deformation load of surrounding rock under deep burial conditions was proposed through statistical analysis of the contact pressure samples of the surrounding rock on the on-site support structure. Based on this, a load structure model was used to design the support structure.

The deformation load of the surrounding rock is as follows:

$$q = \alpha \cdot B \cdot e^{0.5s - \frac{15}{H}} \quad (12)$$

$$e = \lambda q \quad (13)$$

Where, q is vertical deformation pressure; e is the horizontal deformation pressure; α is the correction factor ($\alpha=1.2$); B is the tunnel span; s is the level of surrounding rock; H is buried depth of tunnel; λ is lateral pressure coefficient.

3.3 Total safety factor method for tunnel support structure design

In response to the overall safety evaluation of composite lining structures, the total safety factor method for tunnel support structure design has been proposed for railway tunnels (Xiao, 2020). This method suggests that when the composite lining structure is designed using the safety factor method, the total safety factor should include the respective contributions of the initial support and secondary lining. In the design, the relationship between the surrounding rock and support structure is regarded as the relationship between force and reaction force. The characteristic value of surrounding rock pressure is used as the load value for support design, and the support structure is divided into four calculation models: spray layer, anchor bolts - surrounding rock bearing arch, anchor bolt, and secondary lining. The safety factors of spray layer, anchor bolt-surrounding rock bearing arch, and secondary lining are calculated using the load structure method, as shown in Figure 3. Finally, based on the actual engineering situation, the total safety factor of the support structure is given.

After calculating the safety factors of anchor bolt-surrounding rock bearing arch, spray layer and secondary lining respectively according to the above model, the lower limit value of the total safety factor of the structure can be approximately calculated as follows under the condition that no tensile failure occurs:

Construction phase (without secondary lining):

$$K_c = \eta K_1 + K_2 \quad (14)$$

Where, K_1 and K_2 are the safety coefficients of anchor bolt-surrounding rock bearing arch and the spray layer when they bear the design value of all surrounding rock pressure; η is the correction factor for the safety factor of the anchor bolt-surrounding rock bearing arch.

During the operation phase, when using durable or non-durable anchor bolts, calculated according to Eq. (15) and Eq. (16) respectively:

$$K_{op} = \eta K_1 + \zeta K_2 + K_3 \quad (15)$$

$$K_{op} = \zeta K_2 + K_3 \quad (16)$$

Where, K_3 is the safety factor of secondary lining under the design value of all surrounding rock pressure; ζ is the adjustment coefficient of spray layer bearing capacity.

The total safety factor during the construction period is recommended to be not less than 1.8 when the spray layer is steel fiber concrete or steel frame,

Figure 3. Calculation model of total safety coefficient method for composite lining.

and not less than 2.1 when the spray layer is plain concrete.

The overall safety factor during the operating period is recommended to be not less than 3.0 when the secondary lining is reinforced concrete and not less than 3.6 when the secondary lining is plain concrete.

3.4 High performance active support design method for tunnels

Combining the support characteristics of new support components such as early high-strength shotcrete and

prestressed anchor bolts (cables), a high-performance active support design method has been developed for railway tunnels (Tian et al., 2022), as shown in Figure 4. This method categorizes the instability of surrounding rock into two categories: the overall deformation instability of soft rock and the sliding instability of key blocks in hard rock. In terms of deformation instability control, the goal is to control the overall deformation of surrounding rock in three-dimensional space, with the improvement of surrounding rock stress and mechanical parameters by support as the core, and the comprehensive effect of spatiotemporal factors on the deformation of surrounding rock and support forces (such as the age strength of sprayed concrete) is considered, the mechanical analysis model and design method of the supporting system is established; In terms of controlling the instability of block sliding, with the goal of controlling the stability of key blocks, a local load mechanics analysis model was established through mechanical balance analysis of block self-gravity, shear resistance of sliding surface, radial and tangential forces of support, etc., to guide the design of anchor-spray support structure.

A quantitative design method for prestressed anchor bolts based on active control of surrounding rock deformation is mentioned in the high-performance active support design method. The specific process is as follows:

(1) Calculation model of surrounding rock layers

Based on the ideal elastic-plastic solution of the surrounding rock, a calculation model for the surrounding rock layer considering the reinforcement area of prestressed anchor bolts was established, as shown in Figure 5. And the final deformation value of the surrounding rock is obtained through the circle layer calculation model, as shown in Eqs. (17) ~ (20).

$$\mu_0 = R_0 \sin \varphi \left(\frac{1 + \nu}{E} + \frac{1 + \nu R_p^2}{E R_L^2} - \frac{1 + \nu R_p^2}{E R_L^2} \right) \times \left[\frac{(P_0 + c \cot \varphi)(1 - \sin \varphi)}{c' \cot \varphi'} \right]^{\frac{2}{M_\varphi}} \quad (17)$$

$$R_p = R_0 \left[\frac{(P_0 + c \cot \varphi)(1 - \sin \varphi)}{c \cot \varphi} \right]^{\frac{1}{M_\varphi}} \quad (18)$$

$$M_\varphi = 2 \sin \varphi / (1 - \sin \varphi) \quad (19)$$

$$M_{\varphi'} = 2 \sin \varphi' / (1 - \sin \varphi') \quad (20)$$

Where, c , φ , E , ν represents the original surrounding rock cohesion, internal friction angle, elastic modulus, and Poisson's ratio; c' , φ' , E' represents the cohesive force, internal friction angle, and elastic modulus of the surrounding rock in the reinforcement area; P_0 is the initial geostress; R_L refers to the reinforcement range of prestressed anchor bolts; R_0 is the radius of the tunnel.

For non-circular cross-section tunnels, the equivalent circle calculation method can be used to convert them into circular tunnels for analysis, and the value of R_0 is as follows:

Figure 4. Schematic diagram of high-performance active support design principle.

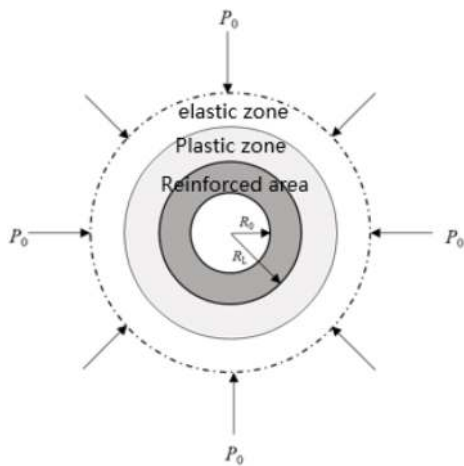

Figure 5. Calculation model for the surrounding rock layer.

$$R_0 = \frac{h + b}{4} \quad (21)$$

Where, h and b are the height and span of the horseshoe shaped tunnel section.

(2) Determination of the reinforcement range of prestressed anchor bolts

Considering the length, spacing and prestress value of prestressed bolts, the calculated thickness of the continuous pressure zone under the supporting action of multiple prestressed bolts is established, as shown in Eq. (22).

$$R_L = L - \frac{S_r - B}{2 \tan \varphi_p} \quad (22)$$

Where, B is the width of the base plate; S is the circumferential spacing of the anchor bolts; L is the length of the free section of the anchor bolts; φ_p is the diffusion angle; R_L is the thickness of the compression zone.

The calculation method of additional stress in the reinforced area is shown in Eq. (23).

$$\Delta\sigma_3 = \frac{F}{S_l S_r} \quad (23)$$

Where, F is the pre tightening force of the anchor bolts; S_l and S_r are the longitudinal and circumferential spacing of the anchor bolts.

The calculation method for the mechanical parameters of the surrounding rock in the reinforcement area is shown in Eqs. (24) ~ (29).

$$E' = E + \Delta E \quad (24)$$

$$\Delta E = A_E (\Delta\sigma_3 + 1)^{B_E} \quad (25)$$

$$\varphi' = \varphi + \Delta\varphi \quad (26)$$

$$\Delta\varphi = A_\varphi \ln(\Delta\sigma_3 + 1) + B_\varphi \quad (27)$$

$$c' = c + \Delta c \quad (28)$$

$$\Delta c = A_c (\Delta\sigma_3 + 1)^{B_c} \quad (29)$$

Where, A and B represent the undetermined fitting coefficients of the calculation model of the mechanical parameters of each surrounding rock respectively, which can be obtained according to the indoor triaxial test.

(3) Control criteria for surrounding rock deformation

According to Technical code for monitoring measurement

of railway tunnel (China Railway Eryuan Engineering Group Co., 2007), the required control criteria for surrounding rock deformation control are selected, as shown in Table 1 and Table 2.

(4) Design process of pre-stressed anchor bolts

Determine the grade of surrounding rock in the design area based on the geological conditions and rock grade parameters in actual engineering, and

Table 1. Ultimate relative displacement of primary support for tunnels with a span of $7\text{m} < B \leq 12\text{m}$.

select the deformation control values of the surrounding rock according to the engineering needs.

According to the deformation control criteria of surrounding rock, the required reinforcement parameters are solved, and the scope of reinforcement and the lifting ratio of mechanical parameters are determined.

According to the calculation model of the reinforcement range of the prestressed bolts, the length and spacing of prestressed bolts are determined.

The prestress value of the prestressed bolt is determined according to the calculation model of the lifting rate of the mechanical parameters in the reinforcement range of the prestressed bolt.

4 DEVELOPMENT DIRECTION OF SUPPORT SYSTEM DESIGN FOR RAILWAY TUNNELS IN CHINA

The essence of tunnel support system design is to control the change process of tunnel construction mechanic's state. In fact, there are many factors affecting the change of tunnel construction mechanic's state. In addition to geological objective factors, it

is also closely related to construction method, support timing, support closing distance and other construction human factors. How to comprehensively consider the comprehensive influence of various factors in the design of support systems, in order to achieve dynamic and precise design of support, has become an important direction for design development.

With the continuous improvement of digitalization, informatization, and intelligence in tunnel construction, it is possible to use multi-source information data obtained during the construction period to carry out precise and dynamic design of tunnel support systems. Based on this, some experts and scholars have conducted active research and exploration on the dynamic design and intelligent decision-making methods of informationization throughout the entire process of tunnel support construction (Tian et al., 2023). The core idea is to use the information of all elements in the entire construction process to construct an information sample database, and use artificial intelligence algorithms to find the nonlinear mapping relationship between various elements in the entire construction process and the safety of the support structure. By quantitatively evaluating and analysing the safety of the support structure, and based on the set optimization feedback rules, reasonable optimization decisions are provided for the design and construction control of the support system. The key technical steps of this method mainly include the following four aspects:

(1) The Expression of All Element Information in the Whole Construction Process and the Construction of a Sample Database

The expression of all element information in the entire construction process refers to the qualitative or quantitative expression of indicator information for various element indicators that affect the safety of support structures during the construction process. By collecting the above indicator information, an information sample database can be constructed, providing a foundation for the learning and training of intelligent algorithm models.

(2) Training and Selection of Intelligent Algorithm Models

The purpose of using an intelligent algorithm model is to provide a nonlinear mapping relationship between various elements in the entire construction process and the safety degree of the support structure. Essentially, it is to predict the safety index information of the support structure based on the indicator information of each element. Therefore, it is advisable to use supervised learning regression machine learning algorithms for implementation.

(3) Quantitative Evaluation and Analysis of the Safety Degree of Support Structures

For the surrounding rock mainly characterized by deformation and instability, the deformation of the support structure is the most intuitive indicator reflecting the safety of the support structure. The deformation value of the support structure can be directly obtained through monitoring and

measurement methods, and the stress of the support structure can be obtained through the stiffness matrix displacement method from the deformation of the support structure. Based on this, the safety of the support structure can be uniformly measured and evaluated. For the surrounding rock mainly characterized by sliding and instability, the safety of the support structure should be quantitatively evaluated based on mechanical analysis such as the weight of the sliding block, the radial and tangential forces provided by the support, and the three dimensional indicators of anchor bolts axial force, sprayed concrete stress, and shear force at the contact surface between sprayed concrete and surrounding rock.

(4) Intelligent Decision Feedback Mechanism for Support Optimization

When the safety evaluation redundancy of the support structure is high, it is necessary to develop corresponding intelligent decision feedback rules for support optimization, guiding the machine to carry out automatic iterative optimization and feedback work on the support, in order to find the optimal support parameters and construction control plan for designers to make decisions. Support optimization mainly takes safety, efficiency, green and low-carbon as feedback goals, prioritizing the optimization of support components and parameters with low efficiency and long-time consumption until the safety redundancy of the support structure meets expectations.

5 CONCLUSIONS

Overall, the design of China's railway tunnel support system has undergone more than 40 years of development, with constantly improving design theories and methods. It has gradually evolved from traditional emphasizing support concepts and experiential design methods to highlight surrounding rock concepts and quantitative analysis design methods,

and has formed many original technical achievements, greatly improving the design level and quality of China's railway tunnel support system. However, there are still a lot of technical challenges to be overcome in further improving the accuracy of tunnel support system design and meeting the dynamic requirements of support design during construction, which is also an important direction for the future development of tunnel support system design.

ABSTRACT: This paper describes the challenges faced in the design of primary supports for the City Rail Link Maungawhau Mined Tunnels through extremely to very weak sedimentary rocks of the East Coast Bay Formation. The tunnels, designed to accommodate the rail alignments, including turn-outs, TBM transits and launches, were excavated by road headers in an area of low cover. The primary support designs were a mixture of passive lattice girders and sprayed concrete and active designs utilizing rock-bolts, executed in an intricate sequence to accommodate the complex geology, geometry and schedule constraints. One of the particular challenges involved the excavation and support of large tapered caverns to accommodate the track turnouts. These are efficient in terms of excavation volumes but require attention to design and construction detailing to successfully complete. The design was amended in the lead-up to construction, and through the early stages of construction, in order to optimise the schedule outcomes, which had been affected by supply-chain issues stemming from the Covid-19 pandemic.

Keywords: Sprayed concrete lining, tapered cavern

1 INTRODUCTION

The City Rail Link (CRL) Project includes the design and construction of two underground rail stations; a redevelopment of an existing surface rail station; two new rail tunnels; and connections to the existing North Auckland Line (NAL). The twin tunnels connecting the stations extend from Albert Street to Newton where they bifurcate through a grade separated interchange with terminations at Mt Eden Station and between Mt Eden Road and Normanby Road bridges. Connections to the NAL are via east and west grade separated connections.

The twin tunnels were driven northwards from Mt Eden towards the CBD via TBM drives. The initial, complex geometry at Mt Eden was negotiated in cut

Figure 1. Overall scheme layout.

and cover and mined tunnels. The mined tunnels (Maungawhau Mined Tunnels, previously known as the Mt Eden Mined Tunnels) were excavated by mechanical excavators and roadheaders. The Maungawhau Mined Tunnels consist of:

*Corresponding author: Howard.Toi@smec.com

- MC30/MC60 Cavern: Accommodating the convergence of two tracks (MC30 and MC60) into turnouts to a single track (MC30). The northern end of the cavern was arranged to allow for the launch of the TBM along the MC30 alignment.
- MC20 Stub Tunnel: Excavated through a highly skewed headwall and arranged to allow for the launch of the TBM along the MC200 alignment southwards.
- MC50 Mined Tunnel: Excavated through a highly skewed headwall mined northwards towards the MC20/MC50 Cavern,
- MC20/MC50 Cavern: Accommodating the convergence of two tracks (MC20 and MC50) into turnouts to a single track (MC20). The northern end of the cavern was arranged to allow for the launch of the TBM along the MC20 alignment.

Figure 2. Maungawhau Mined Tunnel layout.

The mined tunnels are designed with a temporary primary lining, within which cast concrete, drained, secondary linings are constructed. This paper focuses on the challenges associated with the design, and design refinements for, the primary support two turn-out caverns.

2 TAPERED CAVERN GEOMETRY

One of the particular challenges involved the excavation and support of large tapered caverns to accommodate the track turnouts. The tapered caverns are efficient in terms of excavation volumes but require attention to design and construction detailing to successfully complete.

The MC30/MC60 Cavern profile gradually tapers over a length of 12m from the portal wall with a maximum cavern span of approximately 13m. The cavern profile maintains a constant profile for about 35m towards the northern end. A stub tunnel at the end of the MC30/MC60 cavern facilitates launch of the MC30 TBM (Figure 3).

Figure 3. MC30/MC60 cavern arrangement.

The MC20/MC50 tapered cavern profile extends approximately 54 m north from the southern headwall. The maximum cavern span is approximately 17 m and is located at the southern headwall. The cavern profile then reduces to the north terminating in a short stub similar to that for MC30/60 (Figure 4).

Figure 4. MC20/MC50 cavern arrangement.

3 PRIMARY SUPPORT DESIGNS

3.1 Ground conditions

Ground conditions at the two caverns generally comprises East Coast Bays Formation (ECBF), including the following units:

- Highly to moderately weathered EBCF rock (EW).
- Slightly to unweathered extremely weak, poorly cemented sandstone (EU1).
- Predominantly interbedded very weak, sandstone and siltstone (EU2). Typical unconfined compressive strength (UCS) values for un-weathered EU2 is 1-5 MPa.

EU1 was often washed away during borehole drilling resulting in zones of core loss. When recovered, it appeared in boreholes as sand, or where recovered as a full core stick can be easily peeled by a knife and broken by hand. Typical geological sections at the two caverns are shown in Figures 5 and 6.

At MC30/MC60 cavern, a significant amount of EU1 was encountered in the face and above crown. For MC20/MC50 cavern, the dominant rock type is EU2 within the cavern face, with significant EW and EU1 above the crown at the cavern's widest span near the southern headwall.

3.2 Turn-out caverns - Proposed support types

The extremely weak uncemented sandstone EU1 was recognized as being potentially unstable, posing a significant risk of instability. Low rock cover was also expected above both caverns. A passive support system was proposed for areas affected by significant lenses of EU1 and in areas of low rock cover. Details for the proposed primary support types for each of the caverns are listed in Table 1.

Figure 5. Typical geological section for MC30/MC60 cavern.

Figure 6. Typical geological section for MC20/MC50 cavern.

Table 1. Proposed primary support types.

Cavern – Zone	Primary support	Sequence
MC30/60 (see Figure 7)	200mm thk. fibre reinforced shotcrete with lattice girders. Pre-support consisting of canopy tubes. Glass reinforced plastic (GRP) face dowels. Allowable advance in top-heading 1.1m	Top-heading and bench
MC20/50 – Low cover area at south (see Figure 8)	200-350mm thk. fibre reinforced shotcrete with lattice girders. Pre-support consisting of spiles. Glass reinforced plastic (GRP) face dowels. Allowable advance in top-heading 1.1m	Split top-heading and bench; becoming full width top-heading as span reduces
MC20/50 – EU2 crown pillar > 3m thk.	4m long rock-bolts with 100-150mm thick fibre reinforced shotcrete	Top-heading and bench

Each tapered cavern narrows northwards in the direction of the TBM drives. Key dimensions are listed in Table 2.

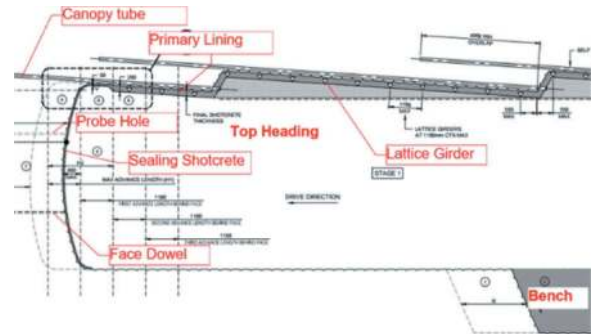

Figure 7. Primary supports for MC30/MC60 cavern.

Figure 8. Primary supports for MC20/MC50 cavern tapered profile KTN-3.

Table 2. Approximate cavern dimensions.

Cavern – Zone	Span (m)	Height (m)	Comment
MC30/60	13	8	Excavation profile varies to follow canopy tube look-out
MC20/50	17	10	Southern most section, narrows northwards; Profile KTN3
MC20/50	13	8	Central section, identical geometry to MC30/60 Cavern
MC20/50	10	8	Northernmost section

3.3 Ground relaxation

To address the three-dimensional arching effect near the advancing tunnels, the Convergence Confinement Method (CCM) was employed. Ground relaxation in CCM is evaluated by numerical analysis using Plaxis 2D and 3D Finite Element (FE) modelling. A Plaxis 3D model was developed to simulate the process of tunnel excavation and lining installation with time dependent stiffness, as indicated in Figure 9. For the Plaxis 2D analysis, ground

relaxation associated with tunnel excavation is modelled by the multiplier Mstage which controls stepwise ground stress and associated ground deformation of the excavation. Mstage value corresponding to the excavation stage and subsequent ground support are assessed based on the comparison of the 2D and 3D analysis results. The ground relaxation study for the MC30/MC60 cavern was used as a basis for subsequent mined tunnel designs. The MC30/60 simplified ground model assumed for the 3D analyses is illustrated in Figure 10.

Figure 9. Plaxis 3D model for ground relaxation assessment.

Figure 10. Analysis model for MC30/MC60 cavern.

Canopy tubes are required for the MC30/MC60 Cavern, and were included in the 3D model as embedded beams above the tunnel crown. They are spaced at 350mm intervals, have a length of 15m, and feature a 4m overlap. In the analysis, the primary lining thickness is set at 200mm. This assumes that the full lining thickness will be attained through the application of two sprays, the initial spray measuring 50mm, followed by a second spray of 150mm.

The 3D modelling considers both lining thickness and stiffness build-up with time, and age of sprayed concrete. Advance rate is assumed to be 2 rounds per day, while advance length is 1.1m per round. Thicknesses and ages of the respective lining segments (1.1m per segment) behind Advance N are indicated in Figure 11.

Advance ID	N	N-1	N-2	N-3	N-4
Lining Thickness (mm)	0	50	200 (50/150)	200 (50/150)	200 (50/150)
Age (days)	NA	0.5	1.0/0.5	1.5/1.0	2.0/1.5

Figure 11. Assumed shotcrete build-up.

Shotcrete stiffness build-up with time is assessed based on the research by Chang and Stille (1993), as shown in the equation below:

$$E = aE_{28}e^{c/t^{0.7}}, \text{ where}$$

$$E_{28} = 27.4 \text{ GPa (shotcrete modulus at 28 days)}$$

$$a = 1.062$$

$$c = -0.446$$

In the analysis, the overall stiffness of a full-thickness lining segment is evaluated to be a weighted average of the first and second layers.

John and Mattle (2003) investigated the effects of shotcrete creep and rock mass behaviour and stress re-distribution on tunnel deformation and derived the computational or hypothetical modulus of shotcrete from ground deformation.

Two scenarios to investigate the effect of modulus on deformation were used (see Figure 12):

- Option 1: Modulus determined based on Chang and Stille.
- Option 2: Similar to Option 1 but lower modulus values used for shotcrete with ages ≤ 2 days (John and Mattle; 2003).

Figure 12. Shotcrete lining thicknesses and stiffness.

The Plaxis 3D analysis simulates tunnel excavation/lining installation time intervals of half day steps until 9.5 days (19 time steps) until the total excavation length reaches 20.9m (19x1.1m). Theoretically the simulation requires 19 lining stiffness values corresponding to the 19 time steps. The increase of lining stiffness after 3 days becomes less significant and hence seven property cases are adopted in the simulation to characterise build-up of lining thickness and stiffness. The modulus values evaluated in accordance with Chang & Stille and

those adopted in the analysis are indicated in Figure 11 for the 1st round (Round 1) shotcrete lining from Day 0.5 to Day 9.5. The other rounds (Rounds 2, 3, ..., 18) follow the same pattern for both lining thickness and stiffness build-up, having their respective starting time (Day 0.5, 1, 1.5, ..., 9) to Day 9.5.

3.3.1 Plaxis 2D analysis

Plaxis 2D models were developed using the same cavern profile and ground profile as that of Plaxis 3D. The ground relaxation considering 3D effect near tunnel face is represented by the parameter Mstage in Plaxis 2D analysis. Ground relaxations (Mstage) for the excavation and 50mm shotcrete stages are assessed by comparing deformations at tunnel crown from the 2D and 3D analyses. Ground relaxation for the full thickness young shotcrete is assumed to be 100%.

- Excavation stage: Excavation prior to applying shotcrete lining is modelled in Plaxis 2D. Mstage assumed in the analysis increased from 0 at intervals of 0.1, i.e. Mstage = 0, 0.1, 0.2, 0.3, ... until the 2D analysis reaches similar deformation to 3D. The corresponding Mstage is then assigned as the Mstage for the excavation.
- 50mm shotcrete stage: Following the analysis of the excavation using the Mstage determined above, a 50mm shotcrete lining is applied and analysed. Under the same approach, Mstage is progressively increased (0.1, 0.2, 0.3, ...) until the 2D analysis has similar deformations to the 3D model, and the corresponding Mstage is then assigned for the initial shotcrete stage. Modulus of the 50mm shotcrete is assumed to be 15GPa for Option 1 and 5GPa for Option 2.

3.3.2 Analysis results

Plaxis 3D deformation profile: The estimated deformation profiles at tunnel crown from 3D analyses are plotted in Figure 13 for Option 1 and Figure 14 for Option 2. Deformations at the mid-point of the nearest round to the face (0.55m to tunnel face) and 2nd nearest round (50mm shotcrete round, 1.65m to tunnel face) are also shown.

Figure 13. Deformation profile from 3D analysis - Option 1.

Figure 14. Deformation profile from 3D analysis - Option 2.

The results indicate that deformations are not very sensitive to the shotcrete modulus adopted.

Plaxis 2D Mstage for the excavation round (0.55m to tunnel face): For the initial excavation, tunnel crown deformations associated with ground relaxation (Mstage) from Plaxis 2D analysis are plotted in Figure 15. Plaxis 3D result for the excavation round is 13.9mm as presented above. An Mstage-value of 0.57 (rounded to 0.55 for the purpose of further analysis) closely matches the 3D analyses.

Figure 15. Ground reaction for excavation stage.

Plaxis 2D Mstage for 50mm shotcrete (1.65m to tunnel face): Following analysis of the tunnel excavation using Mstage = 0.55 as determined above, a 50mm shotcrete lining is applied and the analysis continues with varying Mstage of 0.1, 0.2, 0.3, ..., etc. Modulus of shotcrete is assumed to be 15GPa (Option 1) and 5GPa (Option 2) respectively to assess the impact on analysis results. The difference of deformations from the two cases is small. Hence, the deformation at the initial shotcrete stage are not considered sensitive to the shotcrete modulus. Plaxis 3D result for the 50mm shotcrete round is 15.5mm as presented above. Mstage-values of 0.22 for Case 1 and 0.25 for Case 2 closely match the 3D analyses. An Mstage-value for the 50mm shotcrete stage of 0.25 was adopted for design.

3.4 Mined tunnel construction sequence

Defining the overall construction sequence was critical given that the proposed tunnels are in close proximity

The following sequence was assumed for design: a) first the MC30/MC60 Cavern (assumed that TBM launch from the northern end of the cavern could then proceed at any time, independent of the mined tunnel works); b) followed by the MC50 Mined Tunnel; c) the MC20 Stub Tunnel; and finally d) the MC/20 Cavern.

3.5 Primary lining design

Polypropylene fibre reinforced shotcrete (PFRC) was used as the principal element for the primary lining for the mined caverns and tunnels. The PFRC was designed in accordance with the methodology in NZS 3101 for steel fibre reinforced concrete (SFRC).

The characteristic stress-strain relation for PFRC is shown in Figure 16 as extracted from NZS 3101 for SFRC. Design strength parameters are as follows:

Figure 16. Characteristic stress-strain relation for PFRC.

- Characteristic compressive strength, $f_c' = 30\text{MPa}$
- Peak flexural tensile strength, $\sigma_1 = 4.8\text{MPa}$
- Residual flexural tensile strength $\sigma_2 = 2.0\text{MPa}$
- Residual flexural tensile strength $\sigma_3 = 1.5\text{MPa}$

Bending moment (M) and axial force (N) interaction diagrams were developed based on the stress-strain relationship shown above. It is assumed that plane section of a structural member remains plane after straining. Rectangular parabolic stress distribution

Figure 17. Structural capacity of 200mm PFRC lining.

is assumed in the compression zone, with a bi-linear stress distribution in the tension zone. Strength reduction factors of 0.85 for flexure and 0.75 for compression were applied. The M-N interaction diagram for a typical 200mm thick PFRC lining is shown in Figure 17 together with design moments and axial forces from Plaxis with an overall load factor of 1.35.

3.6 Canopy tube & pile design

Fore-piling pre-support was employed for tunnelling in EU2 dominant rock, or in areas where rock cover $< 3\text{m}$ was anticipated. For the MC30/MC60 Cavern, fore-piling typically comprising canopy tubes as described in Section 3.3 were installed. The canopy tube design was based on the beam model suggested by John and Mattle (2002). Ground load is assessed using Terzaghi silo method. Unsupported length for beam span calculation is taken as 2 times advance length L. Comparison with the Plaxis 3D analysis indicates that calculation based on the beam model is conservative. Similarly, the same method is applied to the canopy tubes employed elsewhere (MC20 Stub Tunnel, MC50 Mined Tunnel) and pile design for tunnels and caverns.

3.7 Face stability analysis

Tunnel face stability was analysed in accordance with the method suggested by Anagnostou and Kovari (1997). The method assumes a three-dimensional wedge slides from the face of the excavation into the tunnel opening. The following assumptions are used to determine face stability.

- Driving forces result from the self-weight of the sliding wedge and any additional acting on the wedge. The additional load is derived from maximum block sizes according to wedge analysis or from the silo theory if the excavation is in weak ground.
- Resisting forces are provided by friction and cohesion on both the sliding and the side planes.

Factor of safety (FoS) for face stability, i.e. the ratio of resisting force to driving force was required to be at least 1.5. The analyses indicated that for the MC30/60 Cavern located in EU2 dominant ground, the required FoS for the top heading cannot be achieved without reinforcement of the face. As a result GRP dowels 9m long with 4m minimum overlap at 1.5m spacing were specified. Figure 18 shows indicative arrangement of face dowels for MC30/MC60 Cavern.

For the MC20/MC50 Cavern, the face ground conditions were anticipated to be EU2 material. Face stability assessments show that the factor of safety is likely to be adequate for the top heading excavation in EU2 ground conditions or partial top heading excavation in EU2/EW ground conditions.

Figure 18. Tunnel face dowel arrangement for MC30/MC60 cavern.

4 OPTIMISATION OF SUPPORT DESIGNS AND SEQUENCE

4.1 MC30/MC60 Cavern

4.1.1 Optimisation of primary support designs

The excavation of MC30/MC60 Cavern was on the critical path in the construction program. In order to optimise the schedule outcomes, the design was amended in the lead-up to construction, and through the early stages of construction.

The MC30/MC60 Cavern profile was carefully selected for allowing the re-use of secondary lining formwork in the MC20/MC50 Cavern. The tapered section was constructed by travelling shutters with inserts in the crown to achieve the required profiles. Additional formwork segments could be included at the footings to increase the cavern height as required.

The primary support geometries naturally respond to the proposed secondary lining geometries, and hence determination of lattice girder geometries became critical. The lead times for the lattice girder significantly increased due to the supply-chain issues stemming from the Covid-19 pandemic. In order to meet the construction program, the lattice girders were ordered based on the setout in the early stage of the primary support design. Each lattice girder round features unique geometry and was divided into several standardised segments of varying lengths to ensure constructability. Due to its complexity, the setout of the lattice girder was executed using the Navisworks BIM model.

4.1.2 MC30/MC60 Cavern excavation sequence

The MC30/MC60 Cavern tapered section has the largest span of approximately 13 m. The presence of extensive EUs1 at the tapered section in an area of low cover added further complexity to the excavation. Therefore, the excavation for the tapered section was undertaken in two stages: top heading and bench, as indicated in Figure 18. Bench excavation only commenced after the completion of the top heading excavation. Following the preferred construction sequence,

bench excavation only commenced after the completion of the top heading excavation. The bench excavation design sequence was modified in the early construction stages to incorporate berm excavation adjacent to the top heading shotcrete lining footings. This design amendment allowed for a minimum width of 2.2 m at the centre of the cavern to accommodate construction traffic and facilitate efficient spoil management during excavation. Subsequently, the removal of berms and construction of the bench shotcrete lining were carried out simultaneously at two locations, optimising the overall schedule outcomes. Figure 19 shows the typical section of modified bench excavation with berms supporting the top heading lining.

Figure 19. Typical section of modified bench excavation.

4.2 MC20/MC50 cavern

4.2.1 Optimisation of primary support designs

Similar to the tapered cavern for MC30/60, the design development of the MC20/MC50 primary support accommodates varying geometry, with the cavern narrowing northwards as the MC30 and MC50 tracks converge. In order to further reduce the excavation volumes, the tapered cavern profile was designed to have the eastern invert level about 1m higher than the western invert level. The difference in invert levels gradually reduces along the cavern.

Weaker ground conditions, extensive EW/EUs1 zones and reduced rock cover above the cavern crown at the tapered section was also a challenge to be managed. Figure 20 shows the anticipated ground conditions at the MC20/MC50 Cavern tapered section. Monitoring data from the MC30/MC60 Cavern excavation was used to assess EUs1 properties, and the performance of the installed support. Measured deformation in the inclinometers installed within the canopy tubes was in the order of 2 mm to 9 mm, and typically less than 5 mm as compared to the predicted deformation of 18 mm. The ground movement data was used to refine the EUs1 geotechnical parameters and justify the use of a larger tunnel advance for

MC20/MC50 Cavern excavation. The initial tunnel advance increased from 1.10 m to 1.35 m during design development and was revised to 1.80 m during construction based on the ground monitoring data.

Figure 20. Anticipated ground conditions – MC20/MC50 cavern tapered section.

Similar to the MC30/MC60 cavern primary support, the setout and geometries of the lattice girder in the tapered section are complex. Each lattice girder round features unique geometry and was divided into six standardized segments of varying lengths at the tapered section, where partial top headings were required, to ensure constructability. Given its intricate nature, the setout of the lattice girder was executed using the Navisworks BIM model. Figure 21 presents a typical section of the lattice girder setout for MC20/MC50 Cavern.

Figure 21. A typical section of the lattice girder setout for MC20/MC50 cavern.

The transition from the MC50 Tunnel to the MC20/MC50 Cavern involves a rapid increase in profile from the single track MC50 into the largest span within the cavern. A GRP spine system was adopted to provide pre-support and reinforcement in the area of the transition, which corresponds to an area of very limited rock cover (see Figure 20). The use of GRP spiles facilitated smoother excavation at the transition zone. Figure 22 presents the primary supports at transition from the MC50 Tunnel to the MC20/MC50 Cavern.

Stability of the rock pillar between the MC30 TBM tunnel and MC50 Mined Tunnel where these tunnels intersect the southern headwall of the MC20/MC50 Cavern, as illustrated in Figure 23, was addressed

Figure 22. Primary supports at transition between MC50 mined tunnel and MC20/MC50 cavern.

through reinforcement of the pillar. The pillar width gradually reduces to approximately 0.5 m at the headwall. GRP dowels were installed as part of the temporary headwall and MC50 primary support system, effectively “stitching” the pillar prior to the MC20 TBM breakout.

A segment of the MC50 secondary lining, approximately 8 meters long, along with the permanent headwall of the MC20/MC50 Cavern, were constructed in advance of the MC20 TBM breakout. This preventative measure was taken to withstand the thrust exerted by the TBM and the pressure from the surrounding ground at the junction. The MC50 KTN-8 secondary lining consists of a 700mm thick reinforced concrete side wall engineered to withstand the force of the TBM drive and to provide additional support to the rock pillar. The permanent headwall of the MC20/50 Cavern features a 600mm thick reinforced concrete wall, complete with openings to accommodate the MC50 Mined Tunnel and MC20 TBM Tunnel.

4.2.2 MC30/MC60 Cavern excavation sequence

The excavation for the tapered section of the cavern was executed in multiple stages to optimise the construction schedule as follows:

- 1) Stage 1 top heading from MC50 was mined until the cavern section where the primary supports change from passive support to active support.
- 2) Northbound top heading with active support was mined for the rest of the cavern. Concurrently, an escape structure was constructed within the Stage 1 top heading area to facilitate the safe evacuation of workers in the event of an emergency.
- 3) Stage 2 top heading (Southbound) was mined while Northbound top heading excavation was carried out simultaneously to improve the excavation program.
- 4) Bench (only commenced after the completion of the top heading was mined) completed utilizing a similar approach to that adopted for MC30/60, allowing for advances on multiple fronts.

Figure 23. MC20/MC50 cavern excavation sequence.

5 CONCLUSIONS

The Maungawhau Mined Tunnels excavation faced a series of design and construction challenges, including intricate geometry, challenging ground conditions and unforeseen disruptions in the supply-chain due to the Covid-19 pandemic. This paper has outlined the core principles behind the primary support design, the design challenges for the cavern excavation as well as

the strategies employed to enhance the design and construction schedule. The successful completion of this project highlights the collaborative efforts between the design and construction teams, ultimately resulting in a highly favourable outcome.

“SINTEF-TriPOD” in underground design – A demonstration for two projects in Norway

Nghia Trinh* & Eivind Grøv
SINTEF AS, Trondheim, Norway

ABSTRACT: Many rock engineering projects today may face rock mechanics challenges such as particularly complicated profile or excavation plan, located near to existing infrastructure and thus pose a high risk to such structures, and complicated geological conditions. In such situation, there may be no similar existing experience to lean on. Thus, empirical methods have limitations and uncertainties in such cases. Therefore, SINTEF has developed a rock engineering tool to deal with the challenges. The tool is a combination of Investigation, Numerical modelling, and Monitoring. We use the term “SINTEF-TriPOD” for the methodology, and through projects it has proved to be a reliable tool.

This paper presents the application of the SINTEF-TriPOD for two important infrastructure projects in Oslo, Norway, which are Follo Line metro project (4 billion USD) and a fresh water supply project (approximately 1.2 billion USD).

Keywords: Stress measurement, Numerical modelling, Monitoring, Metro railway, Water supply, Underground complex

1 INTRODUCTION

Many rock engineering projects today may face rock mechanics challenges such as particularly complicated profile or excavation plan, located near to and thus cause a high risk to existing structures, and complicated geological conditions. In such situation, there may be no similar existing experience to lean on. Thus, empirical methods have limitations and uncertainties in such cases. Therefore, SINTEF has developed a reliable rock engineering tool to deal with the challenges. The tool is a combination of Investigation, Numerical modelling, and Monitoring:

- Investigation: The investigation can be rock stress measurements before and during construction (hydraulic fracturing from rock surface, 2D and 3D over-coring), different geological surveys, drill holes, and geological engineering mappings to evaluate the rock mass quality. Obtained information is used for the second component of the “SINTEF-TriPOD” – a numerical model.
- Numerical model: Establish a comprehensive numerical model, normally 3D numerical model is preferred as the model can handle complicated geometry and construction plans and methods. Simulations are to be carried out in certain order with clear objectives for each simulation steps. This is

done to follow the planning and construction closely, helping the project team in making correct decision.

- Monitoring: To improve the numerical model even further, stress and displacement are monitored continuously, and comparing them to the modelled values. The model is calibrated, verified, and improved with the observations made in the surveillance program. This gives us a reliable tool to help for decision making during implementation of the project.

We use the term “SINTEF-TriPOD” for the methodology, as shown in Figure 1.

This paper presents the application of the “SINTEF-TriPOD” for two important infrastructure projects in Oslo, Norway, which are Follo Line metro project (4 billion USD) and a fresh water supply project (approximately 1.2 billion USD).

2 FOLLO LINE PROJECT

2.1 Project information

BaneNOR (Norwegian National Rail Administration) has decided to construct the Follo Line Project with new railway tunnels connecting Oslo and Ski. The excavation period commenced in 2015, and it was opened for operation in early 2023. In 2015, the estimated cost of the project was 25 billion Norwegian kroner (NOK) (Kruse, 2017). The location and layout of the Follo Line project and the junction is shown in Figure 2.

The project comprises a 22 km long twin-tube-tunnel to be excavated mainly with tunnel boring machines (TBM, $D = 9.96$ m), but also by drill & blast and drill & split ($D = 9.5$ m). The drill & blast and drill & split tunnel section was in the first part of the Follo Line tunnels, near Oslo Central Station, and where the Follo Line tunnels go below the Ekeberg tunnels. Vertical distance between Follo Line tunnels and Ekeberg tunnels in this junction was just less than 4 m, as shown in Figure 2. This made the construction of the intersection to be very challenging. In addition, the Ekeberg tunnels have high traffic as part of European highway No.18 and No.6. Thus, the construction of the Follo Line tunnels in this intersection is performed with the following requirements from The Norwegian Public Roads Administration (SVV):

- No negative effect on the stability of the Ekeberg tunnels.
- No stopping of traffic in the Ekeberg tunnels during the construction of the Follo Line tunnels. Thus, the stability of the existing tunnels must be ensured at all time.
- Any risk of instability in the existing tunnels must be detected beforehand to make necessary precaution actions.

Since 2014, SINTEF assisted Bane NOR in dealing with the rock mechanics challenges and safety requirements for the construction of the mentioned intersection in this project. To meet the requirements from SVV and to study the stability of the existing Ekeberg road tunnels and the Alna river tunnel in connection with the construction of the Follo Line tunnels,

Figure 2. Junction between Ekeberg tunnels (existing) and the Follo Line tunnels with the following names: Inbound Østfold Line (IØL), Inbound Follo Line (IFL), Outbound Follo Line (OFL), 3-Tracks Tunnels (3TT) (BaneNOR, 2021).

SINTEF used a comprehensive approach, which is a combination of three components: Investigation – Numerical modelling – Monitoring, forming a rock mechanic tool for the project.

2.2 Investigations

Detailed description of the geological conditions and different surface and sub-surface investigations have been presented in Holmøy et al. (2015). This paper briefly presents the in-situ rock stresses measurements and rock mass properties.

In pre-excitation stage, SINTEF carried out stress measurements in 2011 and 2012. During excavation of the Inbound Østfold Line (IØL), in 2016 when the tunnelling face was at chainage 1890, an additional 3D stress measurement was carried out to obtain the in-situ stress condition at the site. The measuring method was over-coring method, as described in Trinh et al. 2016. The measurements in 2011, 2012, and 2016 were 3D- and 2D-stress measurements. Results from the 3D-stress measurements are given in Table 1.

Table 1. Results from 3D-stress measurements carried out by SINTEF.

Year	Measure stress 3D overcoring	Value (MPa)	Trend (Degrees)	Plunge (Degrees)
2011	Sigma 1	9.9±1.9	N248.4	24
	Sigma 2	7.5±1.9	N145	27
	Sigma 3	1.9±2.8	N14	61
2016	Sigma 1	21.6±2.1	N338	35
	Sigma 2	17.3±3	N224	27
	Sigma 3	10.9±0.9	N104	61

The in-situ stress level measured in 2016 was much higher than the measurements in 2011, sigma 1 was twice and sigma 3 was 5 times higher than the measurements in 2011. This may be explained by a local weakness zone or maybe existing caverns/tunnels or the existing Alna river tunnel not too far away from the location of 2016 measurements. Comprehensive calibrations of the numerical model with result of stress measurements in 2011 and 2016 were done during planning and early construction stages of the Follo Line project. It was found that all the numerical model results with input from 2016 measurement gave far higher values than the results obtained from 2D stress measurements measured in the existing infrastructure, whilst with input from the 2011 measurement, the numerical model results fitted quite well. Thus, it was decided that the results from the stress measurement in 2011 can be used as a representative in-situ stress for input in the numerical model for this project. In-situ stress for the model was estimated based on the measurement in 2011. At elevation zero, the sigma in east-west direction was 10 MPa, north-south 6 MPa, vertical 4.5 MPa, and the stress had gravitational gradient.

During early establishment of the model and simulation, the input for rock mass properties have been estimated based on mapping and laboratory tests. Results of this model were verified with the registered data obtained from monitoring equipment (stress change and displacement in connection with the tunnelling progress). Through certain construction progress, a very comprehensive calibration and testing of the model with collected data from monitoring equipment were carried out. This work was done with weekly excavation reports and monitoring data. Result of this calibration was that the rock mass properties used in the initial analyses were updated. The updated inputs of the rock mass properties for the 3D numerical model are rock mass Young's modulus (E_m) = 10 GPa, Poisson's ratio = 0.15, internal friction angle = 55 degrees, and cohesion = 2 MPa.

2.3 Numerical model

Based on the scanning of the existing tunnels and the drawings of the planned Follo Line tunnels, a 3D numerical model was established, as shown in Figure 3. FLAC3D (Itasca, 2021) code was used to model a 3D picture of the crossing of these tunnels. Geometry of the Ekeberg and Follo Line tunnel system is presented in Figure 3. When constructing the geometry for the simulations, the excavation method and sequence were modelled as per a specific process according to the contractor's plan.

The excavation method was conventional "drill and blast" in the area outside the crossing. Whilst near or under the existing tunnels, the excavation method "drill and split" was applied to minimise damage to the rock mass around the tunnel. In the "drill and blast" sections, a normal pull length of 5 m for each blasting round was used. In the "drill and split" section, a pull length of 2.5 m for each splitting round was used. Thus, in the model geometry, the Follo Line tunnels were divided into every 5 m and 2.5 m in the "drill and blast" and "drill and split" area, respectively. By doing this, every excavation step was simulated to obtain the whole development of stress distribution and displacement from the starting of the construction process.

Simulation process in this project is as follow:

- Simulation 1: No excavation in the model. This simulation was dedicated to obtain the original in-situ stress condition within the site boundary.
- Simulation 2: All existing tunnels were excavated to model the existing condition, before the construction of the Follo Line tunnels. This simulation was done to obtain the existing stress situation and deformation and verify with the observation and 2D measurements in the existing tunnels. This step was considered as an early verification of the model.
- Simulation 3: This was the most complicated simulation for the project, where all the planned excavation steps and sequences were strictly

followed: 63 simulation steps for the excavation of the Inbound Østfold Line, 58 simulation steps for the Inbound Follo Line (IFL) and Outbound Follo Line (OFL), 65 simulations steps for the "Three tracks" tunnel.

Figure 3. Geometry of the 3D numerical model for the intersection between Follo Line tunnels and Ekeberg tunnels.

Some results of the 3D-model are shown in Figures 4 to 6. According to the figures, the following comments were made:

- The maximum stress component (σ_1 , as shown in Figure 4) around the tunnel was estimated to increase slightly from about 12 MPa (in-situ original condition) to about 17.5 MPa. In the critical area (the horizontal rock pillar between Follo Line tunnels and Ekeberg tunnels), the model estimated the same amount of stress increase.
- The minimum stress component (σ_3 , as shown in Figure 5) around the tunnel decreases from about 5 MPa (in-situ original condition) to about 2.5 MPa. The reduction is approximately 2.5 MPa.
- The tunnel excavation results in a displacement of about 2 to 3 mm around the tunnel, as shown in Figure 6. Below the existing Alna river tunnel, the model showed that displacement in the new tunnel is from 4 mm to 6 mm. It is thus expected that the maximum displacement in the junction will be 4 to 6 mm after completion of the construction of Follo Line tunnels.
- Before excavation of the Follo Line tunnels, the model result showed yield elements in the floor of the Ekeberg tunnels; whilst after excavation of the Follo Line tunnels, the model results showed slightly more yield elements in the horizontal pillar.
- In general, the model results showed that there is a certain impact from the excavation of the Follo Line tunnels on the Ekeberg tunnels. However, the amount of change was estimated to be modest (stress change of about 5 MPa, and the displacement change of 2 to 6 mm depending on excavation stage). Model results gave an impression of overall stable condition for both tunnel systems.
- A monitoring system consisting of extensometers and long-term-door-stopper monitoring (LTDM)

were installed at key locations for better control of the stability situation. The monitoring system will be presented in the next chapters.

Figure 5. Distribution of sigma 3 at final excavation stage – Vertical section along IFL (negative value means compression).

Figure 6. Distribution of displacement at final excavation stage – Vertical section along IFL.

2.4 Monitoring of stress and displacement

In this project, it was very important to capture the stress and displacement development in a very early stage, well before any instability problem may appear. The purposes to get early information were:

- Early information can be used to calibrate the numerical model, improving the model during the early construction so that the model becomes a reliable tool for testing the critical excavation stages – excavation close to or directly below the Ekeberg tunnels.
- The stress redistribution and displacement development in the rock mass can be followed from

the beginning, so that any “unexpected development” can be detected in a good time for further study and actions.

- Early registered data from monitoring equipment can be used with the corresponding rock mass behaviour observed during the construction to design and test the warning system well before the construction progress to the critical area – under the Ekeberg tunnels.

Description of the monitoring program and warning system can be found in Trinh et al. (2016 and 2021). The locations of the monitoring system are presented in Figure 7.

Data from monitoring equipment was used to control the quality of the numerical model, to make the model becoming a reliable forecasting tool. Results from the numerical model were compared with the stress data from the monitoring devices, the data from two critical LTDMs (“LTDM-Pillar” and “LTDM-Floor”) are presented in Figures 8 and 9. These two LTDMs were installed to monitor the stress evolution in the existing Ekeberg tunnels as a result of the excavation of the Follo Line tunnels. The LTDMs were installed at the most critical locations, where the Follo Line tunnels were at their closest to the Ekeberg tunnels – less than 4 m vertical distance. Both LTDMs were installed in May 2015, when the excavation of the Follo Line tunnels was still a very long distance away (more than 150 m) and, therefore, having practically no influence on the Ekeberg tunnels. Early installation of the LTDMs provided a good possibility of obtaining, from the start, the evolution of induced stress in the Ekeberg tunnels as the excavation of the Follo Line tunnels approached. Any abnormal change or evolution of stresses during the excavation progression could be detected early enough to implement appropriate precautionary measures, if necessary. The early monitoring data were also used for model verification.

Figure 7. Locations of monitoring equipment for monitor the stress and displacement (Trinh et al. 2021).

The results from the numerical model and the recorded data at the “LTDM-Pillar” show that they fit relatively well as shown in Figure 9. The model results versus the monitoring data for the “LTDM-

Figure 8. Comparison of stress from monitoring (LTD-M-Pillar) versus numerical model.

Floor” are presented in Figure 10. As can be seen from the figure, the model results did not fit well before September 2017. After September 2017, the stress in this location quickly increased, and the model results fitted better with the monitoring data. A possible explanation for this could be joint movement and better rock contact to increase the stress evolution. After the “no reading” period, data from the LTDMs became unreliable as pointed out in Trinh et al. (2021).

Displacement result from the numerical model was compared with the data from “Extensometer-Floor”, as shown in Figure 10. The verification of the numerical model with the displacement monitoring data can be divided into three periods:

- Before September 2017: Displacement monitoring in this period is presented in Figure 9. This period includes both the non-critical excavation stages and part of the critical excavation stage which started in February 2017 with the top heading. During the non-critical excavation stages when excavation was relatively far from the junction, the displacement results from the numerical model fit well with the monitoring data. During the critical excavation stage, the numerical model displacement prediction was approximately 0.5mm greater than that from the monitoring data. This numerical model result was acceptable due to: (a) The difference being only 0.5mm, (b) The model result and monitoring data show the same evolution pattern, and (c) Full face excavation was implemented in the model whilst in reality only top heading excavation was carried out. Thus, it is reasonable that displacement in the numerical model is higher than the registered data from the “Extensometer-Floor”. This concludes that for this period, the numerical model appears to be a reliable tool for planning, construction, and decision-making. The model can be used for predicting displacement and stability evaluation of the upcoming critical excavation steps.
- Between September 2017 and March 2018: Displacement monitoring in this period is as shown in Figure 10. During this period, the benching in

the IFL tunnel was excavated producing full face conditions as simulated in the numerical model. The results from the numerical model and the recorded data were almost identical during this period, which demonstrates a very good match between the numerical model and the actual recorded data. With this level of accuracy, the numerical model proved to be a reliable and an important tool for evaluating the stability condition at the junction during the critical excavation stage. The monitoring data indicates that the excavation of tunnel bench can cause 0.5 mm of displacement above the tunnel.

- After March 2018: Critical excavation had already been completed in February 2018. After March 2018, the excavation activities were (a) at Three-Tracks Tunnel (3TT) with approximately 30m span, and (b) excavation of a small trench in the floor of the OFL and IFL tunnels by drill and blast. During this period, the numerical prediction gave 1.0 to 1.5mm displacement less than that from the monitoring data. It seems that the numerical model was unable to fully calculate the displacement caused by drill and blast in the Three-Tracks Tunnel (3TT), which was approximately 100m away from the extensometer. Studying the excavation progress in the 3TT and the monitoring readings during the same period, the displacement caused by the 3TT excavation was estimated to be approximately 0.5mm at the “Extensometer-Floor” location. The additional 1mm displacement recorded at “Extensometer-Floor” occurred during the excavation of the trench in the floor of the OFL and IFL tunnels. This excavation was by drill and blast, directly below the extensometer. Even though the size of the trench was only 1m x 1m, it had a greater influence on the displacement than the excavation of the 3TT with a 30m span. This is most likely due to the much shorter distance to the excavated trench compared to that from the 3TT which was 100m away. Displacement for the whole period from 2016 to 2019 is as shown in Figure 11.

Figure 9. Displacement registered by the “Extensometer-Floor” versus predicted value from numerical model – Just before critical excavation steps.

Figure 10. Displacement registered by the “Extensometer-Floor” versus predicted value from numerical model – During critical excavation steps.

3 NEW WATER SUPPLY PROJECT

Oslo is the fastest growing city in Europe. The prognosis indicate that the population growth will continue. Today 90% of the water supply to Oslo is from a limited source named Maridalsvannet and its water treatment plant is at Oset. This makes the city very vulnerable to incidents that strike either the source or the treatment plant. The Oslo Municipality Water and Sewage Administration (VAV) is therefore in the process of building a secondary water supply. According to the plan, by 1st January 2028 the new water supply to Oslo will be ready. The new water treatment plant is located at Huseby. The treatment plant consists of six large caverns with cross sections BxH varying between 20m x 24m to 26m x 43 m. In addition, an assembly chamber for a TBM is being excavated within this underground complex. The treatment plant consists of three different levels and is a complicated system of caverns and connecting tunnels. The volume is approximately 1 million m³ which is all excavated in a relatively small area (Mørck et al., 2022).

Based on initial geological investigation and design, it was expected that the geological conditions were not very favourable in this underground treatment plant. The plan was to use heavy rock support with arches of lattice girders in combination with

rock bolts and sprayed concrete. As a reference, similar but smaller and less complicated caverns nearby were built using the same rock support concept. There were also identified several weakness zones, adding the reason for the need of the designed lattice arches.

VAV found it necessary to follow-up the effect the excavation of such a large volume on such a small area could have on the stress conditions in the rock mass and the potential deformations in the caverns. In collaboration with the contractor Skanska, SINTEF was engaged to model the development of the stress redistribution and displacement before starting the actual excavation. The same “SINTEF-TriPOD” procedure was applied in this project as in the Follo Line project. The whole campaign is as follows:

- Investigation: Rock stress measurements were carried out before construction (hydraulic fracturing from rock surface and 3D over-coring in an existing cavern nearby) and during early stage of construction (2D and 3D over-coring). Different geological investigations were made, including drill holes and geological engineering mappings were made before and during early stage of construction to evaluate the rock mass quality.
- Numerical model: Comprehensive 3D numerical model was established. In this project, FLAC3D program was used. Several simulations were carried out including simulation of original condition, simulation of up-to-date excavation progress, simulation with and without rock support. This was to follow the planning and construction closely, helping the project team in making correct decision.
- Monitoring: Stress-meters, extensometers, and instrumented bolts were installed in this project. Stress and displacement were monitored continuously and comparing them to the modelled values. The model has been calibrated, verified, and improved during construction of the project.

Examples of simulation result are presented in Figures 12 and 13.

Figure 12. Axial force in the systematic bolts. The result indicated that maximum axial load in bolts is 0.37 ton, whilst the capacity of the bolts is design to be more than 30 tons.

During early stages, displacement result from the numerical model was almost identical to the monitoring data at MPBX1, as shown in Figure 14. At MPBX2, the displacement result in the numerical model (3 mm) was higher than the monitoring data (less than 1 mm), as shown in Figure 15. This is an expected result due to a conservative assumption used in the numerical model. The model results versus the monitoring data for the stress were not as good as those for the displacement, as can be seen in Figures 16 and 17. Stress results in the model were only comparable to the monitoring data in term of the order of magnitude. Due to the differences only about 5 to less than 10 MPa, stress results from the numerical model were acceptable from the practical point of view. Despite of the stress result, general impression of the model results, displacement monitoring, in-situ observations, it is concluded from the early stage that the numerical model can be used as a reliable tool for the planning and construction.

Figure 13. Minor principal stress (due to mathematical convention in FLAC3D this is named as “maximum principal stress”) in sprayed concrete. Red areas indicate tensile stress is larger than tensile strength of the sprayed concrete.

Figure 14. Deformations modelled versus recorded deformations in extensometer MPBX1.

The comprehensive simulations and the monitoring gave the project owner’s site team the confidence to reduce the amount of rock support in the caverns. The caverns are now supported by 20 cm thick sprayed concrete applied in two layers and rock bolts with length between 5 m and 6 m applied between the two rounds of sprayed concrete (lattice girders were planned originally). Based on the results from the numerical model, a list of areas has been identified for frequent visual inspection throughout the excavating process. So far, fracturing of sprayed concrete has

Figure 15. Deformations modelled versus recorded deformations in extensometer MPBX2.

Figure 16. Stress modelled versus stress obtained in LTDM-T1.

Figure 17. Stress modelled versus stress obtained in LTDM-T2.

been found, which could be due to overloading, but may also be shrinkage. No or very little spalling of sprayed concrete have been found. Actual construction is as shown in Figure 18.

4 CONCLUDING REMARKS

The Follo Line project was successfully excavated in 2019. Experience from the construction was that the entire rock mechanics procedure (the “SINTEF-TriPOD”) was working smoothly providing reliable information for evaluation of the safety situation for both the new and existing tunnels. With help from

Figure 18. Photo from the end wall in one of the halls. The picture shows the rock support of the end wall in the roof and the upper part of the wall (Mørck et al., 2022).

other components, the 3D numerical model established for the Ekeberg and Follo Line junction demonstrated that it is a reliable tool for planning and construction of such complicated crossings.

The application of the “SINTEF-TriPOD” to the New Water Supply project provided vital inputs to optimise the rock support for the underground complex. Project cost saving from the optimisation process was estimated to be more than 100 million Norwegian krone. It is also expected a lot of time saving from construction work with the reduction of the rock support.

The described rock mechanic toolbox (the “SINTEF-TriPOD”) in this paper can be divided into three components, which are:

- Investigations: Stress measurements 2-D and 3-D, laboratory tests, and geological mapping. The investigations provide input parameters for the numerical model.
- Numerical model: Comprehensive numerical model (two- and/or three-dimension) was established for stability analyses of the project. The numerical model should be able to include as much as possible the geometrical details such as existing and future tunnels, and the construction sequence was simulated carefully. The obtained results were used for model calibration in the

existing tunnels and evaluation of the overall stability related to the construction of the new tunnels.

- Monitoring: A monitoring program was established to monitor the displacement and stress change at the junction during the construction of the Follo Line tunnels. The monitoring program was established for stability monitoring and the data was also used for model calibration.

With successfully application in these projects, it is believed that the “SINTEF-TriPOD” toolbox, which is a combination of three components (Investigation, Numerical model, and Monitoring), is an important tool for dealing with challenged rock engineering projects.

Automatic computation for design of tunnel shafts

C.K. Tsang*, Andrew Koay & Tong Sia
SMEC Australia Pty Ltd, Melbourne, Australia

ABSTRACT: Tunnel shafts are often used for launching the tunnel excavation and the selection on types of retaining structure based on the function of the shafts and excavation depth are critical for the project schedule as it usually falls on the critical path of construction program. The design of excavation and lateral support system for tunnel shafts using 2D finite element software typically involves the development of cross sections with all geometric parameters of ground and groundwater profiles, retaining structures and temporary supports. These together with the engineering properties of soil and rock, loadings are input to the 2D finite element software for modelling the construction stages to calculate the forces and bending moment for structural design. Normally several rounds of iterations are run to develop the most economical engineering solution. The human operation of the process is time consuming and always create a lot of errors. An innovative solution by automatic computation using Python script and smart input data file is developed to automate the manual processes. This paper describes the method by automatic creation of Plaxis 2D finite element models for shaft retaining structure design using Plaxis' remote scripting Python wrapper, Python script and smart input data file. Through this automated process, designers were able to reduce the time used to set up a model significantly, while also eliminating other human errors from tedious work particularly when several schemes need to be performed before an economical solution is developed.

1 INTRODUCTION

Tunnel shafts are often used for launching the tunnel excavation and the selection on types of retaining structure based on the function of the shafts and excavation depth are critical for the project schedule as it usually falls on the critical path of construction program. The design of excavation and lateral support system for tunnel shafts using 2D finite element software typically involves the development of cross sections with all geometric parameters of ground and groundwater profiles, retaining structures and temporary supports. These together with the engineering properties of soil and rock, loadings are input to the 2D finite element software for modelling the construction stages to calculate the forces and bending moment for structural design. Normally several rounds of iterations are run to develop the most economical engineering solution. The human operation of the process is time consuming and always create a lot of errors. Instead of spending most of the engineer's time in doing the computer operation for the numerical analyses, this is more important for engineers to use the time to review the design assumptions, input parameters and interpretation of the analysis results.

Considering the application programming interface (API) is available in Plaxis 2D and Plaxis 3D, this enables remote scripting using Python. Therefore, an innovative solution by automatic computation using Python script for Plaxis input and output is developed.

This paper describes the method by automatic creation of Plaxis 2D finite element models for shaft retaining structure design using Plaxis' remote scripting Python wrapper, Python script and smart input data file. Through this automated process, designers were able to reduce the time used to set up a model significantly, while also eliminating other human errors from tedious work particularly when several schemes need to be performed before an economical solution is developed.

2 DESIGN WORKFLOW

The design of deep excavation and lateral support system using Plaxis 2D modelling typically involves the selection of several cross sections for analysis. Engineering judgement needs to be applied when choosing the locations of these cross sections to ensure that the critical combinations of topography, ground

*Corresponding author: ck.tsang@smec.com

and groundwater conditions, structural geometry, excavation depth and loading conditions are selected.

Currently, the design of tunnel shaft involves deep excavations typically follow design workflow as shown in Figure 1. The steps for Plaxis analysis are summarised below:

- Pick a representative geological cross-section and import the geometry into the model, then input all the soil/rock properties.
- Draw all the structural elements (such as retaining walls, struts/anchors/slabs, plunge columns, tension piles, internal primary structure), loads, water levels, excavation levels. Then, calculate all the structural properties for the various elements and input it into the model.
- Mesh the model
- Set up all the construction stages from the beginning to the end of construction. This includes activation/deactivation of various structural and soil

elements, load conditions, setting water conditions (includes water levels and boundary conditions)

- Run the model
- Review the outputs after the model has finished running
- Export the outputs for reporting as well as use by structural engineers for the design of elements.

For a typical tunnel shaft design, a geotechnical engineer is required to build and setup dozens of typical plaxis models for a detailed calculation with different input datasets, it will be very time-consuming to do it manually.

Python can be utilized to help the process, starting from reading and sorting the input data, building and running the model, up to plotting the analysis output.

3 PYTHON APPLICATION

Python is an interpreted, object-oriented, high-level programming language with dynamic semantics. This can be used in a vast domain of applications. It was designed to be easy to understand and easy to use. As a dynamically typed language, Python is very flexible to engineering software. The Plaxis 2D has already a Python API built-in within their program, thus enables remote scripting using Python for automatic computation. To activate the Plaxis Python environment, it needs to select Plaxis built-in python interpreter which contains all the functionalities required to operate Plaxis.

3.1 Automatic computation developments

The automation development in this paper mainly covers from steps b) to d) as described in Section 2. The aim of the automation procedure is to create a user-friendly general-purpose procedure which can be used for the majority of deep excavation problems. This has the benefit of not having to redevelop scripts for each new problem, and the end-user only needs to learn how to use the script once.

Due to the prevalence of Excel use in the engineering profession, the numerous calculation facilities it possesses as well as the ease of using data from other worksheets, it was decided early on during the development phase that the user input/GUI interface should be in Excel as much as possible, with the Python script simply reading the inputs from the Excel input sheet.

The followings are developed to facilitate the automatic computation using Plaxis model for tunnel shafts design on excavation support and lateral system:

- D1 - Plaxis input data file in excel format
- D2 - Python script_1 to read input from the excel input data file to set up the model programmatically in Plaxis
- D3 - Python script_2 to carry out batch run of models

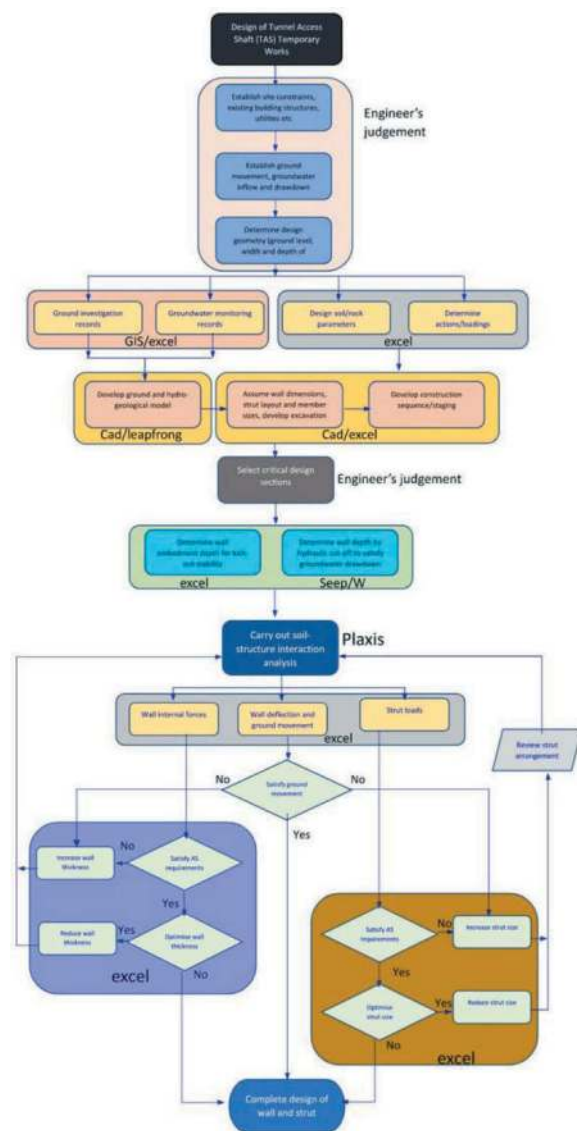

Figure 1. Design workflow for deep excavation and lateral support system.

- D4 – Plaxisimport excel add-in to export Plaxis results to excel file to plot envelops of bending moment/shear force/deflection and strut loads

The script that is developed is highly capable and supports the definition of many different structural elements involved with deep excavations including retaining walls, struts, anchors, slabs, 2 pass systems (including internal walls and setting up the interface between internal walls and external retaining walls), plunge columns (for top-down excavation problems) and tension piles. It also supports the definition of both phreatic water levels (with varying dewatering angles) as well as setting up steady-state seepage. It is designed to be flexible enough to allow for various construction sequencing which can cater for most deep excavation problems.

With the above developments, the workflow for automatic computation using Plaxis programme is streamline into 4 stages as shown in Figure 2.

Figure 2. Simplify workflow for Plaxis analysis.

3.2 Excel input sheet

The Excel input sheet (see Figure 3 below) which allows users to set up all the construction staging, excavation geometry, structural properties. These are arranged in different sheets for convenience. The first tab contains instructions for the end users on how to install and use the automation procedure. The second tab contains global properties such as excavation geometry (width), options to define two pass walls (including defining interface properties between the internal wall and retaining walls) and options to define a jet grout block.

The third tab allows the user to input the excavation sequence which involves defining the excavation level supports that will be installed/removed and water conditions.

The fourth to ninth tab allows the user to define the geometry and properties of various structural elements (retaining wall, struts/anchors/slabs, internal wall, plunge columns, tension piles) and loads.

Stage	Name	Excavation support	Water level	Water level	Plaxis file /	Downloading angle	Transfer	Plunge	Support
1	Year 01								
2	Retain 01	01	01	01	01	01	01	01	01

20	Retain 10	10	10	10	10	10	10	10	10
21	Excav 10	10	10	10	10	10	10	10	10

Figure 3. Excel input sheet.

3.3 Plaxis Python scripts

In order to read Excel files, the openpyxl (<https://pypi.org/project/openpyxl/>) library has to be imported. This is used to read the Excel input sheet, with the data then stored in Python lists and variables. An excerpt is shown below in Figure 4.

```

import openpyxl
import sys
import os
import math

# Read the Excel file
excel_file = 'C:\Plaxis\input_data.xlsx'
wb = openpyxl.load_workbook(excel_file)

# Get the sheet name
sheet_name = 'Sheet1'
sheet = wb[sheet_name]

# Get the data from the sheet
data = sheet.values

# Define variables
width = float(data[1][2])
height = float(data[1][3])
...

```

Figure 4. Excerpt of Plaxis Python script.

The script first imports the selected Excel file and a base Plaxis file (which contains the geological layering as well as the soil/rock properties already input)

Plaxis includes a remote scripting API functionality which allows the user to control all Plaxis functions using Python rather than using the Plaxis GUI.

Using the Plaxis documentation, the script was set up in a way to do the following in Plaxis the following order:

- Draw all the structural elements in the model and define their properties
- Mesh the model
- Define all the construction staging in the model – including excavation, activating/deactivating structural elements and changing water conditions.
- Save the ready-to-run model

The end user can conveniently run the script directly from Plaxis as shown in Figure 5.

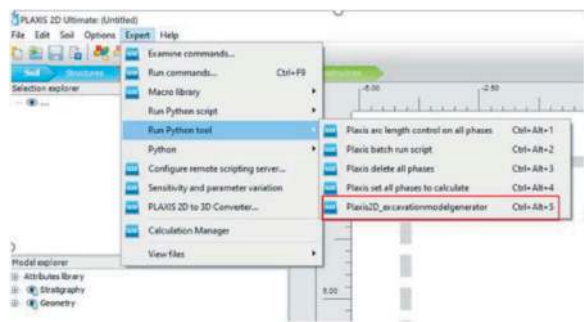

Figure 5. Running the Plaxis Python script.

A sample of a ready-to-run model generated by the script is shown in Figure 6.

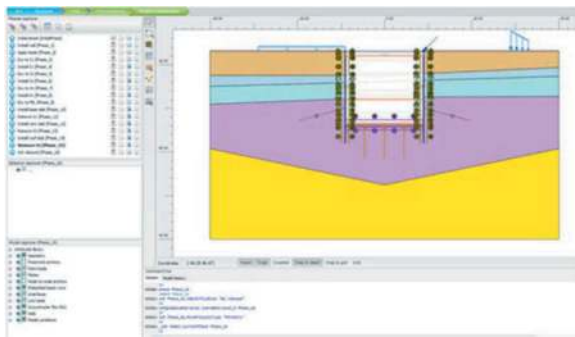

Figure 6. Finished ready-to-run model generated by the Plaxis Python script.

Another Python script is developed for Plaxis batch run that enable the programme to run multiple Plaxis files overnight without supervision. It is designed to automatically increase basic iteration parameters if stages fail (due to numerical issues) to avoid failed runs. If there are real failures happening in the model those will fail to run and the script will skip those stages. Engineers can inspect the finished models the next day rather than having to manually monitor the models running.

The Plaxis batch run script can be called from Python tool in Plaxis as shown in Figure 7.

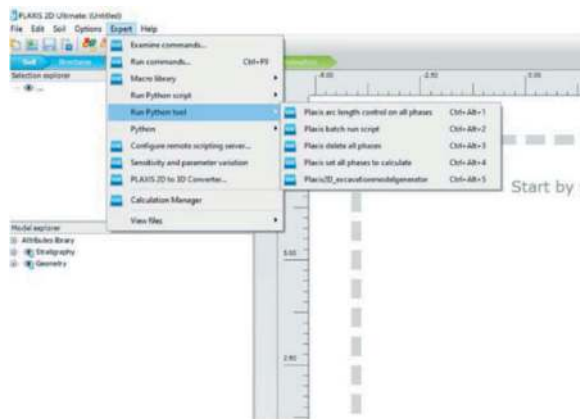

Figure 7. Plaxis Python tool for Plaxis batch run script.

4 PLAXISIMPORT

The excel add-in Plaxisimport is developed to generate stage by stage charts and summary tables for all structural elements. The output strut loads and internal forces of the retaining walls can be used for structural capacity check. The excel add-in function is shown in Figure 8. Some examples of automatic out from Plaxis to excel are shown in Figures 9-11.

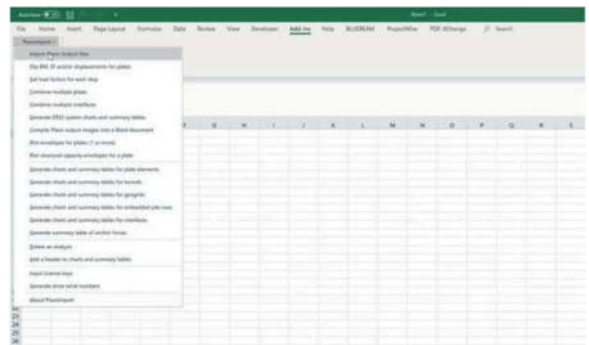

Figure 8. Excel add-in Plaxisimport.

Figure 9. Output of struct loads in excel.

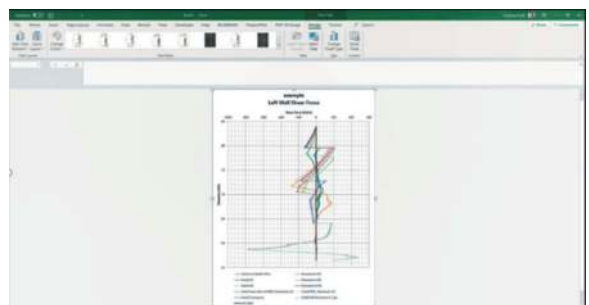

Figure 10. Output of shear force envelope.

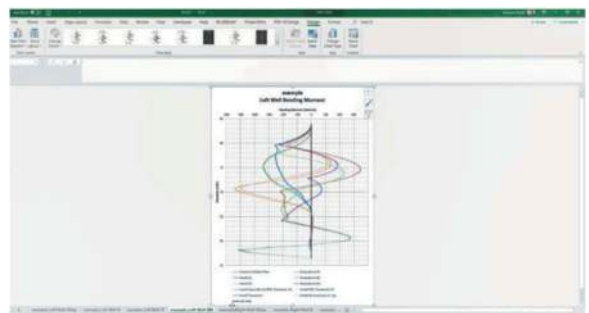

Figure 11. Output of bending moment envelope.

5 CONCLUSION

An automated procedure to generate ready-to-run Plaxis 2D finite element models for tunnel shaft design on excavation and lateral support design has been achieved using a combination of Plaxis' remote

scripting Python wrapper, Python script and a smart Excel input data file. This allows for a complex manual procedure which takes up to a few days to be simplified to a process taking less than an hour (filling up an Excel input sheet and then running the script in Plaxis), which saves a lot of precious engineer time as well as reducing the amount of user errors that can happen when setting up the models.

The key objective of the automatic computation for Plaxis analysis is to reduce the engineer's input in carry out time consuming numerical model input and output for structural design excavation and lateral support system.

- Improve efficiency in design delivery
- Reduce human error during the setting up of plaxis model
- Optimise the design by carryout out more analyses covering full range of design input variables

Case study about adjacent three-arch tunnel

Hoteng Tseng* & Kwojane Kuo

T.Y.Lin Taiwan Consulting Engineers, Inc., Chinese Taipei

Tihju Chu

New Taipei City Government, Chinese Taipei

ABSTRACT: 3D LiDAR scanning monitoring technology can quickly scan the object. It has high-density and high-precision scanning object's three-dimensional spatial data characteristics without reflection prism. At present, Ground-based laser scanner has been widely used in the sliding collapse of hillside slopes, highway bridges, and tunnel for deformation monitoring purpose, i.e., Mass Rapid Transit (MRT) tunnels and hydraulic engineering tunnels. If a new tunnel project is built in a relatively young geological age or in a deformation-oriented stratum, surrounding rock disturbance caused by tunnel excavation may affect the safety of neighboring areas and construction workers. Traditional tunnel convergence deformation measurement cannot fully reflect the full impact of tunnel excavation disturbance. It is also impossible to fully control the deformation behavior mode of rock mass after excavation. This paper presents a comprehensive monitoring study of an adjacent excavation and shallow-covered tunnel consisting of a three-arch tunnel in the Xindian area of northern Taiwan. The displacement of the surrounding rock of the tunnel is reduced due to the effective application of the central RC wall. The paper aims to explain the application of the optical scanning monitoring results, to provide the overall circular displacement trend of the tunnel and the equivalent displacement contour map along the tunnel, which can provide accurate tunnel safety monitoring, and establish a new thinking on tunnel safety monitoring for adjacent construction of tunnel. The 3D LiDAR scanning monitoring results can be effectively applied in subsequent similar cases.

Keywords: Ground-based LiDAR, Adjacent excavation, Shallow-covered tunnel, Three-arch tunnel

1 PREFACE

As road tunnels in the metropolitan area usually pass through densely residential and densely populated areas, land acquisition tends to be limited. The case of this article is about a two-arch, one-way and two-tube road tunnel (with an excavation diameter of about 13 m) in the Xindian area of northern Taiwan. Due to traffic network planning, a light rail Mass Rapid Transit (MRT) tunnel (with an excavation diameter of about 12 m) must be set up between these two road tunnels. Because the land use is limited, the spacing between each two arches of this three-arch tunnel is only about 1.5 m. The three-arch tunnel of this project is adjacent to each other but the geological material is very weak in strength. After the tunnel is excavated, the central rock pillar may not be able to support the load of rock cover above. Therefore, the small-section central pilot method (height \times width = 6 m \times 6.5 m) for excavation is applied and a five-arch tunnel is thus formed, which is the first of its kind in Taiwan. A central reinforced concrete (RC) wall (width 1.5 m) is constructed

between the eastern and western pilots to provide sufficient compressive and shear strength to reduce tunnel excavation deformation. The multi-arch tunnel has the characteristics of shallow coverage, weak rock mass strength and multi-arch adjacent construction. The rock mass disturbance caused by each round of tunnel excavation may impact the surrounding completed tunnels, which makes the deformation behavior of tunnel surrounding rock more complex.

2 INTRODUCTION TO PROJECT CASE

Due to traffic network planning requirements, the tunnel of this case is designed to consist of two one-way and two-tube road tunnels and one light rail MRT tunnel:

2.1 Tunnel section configuration

Figure 1 is the tunnel configuration layout. The shape and dimension of the tunnel section are mainly subject to two factors: spatial configuration and tunnel excavation stability, as well as economic

*Corresponding author: httseng@tylin.com.tw

considerations. As this tunnel is a shallow-covered one and the rock load comes from the weight of the covering soil, a close-to-circular cross-section is adopted for the tunnel cross-section shape rather than a flat cross-section. The arrangement of clearance and the configuration of relevant facilities within the section are mainly based on the design criteria and required to meet the spatial requirements for driving, maintenance, facilities, etc. Therefore, the tunnel section is designed to be the minimum section which meets the above-mentioned considerations.

Figure 1. Tunnel configuration layout.

2.2 Regional geology and terrains

Figure 2 shows the location and geological map of the studied area. This Xindian area has a mountainous topography. The rock mass is weak in cementation and highly deformable due to weathered rock-soil. Therefore, the main discontinuous surface is the interface among stratification, earth covering and bedrock. The exposed strata in this area are mainly the Miocene coastal facies or Nanchung formation of continental facies. The coastal facies are composed of white or gray-white sandstone and thin layers of sandstone, siltstone and shale, and carbonaceous shale. The rock mass is weakly cemented. The main discontinuous surfaces are thus stratification while the jointing is not well-developed. As the structural weak surfaces are not well-developed, the rock mass is regarded as a homogeneous isotropic material.

Figure 2. Case location and geological map.

2.3 Strength parameters of rock mass material

Table 1 shows the design parameters of various rock mass supports. The factors affecting the strength and deformability of rock mass include the following:

stratum, lithology, single pressure strength, geological strength index (GSI) and coverage depth, etc. Therefore, there will be quite a lot of permutations and combinations of rock mass parameters. According to the geological survey results, the input parameters required by the numerical calculation software are the basis for tunnel support stress analysis and verification. During the analysis, the 2D plane strain element is used to simulate soil, the beam element is used to simulate shotcrete and trussed steel supports, and the cable element is used to simulate rock bolts. Meanwhile, it is assumed that the soil is a homogeneous and isotropic material, the elasto-perfectly plastic model is adopted as the constitutive model, and the Mohr-Coulomb criterion is adopted as the material failure criterion.

Table 1. Parameter table for numerical analysis of various rock masses.

Mileage	South side of main line 0k+125~0k+220		North side of main line 0k+200~0k+300		
	BIV	BV	BVI	Ci(s)	Cii(s)
Rock class	BIV	BV	BVI	Ci(s)	Cii(s)
Unit weight (kN/m ³)	22	22	22	22	22
Core single pressure (MPa)	5	4	3	0.25	0.15
GSI	45	35	25	-	-
mi	13	13	13	-	-
D	0	0	0	-	-
Cohesion (kPa)	105	80	58	73	44
Internal friction angle (°)	42.2	37.4	31.8	29.4	29.4
Elastic modulus (E) (MPa)	300	200	150	50	50
Poisson's ratio (ν)	0.3	0.3	0.3	0.3	0.3
Volume modulus (K) (MPa)	250	167	125	83	83
Shear modulus (G) (MPa)	115.4	76.9	57.7	38.5	38.5

The volume modulus is $K = \frac{E}{3(1-2\nu)}$, and the shear modulus $G = \frac{E}{2(1+\nu)}$.

2.4 Stress behavior of central pillar

Based on the analysis grid in the analysis with finite difference program *Flac*, different sections, i.e. upper, middle and lower ones, are selected, and the axial force (P) and bending moment (M) of different sections are simplified to be analyzed with vertical stress σ_y . The material stress formula is shown as Equations (1) and (2), and the symbols are explained as shown in Figure 3. In the formula, A is the unit area of the central wall (1.5 m×1.0 m), and y is the distance from σ_{y1} and σ_{y2} to the center of the central wall. From Equations (1) and (2), the axial force and bending moment values of the central wall in

different sections and different construction steps are obtained, which can be used for the reinforcement design of the central wall.

It can be learned from Figure 4 as well that the stress of the central wall is concentrated and symmetrical, and the displacement change tends to move toward the slope due to the impact of west slope. Therefore, the displacement on west side is larger than on the east side, and the displacement of the central wall itself is that the upper part is larger than the lower part, and the west side is larger than the east side.

$$\sigma_{y1} = \frac{P}{A} - \frac{My}{I} \quad (1)$$

$$\sigma_{y2} = \frac{P}{A} + \frac{My}{I} \quad (2)$$

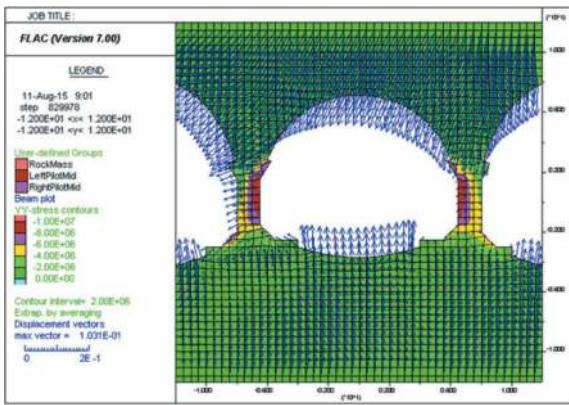

Figure 3. Vertical stress and displacement distribution of central wall.

Figure 4. Axial force bending moment symbol of central wall.

3 RESULTS FROM SCANNING AND MONITORING TECHNOLOGY

The 3D LiDAR scanning technology has been sprouting since 1970s. It was first developed by National Aeronautics and Space Administration (NASA). The 3D LiDAR Scanner can quickly scan the object to be measured to obtain high-density, high-precision 3D spatial data with a relative coordinate system without

reflection prism. Such an instrument which quickly obtains comprehensive spatial 3D information is a brand-new surveying tool.

3.1 3D LiDAR scanning and monitoring

The point cloud data obtained by 3D LiDAR scanning is stacked over multiple periods to obtain coordinate changes of the same position. In other words, the displacement of the said position can be obtained. Regarding the equivalent displacement contour of the eastbound tube of the central pilot as shown in Figure 5, the X-axis on the contour represents the tunnel mileage distance, and the Y-axis is the left and right side walls and roof arch of the tunnel section expanded to the plane. Different colors on the contour represent the displacement changes after tunnel excavation. It can be supplemented by scanning result images to initially evaluate changes in anomalies.

Figure 5. Equivalent displacement contour of surrounding rock on the eastbound tube of the central pilot.

The larger displacements are located at both the upper and lower parts of the equivalent displacement contour (i.e. the left and right side walls of the tunnel). The tunnel roof has no obvious change as the pipe umbrella roofing method has a relatively good supporting effect. The displacement in some mileage areas of the tunnel roof appears to expand outward (blue-purple in the equivalent displacement contour) due to extrusion of the left and right side walls of the tunnel. In addition, it is obvious that the eastern entrance (0K+260~300) and the western entrance (0K+140~160) have large displacements after tunnel excavation due to shallow coverage on the terrain and the position of the unsymmetrical load area.

3.2 Tunnel duration curve

To organize the deformation data of tunnel excavation, Figure 6 shows the duration curve of both eastbound and westbound tubes of the central pilot. Overall, the maximum displacement δ_{max} are 29 mm, 38 mm, and 16 mm for eastern entrance, western entrance, and intermediate section, respectively. The displacement at the eastbound tube is slightly larger than the westbound tube by about 1.9~3.3 mm.

Figure 7 Shows the MRT tunnel duration curve. Since the MRT tunnel was excavated after the construction of the central RC wall between the east and west sides was completed, the maximum displacement δ_{max} is only 6 mm in two months after this tunnel was bored through (on March 18th, 2018). It is obvious that the central wall plays an effective role in mitigating the displacement of the rock mass. Afterwards,

there is continual displacement due to the construction of adjacent tunnels. At the initial stage, the maximum displacement δ_{\max} caused by the eastbound-tube tunnel construction is up to 10~15 mm; then the maximum displacement δ_{\max} caused by the westbound-tube tunnel construction is up to 20~25 mm. The weakened rock mass, caused by rainfall event (July through September, 2018), results in the increment displacement $\Delta\delta_{\max}$ of the tunnel rock mass by about 15~20 mm during the rainfall event period. The final displacement δ_{\max} of the rock mass is about 35~45 mm.

Figure 8 shows the duration curve of the eastbound-tube tunnel. The MRT tunnel has been bored through at the time of the construction of the eastbound tube, which was thus negligibly affected by the MRT tunnel. The maximum displacement δ_{\max} is about only 9.5 mm in 1.5 months after this tunnel was bored through (on June 15th, 2018), and the maximum displacement δ_{\max} gradually increases from 13 mm to 40 mm because of the subsequent rainfall events and the westbound-tube tunnel construction. It is assessed that the terrain ridgeline also affects bedrock that is weakened by rainfall. The road portions affected are mainly between 0K+168 to 264. Figure 9 shows the duration curve of the westbound-tube tunnel. Both the MRT and eastbound-tube tunnels have been bored through at the time of the construction of the westbound tube. However, the construction period was in the rainy season. Overall, the maximum displacement

Figure 6. The duration curve of both eastbound and westbound tubes of the central pilot (eastern entrance, intermediate section and western entrance).

Figure 7. The duration curve of the MRT tunnel (eastern entrance, intermediate section and western entrance).

δ_{\max} are 19.5 mm, 29.6 mm, and 16 mm for eastern entrance, western entrance, and intermediate section, respectively. It is assessed that the weakened bedrock, caused by rainfall, results in the increment displacement $\Delta\delta_{\max}$ by about 10~15 mm.

Figure 8. The duration curve of eastern-tube tunnel (eastern entrance, intermediate section and western entrance).

Figure 9. The duration curve of westbound-tube tunnel (eastern entrance, intermediate section and western entrance).

3.3 Tunnel surrounding rock radial displacement

To organize the deformation data of tunnel excavation, Figure 10 shows the radial displacements of the surrounding rock at the eastern entrance, intermediate section, and western entrance of both eastbound and westbound tubes of the central pilot (facing to eastern entrance). On the whole, the terrain at the eastern entrance is a valley with two high sides; thus the displacement is affected by the unsymmetrical load. The southern side wall of the eastbound tube has larger deformation, while the northern side wall of the westbound tube has larger deformation. The intermediate section is less affected by the terrain behavior due to the unsymmetrical load. Because the terrain at the western entrance is higher in the south, and lower in the west, the displacement is thus also affected by the unsymmetrical load.

The full-section displacement monitoring results of the tunnel provided by the 3D LiDAR scanning technology can obtain the displacement of the tunnel in all directions. It contributes to reasonable assessment for the deformation behavior. The overall terrain is characterized by higher rock cover on the southern side and lower rock cover on the northern side. Therefore, most of the radial displacements are

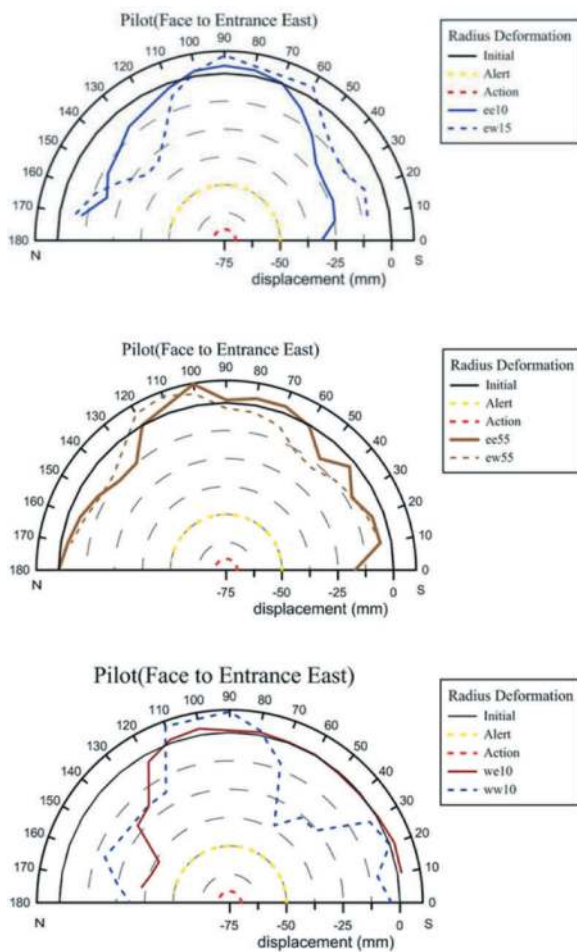

Figure 10. The radial displacements of the surrounding rock at both eastbound- and westbound-tube tunnels of the central pilot (eastern entrance, intermediate section and western entrance).

Figure 11. The radial displacement of the surrounding rock at the eastern entrance of the MRT tunnel (before and after the rainy season).

inwardly squeezed in the southern side, and has an external expansion phenomenon in the northern side (Figures 12 and 13 are relevant to eastbound- and westbound-tube tunnels). The displacement of the weakened bedrock, caused by rainfall, mainly occurred above the junction (about 3 m above the springing line of the side walls) between the central wall and the outer support of the tunnel. The weakest support stiffness is at this junction. From the

Figure 12. The radial displacement of the surrounding rock at the eastbound-tube tunnel (eastern entrance, intermediate section and western entrance).

Figure 13. The radial displacement of the surrounding rock at the westbound-tube tunnel (eastern entrance, intermediate section and western entrance).

monitoring results of the radial displacement contour of the MRT tunnel in Figure 11, it can be seen that the displacement range is consistent. Using 3D LiDAR scanning technology can provide a safety monitoring for adjacent tunnel excavation construction and can have better control in the deformation behavior of rock mass after tunnel excavation. It can maintain tunnel construction safety, and provide reference basis for on-site construction adjustment and design correction.

4 CONCLUSION

This paper highly recommends the use of 3D LiDAR scanning technology for tunnel construction monitoring and tunnel surrounding rock displacement monitoring. It is also applied to multi-arch tunnel, adjacent construction, and cases of shallow-covered tunnels of which the geological rock strength are weak. Through 3D LiDAR scanning technology, it can quickly obtain high-precision, high-density, and comprehensive 3D spatial coordinate information of tunnels after tunnel excavation.

After the scanning and monitoring data are processed and analyzed, more rock mass displacement around the tunnel can be controlled. For the entire tunnel construction safety monitoring, a complete excavation disturbance behavior mode for surrounding rock can be provided. It can also be applied to more complex excavation disturbances such as special geological structures. The blind spots in

traditional monitoring systems for tunnel excavation can be greatly improved, thus providing more comprehensive monitoring results.

As the effective monitoring and central walls are appropriately leveraged in tunnel surrounding rock displacement, the average displacement is within a range of 25~30 mm for the central pilot with an average excavation diameter of 6.5 m. After the completion of the double central wall, it can effectively inhibit the average displacement of the rock mass to be less than 6 mm for the MRT tunnel with an average excavation diameter of 12 m. The weakened rock mass, caused by rainfall event, resulted in the increment displacement Δ_{\max} of the tunnel rock mass increases by about 10~20 mm during the rainfall event period. Due to the adjacent construction and shallow coverage factors, the increment displacement Δ_{\max} of the tunnel rock mass also increases by about 10~20 mm. Due to the results of the full-section scanning data of the 3D LiDAR, the overall radial displacement trend is obtained and the equivalent displacement contour is provided along the alignment of tunnel. These monitoring results help taking effective and comprehensive control over the deformation behavior of the surrounding rock of the tunnel. These results can provide a reference for on-site construction adjustment and design correction. If these data combined with more rigorous numerical simulation and feedback design, it is a great help to modern tunnel construction technology.

Optimizing the tunnel ventilation design related to respirable dust in tunnelling by using CFD

Ranzhu Wei*, Robert Galler & Christian Weiß
Montanuniversität Leoben, Leoben, Austria

ABSTRACT: Fine dust and toxic gases produced by blasting underground are mainly removed by mechanical ventilation. Among them, the removal of respirable dust with diameters of less than 5 μm is important for the occupational safety of the miners. Respirable dust is difficult to settle on the ground resulting in an unacceptably long lasting dust removing process. Therefore, to effectively remove the respirable dust, understanding the movement pattern of dust particles under mechanical ventilation is important. In this paper, computational fluid dynamics software Ansys Fluent is used to simulate the dust particle generation and mechanical ventilation inside the tunnel. The movement characteristics of diffusion, sedimentation and accumulation of dust particles are monitored by particle location and concentration at different time periods after the blasting takes place. These simulations provide more understanding of respirable dust particle movement under mechanical ventilation and offers further guidance on optimization of tunnel ventilation design.

Keywords: Optimization tunnel ventilation, Dust movement, Tunnel construction, Mechanical ventilation, Numerical simulation

1 INTRODUCTION

Tunnel blasting is a common and cost-effective method of excavation in tunnel construction. However, during this process a large amount of dust is produced reducing visibility and adversely affecting the working environment inside the tunnel. Potential irreversible health hazards can be caused by inhalation of quartz dust for tunnel construction workers. There is a high chance of getting Pneumoconiosis or respiratory malignancy if working in a high quartz dust concentration place for a long time (Erol et al., 2013). There has been considerable literature linking quartz dust exposure to lung cancer and the data shows that silica dust greatly increases the risk of death from respiratory and cardiovascular disease (Chen et al., 2012; Chen et al., 2019; Ulvestad et al., 2001; Kera-mydas et al., 2020). Quartz is a kind of ultra-fine particle. It is light in texture and easy to suspend in the air. Because of the small diameter, respirable dust particles are difficult to settle on the ground, so it often takes a long time to remove the dust resulting in a significant impact on the duration of a tunnel construction and the cost of the construction project. It is impossible to visually observe respirable dust, so the concentration is mainly obtained by on-site measurements. Due to the limited number of on-site sampling equipment and complex actual building conditions, computer fluid dynamics simulation is widely used to

investigate the air flow and the dispersion pattern of respirable dust inside the tunnel. The two-phase gas-solid flow model is most widely used to investigate the movement of particles with air (Yin et al., 2020; Hua et al., 2020; Zhang et al., 2021).

Researchers have used numerical modelling methods to simulate the effect of the location of and air flow rate of ventilation ducts on respirable dust removal effect. Guo et al put the ventilation duct at the bottom, vault and haunch of the arch and compared the dust concentrations of personnel respiratory regions (Guo et al., 2023). Xie investigated the effect of the angles of the force ventilation duct on dust removal performance (Xie et al., 2022). Liu adjusted the air flow rate of the force ventilation duct and compared the dust concentration in the working area and effective dust control distance to predict the optimal range of air flow rate (Liu et al., 2021). Hu investigated the maximum air flow rate for dust removal and found the increasing dust concentrations with excessive air flow rate due to the entrainment effect (Hu et al., 2020). Nie and Liu studied the change of diffusion distance of dust over time under mechanical ventilation conditions after tunnel blasting and proposed optimal suggestions on air flow rate to shorten the dust diffusion distance (Nie et al., 2022; Liu et al., 2019).

Therefore, in this paper, movement patterns of respirable dust particles under mechanical ventilation after tunnel blasting will be studied based on discrete

*Corresponding author: ranzhu.wei@unileoben.ac.at

phase particle tracking technology in CFD software Ansys Fluent. In addition, the air velocity and dust distribution characteristics at different distances from the working face along the tunnel will be analysed and compared with the actual measurements in the tunnel. The air velocity and dust distribution characteristics were correlated, and dust transport patterns are explained at a microscopic level. Analysing respirable dust movement characteristics can provide guidance on optimization of respirable dust removal and tunnel ventilation design.

2 GEOMETRIC MODEL ESTABLISHMENT AND SOLUTION

Kaprun tunnel is a road tunnel under construction in the altitude of 786m and the tunnel part chosen for air flow and dust movement analysis is 113.35 meters long and the duct is at the left side of the construction direction as shown in Figure 1.

Figure 1. Kaprun tunnel cross section.

2.1 Geometric model and meshing

The physical model of the tunnel is established in SpaceClaim by considering a 1:1 equal scale of tunnel under construction in Kaprun Austria with the length of 113.35 m and the duct is 61 m from the working face, as shown in Figure 2 (a). The cross section of the tunnel is shown in Figure 2 (b), with the following dimensions: 4.2 m in width and 6.54 m in height. The pressed-in ventilation duct with a radius of 1.6 m is located on the left side of the tunnel 0.25 m from the side wall and 4.5 m from the ground. The air velocity of the duct outlet is 9 m/s.

In numerical modelling, the quality of mesh is crucial to the accuracy of the simulation results. Cell size used in current model is 0.2 m with the element

Figure 2. Physical model a); Cross section details b).

number of 4078296 and the “Orthogonal Quality” value for the adopted mesh is 0.213, which corresponds to “Good” quality in the mesh metrics spectrum.

2.2 Boundary conditions

Based on air flow rate measurement of the duct outlet in Kaprun tunnel and literatures reviewing about dust transport after tunnel blasting, the air flow parameters and discrete phase model settings are listed in Table 1 (Shi et al., 2022; Xie et al., 2023; Yang et al., 2022).

Table 1. Boundary conditions.

Parameter name	Parameter setting
Solver	Pressure-based solver
Viscous model	k-epsilon model
Inlet boundary type	Velocity inlet
Inlet velocity	9 m/s
Outlet boundary type	Pressure outlet
Near-wall treatment	Standard wall function
Particle size distribution type	R-R distribution
Min. particle diameter	1 um
Max. particle diameter	5um
Mass flow rate	0.03 kg/s
Injection type	Surface

The mathematical models used for this paper for simulating gas–solid two-phase flow in the FLUENT is discrete phase model (DPM). Large number of

particles are injected from the working face. Dust particles from blasting are considered as a discrete phase, the air flow field in the tunnel space is considered as a continuous phase. The air flow is analysed in simulation by vectors and air flow velocity along the tunnel. The dust particles are analysed by dust particle concentration and dust location monitor.

3 ANALYSIS OF THE AIRFLOW AND DUST SIMULATION RESULTS

3.1 Analysis of the distribution of the air flow field in the tunnel

The air velocity of 30 measurements points in 5 cross sections at different distances from the working face are measured in Kaprun tunnel. As shown in Figure 3 (a), the measurement cross sections are 46 m, 61 m, 76 m, 91m and 113m from the working. Each cross section has 6 measurement points in the height of 1.25 m and 2.5 m, 1.5 m left and right from the central of the tunnel shown in Figure 3 (b).

The development of the air flow for the central of the duct is shown in Figure 4 (a). Air velocity of 9 m/s is generated from the outlet of the duct. Since in the Kaprun tunnel the duct outlet is 61m far away from the working face, eventually a backflow occurs even before reaching the working face. To better understand the change of air flow direction occurring next to the duct outlet, contours of the axial air flow component are shown in cross sections 40, 50,60 m from the working face in Figure 4 (b). Figure 5 present the air velocity development for the 6 measurement points in each cross section along the tunnel. The orange points in Figure 5 are the data from the onsite measurement and the curve is air velocity along the tunnel from simulation. The calculated results indicate good congruence with the field measurements for most of the measurement points. The velocity is generally decreasing along the tunnel and there is a sharp decrease of air velocity before and behind the ventilation duct. The air velocity

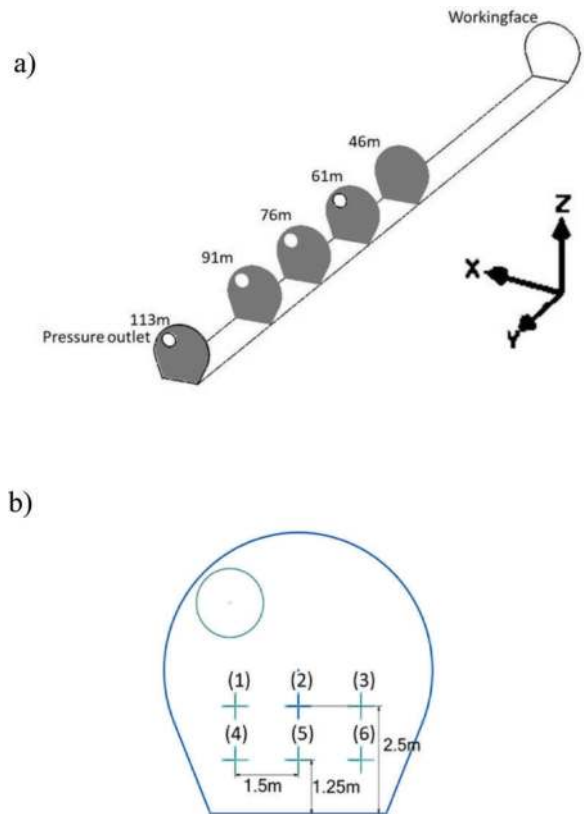

Figure 3. Location of measurement planes (a); measurement positions (b).

before the ventilation duct mostly ranges from 3-5 m/s while the velocity after the ventilation duct is stable at about 0.5-0.6 m/s.

In Figure 4 (a) and (b), at approximately 55 meters from the working face, the air flow exhibits a downward trajectory, eventually collides with the ground at about 49 m from the working face and backflow phenomenon occurring within a zone spanning 50-60 meters from the working face. Within the zone of 40-50 meters from the working face, here is a pronounced reduction in the air velocity along the

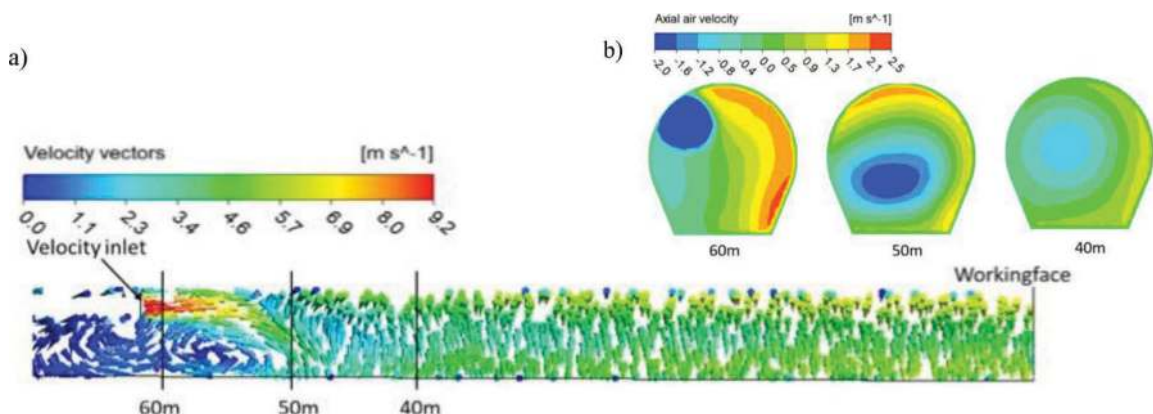

Figure 4. Air velocity vectors in length cut (a); contours of axial velocity for three cross sections (b).

y-axis and the airflow primarily exhibits a rotational motion predominantly confined within the tunnel. Since the measurement points are generally distributed in the middle of lower half of the cross section, this leads to a local peak at 50 meters at points 1 and 2 shown in Figure 5 compared to points 4, 5, 6. This peak is attributed to the collision and subsequent backflow phenomena of the ventilation duct. For the zone of 0-40 meters from the working face, the back flow disappears, and the air velocity tends to be stable at

3-5 m/s. However, due to the high turbulence and the rotation of the airflow, the air velocity of 0-40 meters away from the working face at point 2 which is in the central of the cross section is lower than other measurement points.

With 61 m the ventilation duct is relatively far from the working face, compared to the usual construction site where the distance is often shorter (20 - 40 m). Backflow appears along the duct wall and insufficient amount of air flow reaches the working face.

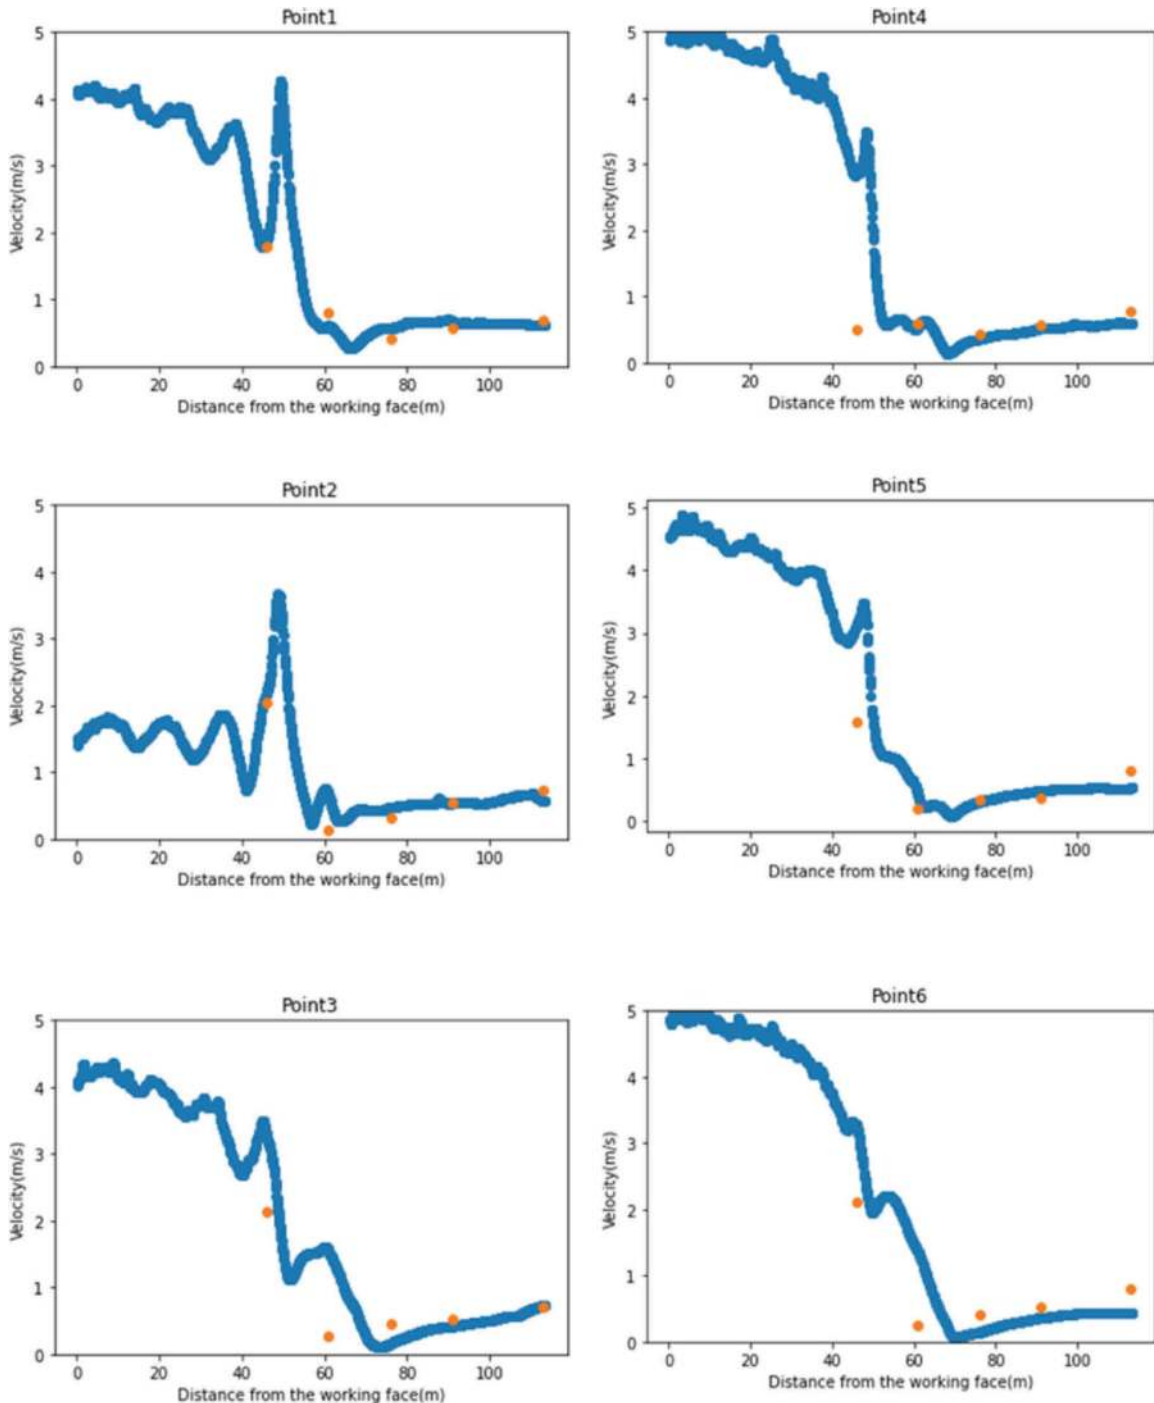

Figure 5. Comparison of simulated air velocity magnitude with measured air velocity at the six measurement points.

3.2 Analysis of respirable dust movement in the tunnel

To better analyse the dust particle movement, particle concentration in different cross section along the tunnel is compared in a 5 min simulation as shown in Figure 6 and dust particle location is recorded at 1,3,5 minutes in CFD-post for better visualization of particle location in Figure 7.

As shown in Figure 6 and Figure 7, at 1 minute the dust particle moving distance is 10m with highest dust concentration of 150mg/m^3 . At 3 minutes, high dust concentration zone near the working face is decreasing and dust moving distance is about 100 m. The dust has not reached the tunnel outlet so the concentration near the outlet is still low, about 5mg/m^3 . At the moving front of the dust cloud (80-100m from the working face) dust concentration can reach up to 60mg/m^3 . At 5 minutes after the ventilation, high dust concentration zone next to the working face has disappeared. Dust particle is fully distributed inside the tunnel. And because of the insufficient air flow in axial direction, high concentration dust zone occurs after 80 m from the working face with the maximum dust concentration of 60mg/m^3 .

Figure 6. Length profile of cross-sectional averaged dust.

Figure 7. Spatial distribution of model dust particles.

4 CONCLUSIONS

In this paper, the CFD simulation method is used to simulate air flow and respirable dust particle movement is modelled using surface particle injection with the diameter of less than 5 micrometres. The following conclusions are reported from the air flow and dust particle movement simulation results:

1. The air flow velocity along the ventilation duct with the air velocity of 9 m/s, Air velocity after 70 m from the working face stable at 0.5-0.7 m/s and the maximum air velocity downstream of the ventilation duct can reach 4-5 m/s. The simulated air velocities of the measurement points are in good agreement with the actual measurement data inside the tunnel.
2. One minute of the blast the dust is still accumulated within 10m near the working face with the highest dust concentration of 150mg/m^3 . After 3 minutes of ventilation, the dust particles have been observed to disperse over approximately 100 meters. High dust concentration zone occurs at 80-100 meters from the working face, with the maximum dust concentration of 60mg/m^3 . At 5 minutes after the ventilation, dust particles are fully distributed inside the tunnel. High dust concentration zone occurs between 80 m and 110 m with the maximum concentration of 72mg/m^3 because of insufficient air flow in the y direction reaching the working face.
3. The simulation and measurement results of air flow and respirable dust particle movement with the long distance of 61 m between ventilation ducts and the working face with air velocity 9 m/s provide reference on air movement for large scale tunnel construction project with a relatively long distance between the ventilation duct outlet and the working face. According to the air velocity and dust concentration results, it is evident that a ventilation duct with an air velocity of 9 m/s is insufficient for a complete dust transport. Backflow occurs next to the ventilation duct outlet preventing a strong air flow from reaching the working face. However, the efficiency of dust removal can be enhanced through better positioning of the duct and an increased air flow rate for this situation.

Study on the mechanism of tunnel structure damage under the combined effects of fault creep and earthquakes

Zhipeng Xia, Sijia Jia, Jianhong Wang & Qi Wang

School of Qilu Transportation, Shandong University, Jinan, Shandong, China

ABSTRACT: Fault creep in active fault zones poses a serious threat to tunnel structure safety, and when coupled with seismic effects, it can easily lead to tunnel disasters. Therefore, it is urgent to study and understand the tunnel structure damage mechanism under the combined effects of fault creep and earthquakes. Taking a railway tunnel crossing a specific fault zone as the engineering background, this study explores the tunnel structure damage mechanism under fault creep and seismic effects through indoor model tests and numerical simulations. The research findings indicate: (1) Under fault creep, the deformation of tunnel structures generally follows an “S” shaped distribution pattern along the longitudinal direction; (2) Under the combined effects of fault creep and earthquakes, stress concentration occurs in the tunnel lining structure at the fractured zone of the fault, necessitating special consideration for seismic design within the range of the left and right arches of the lining structure at the boundary of the fractured zone; (3) A comparison of seismic effects in different directions shows that under the coupling of longitudinal and transverse seismic and fault creep, the stress variation trends are basically consistent. Compared to seismic effects, fault creep has a greater impact on the safety of tunnel lining structures. The study is expected to provide fundamental support for the safe design of tunnels crossing active.

Keywords: active fault tunnel, fault creep, model experiment, seismic analysis, seismic direction

1 INTRODUCTION

In recent years, China has accelerated the pace of its transportation infrastructure construction, inevitably requiring tunnel construction to traverse geological structures such as faults and fractured zones. Active faults can experience fault creep and strong seismic activity, leading to serious tunnel structural damage. Therefore, studying the influence of fault creep and intense seismic activity on tunnel structures, and understanding the mechanism of tunnel structure damage, is of great significance for improving the safety and stability of tunnel structures crossing faults.

In high-intensity earthquake areas, tunnels crossing faults may experience not only the detrimental effects of fault creep but also severe seismic activity, exacerbating tunnel damage. Existing studies largely focus on either strong seismic activity or fault creep, with limited research on the structural damage mechanism under the coupled effects of fault creep and earthquakes. Therefore, it is necessary to conduct research on the dynamic response of tunnel structures under fault creep and seismic activity.

Based on the engineering background of a tunnel crossing an active fault, this paper adopts the method of model test and finite element numerical simulation.

Firstly, the deformation and stress of tunnel structure under fault creep are studied based on experiments. Secondly, the structural response of tunnels under the coupling action of earthquake and fault creep in different directions is studied, which provides the research basis for exploring the deformation mechanism and failure mechanism of tunnels crossing active faults.

2 ENGINEERING BACKGROUND

The tunnel is located in a typical plateau landform area, and the tunnel site area has a high level of strong earthquake activity, and passes through a number of deep and large active fault zones, among which the surrounding rock of F9-1 fault zone is IV level, and the broken zone is V level. The dip Angle of the fault zone is 75° and the width of the fault zone is 12m. The maximum buried depth of the tunnel is about 1215m, the longest diameter is 12m, and the lining is made of C40 concrete with a thickness of 80cm. The tunnel crossing F9-1 fault zone will be directly affected by strong earthquake and fault dislocation, resulting in the cumulative deformation and serious damage of the tunnel.

Figure 1. Geological profile of the fault zone.

3 EXPERIMENTAL STUDY OF CREEP EFFECT

In order to find out the structural response and failure mechanism of the tunnel crossing the fault zone under creep, this experiment takes the tunnel project crossing the F9-1 fault zone as the prototype to build a surround-rock tunnel model, and uses an independently developed fault dislocation testing machine to conduct model tests.

3.1 Test model

The surrounding rock tunnel model mainly includes four parts: fault upper wall rock, fault fracture zone, fault footwall wall rock and tunnel structure. The overall length of the model is 1200mm, the section diameter of the tunnel model is 200mm, the width of the fault fracture zone model is 200mm, and the inclination Angle is 75°. The strength of the surrounding rock is 0.917MPa, and the strength of the fracture zone is 0.056MPa. The surrounding rock tunnel model is shown in Figure 2.

Figure 2. Test model.

3.2 Test loading

In order to simulate the creep slip of the upper wall fault under deep buried conditions, the fault dislocation test device developed in this study was used (Figure 3). In the test, the vertical cylinder of the fault dislocation test device was used for constant velocity displacement loading control, and the surrounding rock of the hanging wall was driven to make upward displacement dislocation at a control rate of 2mm/min, and the load was carried out step by step by 2mm. When the displacement dislocation reached 10mm, the

test was stopped, and the structural damage patterns of the tunnel and surrounding rock were observed. The model loading status was shown in Figure 4.

Figure 3. Test device.

Figure 4. Test loading.

3.3 Result analysis

3.3.1 Failure phenomenon analysis

Figure 5 shows the failure of tunnel structure under the action of fault dislocation in model test and numerical analysis. As can be seen from Figure 5, the tunnel failure range caused by fault dislocation is concentrated near the slip plane, the tunnel arch bottom first occurs tensile failure, and the fracture instability occurs along the fault dip direction. The failure trend of the tunnel structure is basically consistent between the model test and the numerical simulation.

Figure 5. Damage of tunnel structure.

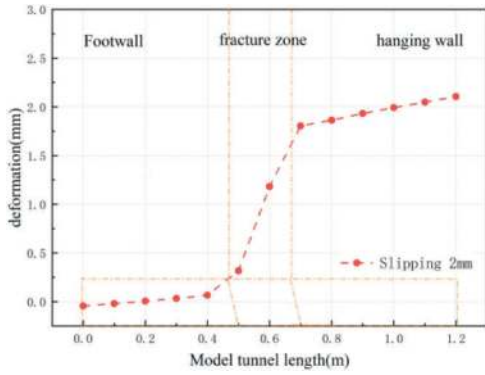

Figure 6. Comparison of vertical deformation results.

Figure 7. Axial force change.

3.3.2 Tunnel deformation

As can be seen from Figure 6, when the upper disk is displaced upward by 2mm, the vertical deformation of the tunnel gradually increases along the lower disk, crushing zone and upper disk. Figure 7 shows that the maximum axial force in the model test occurs at the junction of the fracture zone and the surrounding rock of the footwall, and it is necessary to pay attention to the seismic fortification of the lining structure within the junction of the fracture zone.

4 TUNNEL STRUCTURE RESPONSE UNDER EARTHQUAKE AND CREEP COUPLING

The tunnel and surrounding rock numerical model is established based on the test model. The forced displacement method is used to simulate the creep slip of fault, and the displacement is applied to the surrounding rock of the upper wall. The seismic action is simulated by applying the seismic load along the axial and transverse direction to carry out the seismic time history analysis.

4.1 Tunnel vertical deformation

Figure 9 shows the vertical distribution curve of the vertical deformation of the tunnel through the fault zone under the coupling of earthquake and fault creep in different directions. Obviously, the curves can be divided into three parts: basic stability, non-

Figure 8. Time-acceleration curve.

uniform deformation and overall creep, and the overall distribution is “S”, which is basically consistent with the vertical distribution of tunnel structure deformation under creep. In addition, the results of tunnel deformation under the coupling effects of longitudinal and lateral earthquakes and fault creep are close to those under creep, indicating that creep is a control effect affecting structural safety.

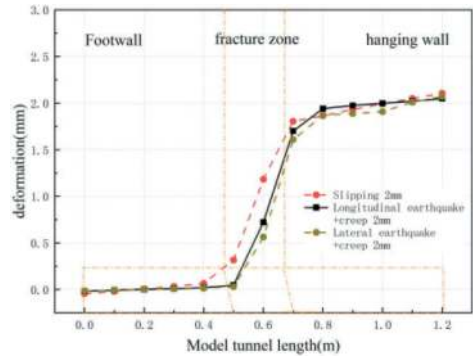

Figure 9. Strain comparison.

4.2 Principal stress

Figure 10 shows the tunnel stress cloud map under the coupling effect of longitudinal and transverse earthquake and fault creep slip. It can be seen from Figure 10 that under the coupling effect of earthquake and creep slip, the tunnel will produce stress concentration at the left and right arches under the coupling effect of earthquake and creep slip, and significant tensile stress appears in the tunnel. The tensile stress of the left and right arches and the stress at the junction between the fault and the surrounding rock are larger, so the seismic fortification of the left and right arches of the lining structure should be emphasized when considering the junction of the lining structure and the fracture zone.

Figure 11 shows the longitudinal variation curves of the axial stress and lateral stress of the tunnel arch under the coupling effects of longitudinal and transverse earthquake and fault creep. As can be seen from the figure, the axial stress is larger and the lateral stress is smaller under the coupling effect of lateral earthquake and fault creep, while the lateral stress is larger

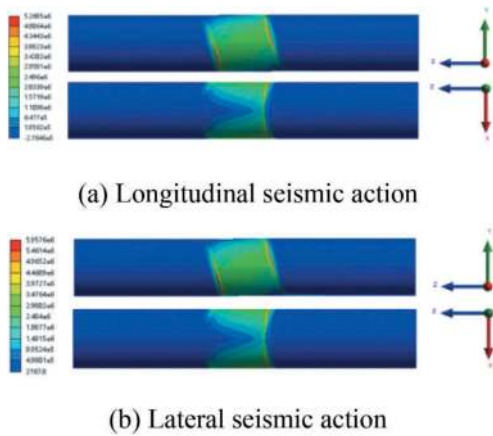

Figure 10. Main stress nephogram of tunnel.

and the axial stress is smaller under the coupling effect of lateral earthquake and fault creep. However, the variation trend of tunnel structural stress under the two conditions is basically the same, indicating that creep is a control effect affecting structural safety, and the impact of earthquake on tunnel structure is relatively small.

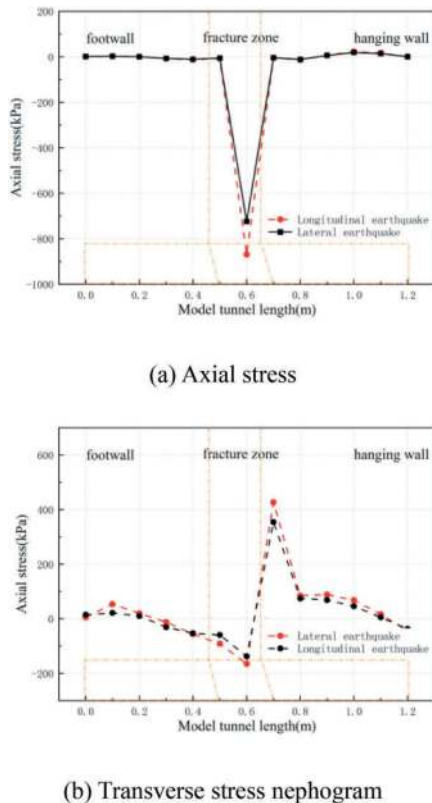

Figure 11. Change curve of tunnel principal stress.

5 CONCLUSIONS

(1) Under the action of creep, the deformation of tunnel structure is generally “S” type

distribution along the longitudinal distribution, and the stress concentration occurs at the interface between the fracture zone and the surrounding rock of the footwall; With the increase of the amount of dislocation, the tunnel invert will crack first, resulting in the overall instability of the tunnel.

- (2) Under the coupling action of earthquake and dislocation, stress concentration occurs at the junction of the fracture zone of the tunnel structure, and the first principal stress at the waist of the left and right arch is much greater than that at the arch and invert, so it is necessary to pay attention to the seismic fortification of the left and right arch of the lining structure at the junction of the fracture zone.
- (3) Compared with the seismic action in different directions, the stress variation trend under the coupling action of longitudinal and transverse earthquakes and fault creep is basically the same, indicating that creep is a control effect affecting structural safety, and seismic action has relatively little influence on tunnel structure.

Theory and practice of total safety factor method for tunnel support structure design

Mingqing Xiao, Biting Xie*, Chen Xu, Kejin Wang & Zhaohui Deng

China Railway Siyuan Survey And Design Group Co, LTD

National & Local Joint Engineering Research Center of Underwater Tunneling Technology

ABSTRACT: The tunnel support systems worldwide primarily rely on an “experiential design” approach, where modifications and validations are based on measurement information during implementation. However, this “empirical design” lacks quantitative analysis of the safety of supporting structures, leading to conservative approaches that can have adverse effects on engineering economics. To address these limitations, a research method called “Total Safety Factor Method” has been developed. This method focuses on tunnels approaching or reaching the failure stage and combines modern numerical analysis techniques with traditional load structure methods. It aims to integrate the surrounding rock load, support structure, and various parameters related to support design. These parameters include the necessity of support, the type of support (systematic or local), the magnitude of support force, structural calculation models, calculation methods, values of the safety factor, deformation analysis of support structures, and dynamic adjustment methods of support parameters. This comprehensive approach has been successfully applied to numerous tunnel projects in China, such as the Yichang to Xingshan High-Speed Railway, Ningbo to Zhoushan Railway, and Jiaozhou Bay Second Submarine Tunnel. The rationality of Total Safety Factor Method has been verified through field tests, model tests, numerical calculations, and other rigorous means. By employing this design method, engineers can quantitatively calculate the parameters of tunnel support structures, thereby ensuring a more precise and efficient approach to tunnel construction and improving the full life cycle safety and cost-effectiveness of tunnel projects.

1 INTRODUCTION

The existing design theories abroad, represented by the New Austrian Tunnelling Method, New Italian Tunneling Method, and Norwegian Tunnelling Method, have played a crucial role in promoting the development of tunnel engineering technology. The concept of the New Austrian Tunnelling Method (L V et al., 1989) proposed by Austrian scholars in the 1950s was based on tunnel engineering experience and the theory of rock mechanics and has become one of the new technological symbols of modern tunnel engineering. New Italian Tunnelling Method, also known as the Rock and Soil Control Deformation Analysis Method (LUNARDI, 2008), is an extension of the concept of the New Austrian Tunneling Method. It is mainly used in tunnel excavation in weak strata to pre reinforce and control the deformation of surrounding rocks in weak strata. The New Austrian Tunneling Method and the New Italian Tunneling Method are mainly based on design concepts and do not propose clear support parameter design methods. The Norwegian tunnel construction method,

abbreviated as NMT, is a refinement, supplement, and development of the New Austrian Tunneling Method. It refers to the classification of surrounding rock and the selection of support based on the Q-value of the surrounding rock quality index, and the summary of charts that can quantitatively select support parameters based on multiple tunnel cases. Its essence is still the engineering analogy method, and Norwegian tunnel engineering mainly focuses on rock strata, with relatively single engineering conditions.

With the rapid development of China’s transportation infrastructure construction, China has built the world’s largest number, largest construction scale, and most complex technical conditions of tunnel engineering. However, there is still no internationally recognized tunnel design method with Chinese characteristics. The tunnel design specifications in China are no longer suitable for the current development requirements of tunnel construction technology in terms of load values for deep buried tunnels. Moreover, the design of tunnel support structures is still in the stage of “engineering analogy as the main method and

*Corresponding author: 983126144@qq.com

theoretical calculation as the auxiliary”. It cannot achieve quantitative design of support parameters so that it is impossible to analyse and evaluate the safety and economy of tunnel support structures, which greatly restricts the development of tunnel construction technology. Meanwhile, with the rapid development of intelligent tunnel construction technology, existing design methods can no longer match it, it is becoming the weakest link in intelligent tunnel construction. Therefore, it is urgent to make an improvement in the design method of tunnel support structure.

Currently, a multitude of scientific research endeavours have been undertaken by domestic experts and scholars to investigate the stress characteristics and bearing capacity of tunnel support structures. Notable contributions include studies such as “Deformation and stability control technology throughout tunnel construction” and “Design method for high-speed railway mechanized large cross-section tunnels” (WANG, 2018). These efforts primarily focus on intelligent classification of surrounding rock and the coordination mechanism of supporting deformation in the context of tunnel construction. However, there is a lack of specific and well-defined design methods for the quantitative design of tunnel support structures. This absence hinders the direct guidance of engineering design processes. In this regard, Total Safety Factor Method for tunnel support structure design has made significant progress in establishing a quantitative design system for tunnel support structures. This approach enables the transition from “analogue design” to “quantitative design” of tunnel support structures. Its implementation has played a constructive role in advancing the development of tunnel engineering design technology. By incorporating Total Safety Factor Method into the design process, engineers can now rely on a systematic and quantifiable approach for designing tunnel support structures. This advancement not only enhances the accuracy and efficiency of tunnel construction but also contributes to improving the overall safety and cost-effectiveness of tunnel.

2 THEORY OF TOTAL SAFETY FACTOR METHOD

Total Safety Factor Method (XIAO,2020a), proposed in 2017, takes the tunnel approaching or reaching the failure stage as the research object, and organically integrates the surrounding rock, load, and support structure with a combination of numerical analysis method and load structure method. A set of quantifiable design methods for calculating support structure parameters has been developed based on the main theme of “whether the tunnel needs support, system support or local support, support force values, structural calculation models, safety factor calculation methods and values, analysis of support structure deformation and dynamic adjustment of support parameters” (Figure 1).

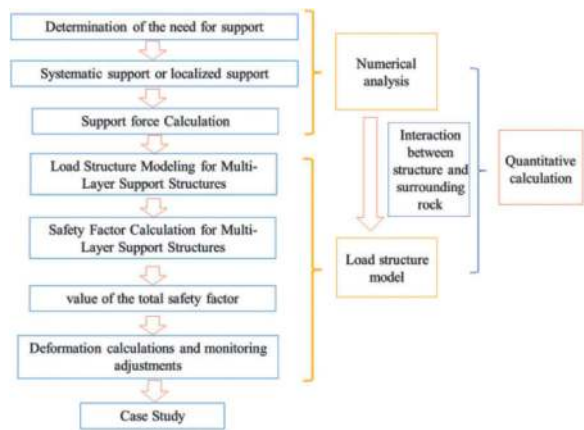

Figure 1. Technical route of total safety factor method.

In addition, systematic research has been conducted based on Total Safety Factor Method including support structure types and optimization of support parameters for high-speed railway double track tunnels (XIAO,et al.,2018), safety analysis of existing tunnel support structures(XIAO,et al.,2019), comparison of tunnel section forms, design of support parameters for high ground stress soft rock large deformation tunnels and ultra large span tunnels. Total Safety Factor Method was used to explore several current hot and controversial issues (XIAO,2019), including the design concept of tunnels(XIAO,2020b), the role of anchor rods, the distinction between the bearing bodies of multi-layer supporting initial support and secondary lining, the optimization method of support parameters, the setting and protection layer of steel frames, the early strength of sprayed concrete, and the selection of support types.

2.1 Determination of the need for support

There is a wide range of caves without any support but can be basically self-stabilizing, such as caves, loess kiln caves, etc., which leads to the theoretical study of the stability of tunnel surrounding rock and the need for support. Based on this, the concept of critical stable section of tunnel and the method of analysing the stability of tunnel surrounding rock based on critical stable section are proposed, which can quantitatively analyse the self-bearing capacity of surrounding rock (XIAO and XU,2020).

As shown in Figure 2(a), the critical stable section of a tunnel is the largest section that has the same depth of burial and similar geometry as the centre of the designed excavation section, and the surrounding rock can achieve self-stability with the designed safety factor under the unsupported condition and basically can maintain its original shape. The critical stability section can be used to determine the stability of the surrounding rock in the unsupported condition of the designed tunnel. The study determines that the damaged area with depth greater than 1m in the side wall area and 0.5m in the arch area after

tunnel excavation is the potential collapse area of the tunnel and takes this as the criterion for critical stability section.

When the excavation section is smaller than the critical stabilizing section, as in Figure 2(b), it is considered that the surrounding rock in the section plays a supporting role for the critical stabilizing section, which can be regarded as a part of the supporting structure. When the excavation section is larger than the critical section, such as Figure 2(c) and (d), the surrounding rock cannot be self-stabilized, and it is necessary to meet the design requirements for the safety factor through engineering support measures.

2.2 Systematic support or localized support

Based on the distribution characteristics of the surrounding rock damage zone after unsupported tunnel excavation, the criteria and methods for the division of local support and system support (XIAO and XU,2021)are as follows:

- ① When there is no potential collapse area in the tunnel, it is judged that the tunnel is self-stabilized. When the designed section is smaller than the critical stabilizing section, and the strength safety factor of the surrounding rock in the section when it is used as a supporting structure is greater than or equal to the design value, the tunnel does not need support.
- ② When the designed section is smaller than the critical stabilizing section, but the strength safety factor of the surrounding rock in the section when it is used as a supporting structure is less than the design value, or the designed section is larger than the critical stabilizing section, and the potential collapse range of the arch wall accounts for less than 30%, the tunnel can adopt the local support scheme.

- ③ When the proportion of potential collapse range of the arch wall is between 30% and 60%, zoned unequal strength support can be adopted.
- ④ When the proportion of potential collapse range of arch wall is more than 60%, equal strength system support can be adopted.

2.3 Support force calculation

Without considering the role of chance factors, the tunnel surrounding rock pressure from construction to destruction of the whole life cycle will generally go through four stage: the construction stage, the working stage, the failure stage, and the post-failure stage (XIAO and XU,2019a; XIAO,et al.,2023; XU, et al.,2019) (as shown in Figure 3). When using the total factor of safety method for design, only the most unfavorable case of the surrounding rock pressure needs to be found. Therefore, it is proposed to adopt the design value of the surrounding rock pressure as the design support force and thus solve the difficult problem that the actual surrounding rock pressure is difficult to determine.

In the tunnel surrounding rock pressure full life stage three (destruction stage), due to the support measures on the surrounding rock support role, only when the destruction of the area of the surrounding rock formed by the loose load is greater than the support can provide the ultimate bearing capacity in order to determine the failure of the support structure, to maintain the limit of the surrounding rock equilibrium state of the support force can be referred to as the minimum support. surrounding rock pressure design value in the minimum support based on the design value should have a certain safety reserve and should not be less than 1.4, so that as far as possible to envelope the service period surrounding rock pressure but not too conservative to affect the economy. Based on the minimum support force $P_{i\min}$ should have a certain safety

Figure 2. Schematic diagram of critical stabilized section of the tunnel and division of support scheme.

Figure 3. Schematic diagram of the change process of tunnel surrounding rock pressure over the whole life cycle.

reserve, and should not be less than 1.4, so that as far as possible to envelope the service period of the pressure of the surrounding rock, but not overly conservative impact on the economy. The safety reserve coefficient can be adjusted according to the importance of the project, the strictness of deformation control and the accuracy of geotechnical parameters and constitutive modeling and other factors.

2.4 Load structure modelling and safety factor calculation for multi-layer support structures

After obtaining the design value of surrounding rock pressure, the tunnel support structure can be used to calculate the internal force using the load structure method. Since the tunnel support structure is generally a multi-layer structure composed of bolt-rock bearing arch, shotcrete layer, and secondary lining layer, it is necessary to establish the calculation models of single-layer structure and multi-layer structure respectively. In each load structure model, the surrounding rock pressure is taken as the design value of all the surrounding pressure, and the safety factor K_1 of the bolt-rock bearing arch, the safety factor K_2 of the sprayed concrete layer, and the safety factor K_3 of the secondary lining are all calculated according to the breakage stage method of the current tunnel design specification (XIAO and XU,2019b; XIAO,2018).

2.5 Methodology for calculating total safety factor

The coefficient of safety of each layer of the structure itself is calculated using the breaking stage method, and the total coefficient of safety of the multi-layer structure includes the contribution of each layer of the structure, which needs to be considered after considering the coordination of deformation and the sequence of damage between each layer of the structure.

(1) Assumptions for calculation of total safety factor

The bearing structure of multi-layer supporting consists of two or three layers. Assuming that the structure of each layer is an ideal elastic-plastic material and linear-elastic structure, when a cross-section of one of the structural layers reaches the breakage stage first, it can continue to maintain the strength, until a cross-section of both the shotcrete layer and the second lining reaches the breakage stage, or the second lining has two or three (three when the load and structure are symmetrical, otherwise two) breakage cross sections, before reaching the overall structural design strength.

(2) Calculation formula of total safety factor

After calculating the safety factors of bolt-rock bearing arch, shotcrete layer and second lining respectively according to the above method, the lower limit value of the total safety factor of the supporting structure can be approximated as follows:

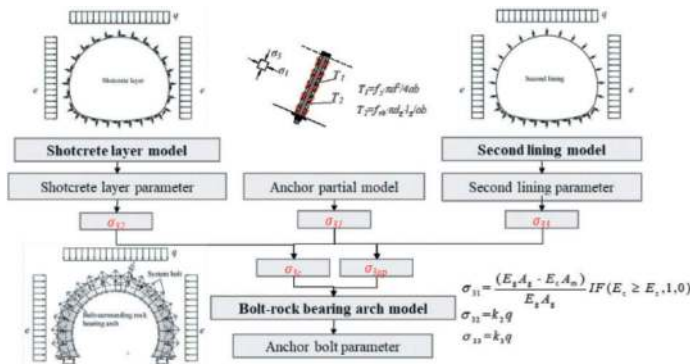

Figure 4. Calculation model and calculation idea of total safety factor method for tunnel support structure design.

Construction stage (no second lining):

$$K_c = \eta K_1 + K_2 \quad (1)$$

Operation stage:

When using durable anchors,

$$K_{op} = \eta K_1 + \zeta K_2 + K_3 \quad (2)$$

When using non-durable anchors,

$$K_{op} = \zeta K_2 + K_3 \quad (3)$$

In the formula, K_1 , K_2 , K_3 are the safety factor of the bolt-rock bearing arch, shotcrete layer and second lining when they bear all the design values of the surrounding rock pressure, η is the correction coefficient of the safety factor of the bolt-rock bearing arch, ζ is the adjustment coefficient of the bearing capacity of the shotcrete layer.

According to the assumption of “ideal elastic-plastic material and linear-elastic structure” mentioned above, η can be calculated according to Eq. (4) by considering only the difference in ultimate strains between the surrounding rock and concrete materials.

$$\eta = \frac{\varepsilon_u + E_0}{\sigma_1} \quad (4)$$

Where ε_u is the ultimate strain of concrete, E_0 is the modulus of elasticity of the anchor rock bearing arch, σ_1 is the compressive strength of the anchor rock bearing arch under the action of supporting force.

Although the shotcrete layer and second lining have similar structural materials, their section shapes (e.g., the second liner has a superelevation arch and the shotcrete layer does not have a superelevation arch) and damage patterns may be different, and it is possible that the first broken cross-section of each layer of the structure does not appear one after another, or the damage patterns of the shotcrete layer structure are different in the construction period and the operation period (from the tensile damage to the compressive damage). According to many calculations, when the shotcrete layer and second lining are both under pressure, can generally be taken as 1.0. When the shotcrete layer and the second liner have different damage patterns, needs to be calculated according to the specific situation, and the design should try to avoid the vegetative concrete structure for tensile damage.

Theoretically, under the premise of the same total safety factor, there can be a variety of support parameter programs. Due to the differences in the strength and stiffness of each layer of structure in different support schemes, the structure of each layer does not always reach the most unfavorable cross-section strength at the same time, so the total safety factor obtained by the above formula is the minimum safety factor of the overall structure, and the actual load carrying capacity is generally higher than the above calculation results.

2.6 Value of total safety factor

(1) Suggested values for the construction stage

Different from the ground structure, the initial tunnel support (or anchor bolt-spray support) is subjected to the pressure of surrounding rock, blasting vibration and other loads from the time of the applying. With the hardening strength of shotcrete (or anchor mortar) gradually increased, the pressure of surrounding rock is also gradually increased. It must be ensured that the support structure during the construction period has a suitable safety, so that it is recommended that total safety factor during the construction stage should not be less than 1.5 ~ 1.8.

(2) Suggested values for the operation stage

Considering the structural characteristics of the tunnel project, the characteristics of the loading and calculation model, the construction quality and other major factors, the total safety factor during the operation period is recommended as follows:

① When only the primary load is considered, the total safety factor is 50% higher than that of a single structural component.

For multi-layer supporting, when the secondary lining adopts reinforced concrete, the total safety factor is recommended to be not less than 3.0; when the secondary lining adopts plain concrete, the total safety factor is recommended to be not less than 3.6.

For shotcrete-anchor permanent support, when the shotcrete layer is made of steel fiber concrete or steel frame with relatively good ductility, and it is recommended that the total safety factor is not less than 3.0. When the shotcrete layer is made of plain concrete, it is recommended that the total safety factor is not less than 3.6.

② When adopting the combination of “main load + additional load”, total safety factor can be reduced by 15% to 20% compared with the value of “only considering the main load”.

2.7 Deformation calculations and monitoring adjustments

To ensure that the safety of the supporting structure meets the predetermined objectives of the design, dynamic optimization and adjustment of the design support parameters must be carried out according to the results of on-site monitoring and measurement.

The deformation value monitored during construction is essentially the deformation value of the supporting structure, and the control value of on-site monitoring can be derived by calculating the allowable deformation value of the supporting structure. The allowable deformation value of the supporting structure refers to the structural deformation value of the supporting structure under the premise of having a safety factor corresponding to the design of structural strength. The ultimate deformation value of the supporting structure refers to the structural deformation value when the shotcrete layer of the supporting structure has the first broken cross-section (plastic

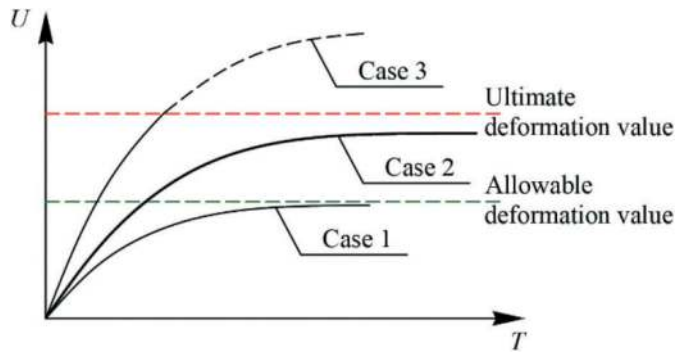

Figure 5. Comparison of measured and calculated displacement-time curves.

hinge), i.e., the structural deformation value when the structural safety factor of the shotcrete layer is 1.0.

During the construction process, the measured displacement-time curve (u-t curve) should be compared with the calculated u-t curve (Figure 5) as the basis for judging the reasonableness of the design parameters. According to the relationship between the measured value and the calculated allowable deformation value, it is divided into three cases, and corresponding adjustment measures can be taken to dynamically adjust the support stiffness and support timing (XIAO and XU, 2019c).

3 CASE STUDY

Taking the two-lane tunnel of China's 350km/h high-speed railroad as an example, which is excavated by the full-section method without considering the influence of tectonic geostress, and the support parameters of Class IV surrounding rock under the working condition of 400m burial depth are designed according to the principle of Total Safety Factor Method. The physical mechanics index of surrounding rock is according to the lower 1/3 quartile of the range value of physical mechanics index in the "Railway Tunnel Design Code (TB 10003-2016)", which is shown in Table 1.

Table 1. Table of physical and mechanical index of surrounding rock.

Surrounding rock level	Bulk weight (kN/m ³)	Elastic resistance coefficient (MPa/m)	Elasticity modulus (MPa)	Poisson's ratio	Internal friction angle (degree)	Cohesion (MPa)
IV	21.0	300	2.87	0.33	31.0	0.367

Table 2. Table of Parameters of tunnel support for two-lane tunnel of 350km/h high-speed railroad.

Project	Initial support								
	Shotcrete		Anchor bolt			Steel frame	Second lining		
	Strength grade	Thickness (cm)	Length (m)	Diameter (mm)	Spacing (m×m)	Specification	Spacing (m)	Strength class	Thickness (cm)
Parameters	C30	20	3	25	1.5×1.2	Φ22@150	1.2	C30	40

Step 1: Judgment of whether the tunnel needs to be supported or not.

The finite element model is established, and the critical stabilized section of the tunnel is only 2.9m under the condition of 400m depth of Class IV surrounding rock, while the excavation span of the tunnel of the high-speed railway is 14.7m, support is needed.

Step 2: Discriminate between systematic support and local support.

The convergence of finite element model is poor under the condition of 400m burial depth of IV class surrounding rock, and there is a large range of tensile damage zone around the hole, so it is judged that system support is needed after tunnel excavation.

Step 3: Design value of surrounding rock pressure.

Calculate the minimum support force $P_{i\min}$ is 115.5kPa, due to the high structural importance of high-speed railroad tunnels, deformation control is more stringent, so the load safety factor takes 2.0, the design value of surrounding rock pressure $q=231\text{kPa}$, $e=155.5\text{kPa}$.

Step 4: Formulate the parameters of the support structure and account for the calculation results of the safety factor.

According to the experience, the support parameters shown in Table 2 are initially formulated and

Table 3. Table of calculation results of safety factor.

Project	Shotcrete layer		Bolt-rock bearing arch in construction stage		Bolt-rock bearing arch in operation stage		Second lining	Initial support	Total
	Discount factor	Safety factor	Discount factor	Safety factor	Discount factor	Safety factor			
Safety factor	1.0	2.72	1.0	2.02	1.0	3.27	3.38	4.74	9.37

the safety factor is calculated, and the results are shown in Table 2.

Total Safety Factor Method was used to calculate the safety factors of the anchor rock bearing arch, the shotcrete layer and the second liner respectively, the calculation results are shown in Table 3.

Step 5: Deformation monitoring allowable deformation value and limit deformation allowable value.

Through previous measurement experience, the surrounding rock pressure-time relationship curve after support is simplified as an exponential function (Eq. 5).

$$P_i = P_0 \cdot e^{-0.385/t} \quad (5)$$

Where: P_i is the surrounding rock pressure at any moment; P_0 is the surrounding rock pressure when the support is stabilized; t is time.

The variation curve of elastic modulus of shotcrete in relation to age is obtained in the laboratory as in Eq. 6.

$$E(t) = 24.7(1 - 0.37e^{-0.008t} - 0.63e^{-0.095t}) \quad (6)$$

The allowable deformation value of the structure under the design value of the surrounding rock pressure is calculated by the variable stiffness incremental method, and then the surrounding rock pressure is increased until the first plastic hinge appears in the shotcrete layer, so that the allowable value of the ultimate deformation of the structure can be obtained, and the results of the calculation are shown in Table 4.

Table 4. Table of deformation value calculation results.

Project	Allowable deformation value (mm)		Limit deformation allowable value (mm)	
	ΔU_y	ΔU_x	ΔU_y	ΔU_x
IV	21.0	300	2.87	0.33

The above obtained tunnel excavation allowable deformation value and limit deformation allowable value, construction can be monitored through the site, evaluation of the safety of the support structure, and dynamic adjustment.

4 ENGINEERING APPLICATIONS AND PRACTICES

To validate the rationality of Total Safety Factor Method, a comprehensive large-scale tunnel structure model test system was developed, focusing on structural testing. Various working conditions, including unsupported cavern, shotcrete layer, bolt-rock bearing arch structure, spraying and anchoring combination structure, and second lining, were simulated. Single-layer and multi-layer supporting structure bearing tests were conducted under these conditions. The model tests involved monitoring the internal stress and strain of the surrounding rock, tunnel displacement, and anchor strain. The damage state and load-bearing capacity of both the surrounding rock and supporting structure were analysed, and their deformation and force characteristics were studied. To facilitate the tests, a model testing device and monitoring schematic diagram were employed (refer to Figure 6).

Table 5 presents a comparison between the theoretical and experimental results of the load carrying capacity for each working condition in the model tests. The test results show a disparity ratio between the theoretical and experimental load carrying capacities ranging from 13% to 27%, and a disparity ratio of ultimate load carrying capacity ranging from 19% to 44%. Notably, the test results exhibit higher values than the theoretical results, indicating that the theoretical design adopts a conservative approach. Total Safety Factor Method demonstrates enhanced accuracy in predicting structural breakage locations and the overall structural state. The theoretical results of the calculations, although conservative, are not excessively so. As a result, this method is deemed suitable for application in the design of actual engineering structures. Overall, the model tests provide empirical evidence supporting the practicality and effectiveness of Total Safety Factor Method, further affirming its merit as a reliable tool for designing tunnel support structures.

Meanwhile, Numerous field tests have been conducted in the Laolingang, Wanjiashan Tunnel, and Xingshan East Tunnel of the Yichang to Xingshan High-Speed Railway project. These tests specifically focused on analysing the surrounding rock contact pressure and the performance of the initial support

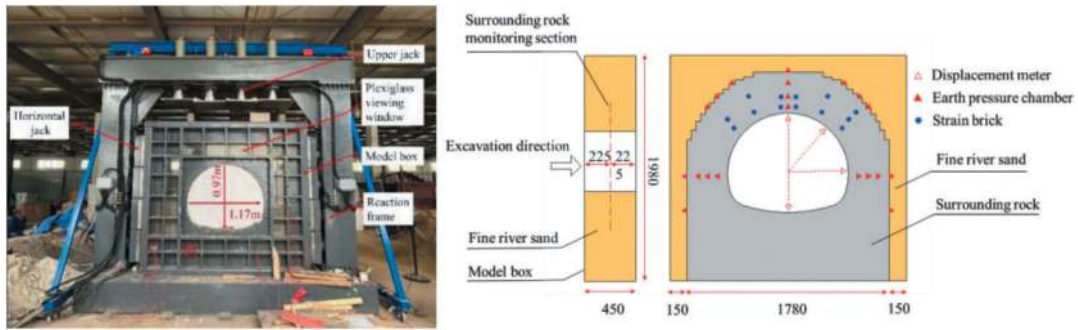

Figure 6. Model testing device and monitoring schematic diagram.

Table 5. Comparison table of theoretical and experimental results of load carrying capacity for each working condition.

Project	Design load capacity			Limit load capacity		
	Test value/ kPa	Theoretical value /kPa	Disparity ratio /%	Test value/ kPa	Theoretical value /kPa	Disparity ratio /%
Unsupported	/	/	/	/	/	/
Shotcrete layer 2cm	100	73	-27.00%	180	126	-30.00%
Shotcrete layer 4cm	140	108	-22.86%	360	232	-35.56%
Second lining	120	90	-25.00%	260	144	-44.62%
Bolt-rock bearing arch	90	65	-27.78%	100	77	-23.00%
Encrypted bolt-rock bearing arch	140	100	-28.57%	220	141	-35.91%
Shotcrete layer 2cm & Bolt-rock bearing arch	160	144	-10.00%	270	199	-26.30%
Shotcrete layer 2cm & Encrypted bolt-rock bearing arch	200	155	-22.50%	450	334	-25.78%
Multi-layer supporting	220	191	-13.18%	400	326	-18.50%

system. The results of the field tests indicate that the designed value of the surrounding rock pressure exceeds the measured pressure. This observation highlights that the designed value adequately accounts for the most unfavourable loading conditions. It demonstrates the capability of the design to encompass extreme scenarios. Moreover, the design safety factor aligns well with the actual working conditions. This finding confirms that the optimized support parameters derived from Total Safety Factor Method meet the requirements of safety factor.

The extensive field tests provide substantial evidence supporting the robustness and reliability of Total Safety Factor Method in designing tunnel support structures. It installs confidence in the practical application of this method in engineering projects. Overall, the field tests conducted in the Laolingang, Wanjiashan Tunnel, and Xingshan East Tunnel underscore the effectiveness of Total Safety Factor Method, ensuring the satisfaction of safety factor requirements and enhancing the stability and security of tunnel construction projects.

Theoretical results based on Total Safety Factor Method were applied to the engineering design of Yichang to Xingshan High-speed Railway, Ningbo to Zhoushan High-speed Railway (TANG, et al.,2019), Shenzhen Airport (Hezhou) to He'ao Expressway (XIAO,et al.,2022), and Qingdao Jiaozhou Bay Second Submarine Tunnel(XIAO, et al.,2023), as shown in Figure 7, which realized the design of the support structure of high-speed railway tunnels and multi-cavity tunnels with small clearances in space based on the premise of the safety factor analysis. In addition, the results are also applied to the safety assessment of the Sichuan-Tibet Railway tunnel, the general map of tunnels in the railroad industry, and the concealed subway station.

5 CONCLUSIONS

The Total Safety Factor Method has been verified through various means, such as on-site testing, modeling tests, and numerical calculations. These practical applications have demonstrated the effectiveness and

reliability of Total Safety Factor Method in designing tunnel support structures. The method has proven its ability to ensure the safety and stability of tunnels while considering both technical and economic aspects. Building on these successful implementations, there are plans to further expand the application of Total Safety Factor Method in the railway system. Efforts will be made to establish industry standards and specifications, aiming to promote widespread adoption of this tunnel design method. This initiative reflects China's commitment to independent innovation and showcases the country's advanced levels of engineering expertise.

In conclusion, Total Safety Factor Method has gained recognition and validation through its application in various tunnel projects in China. With continued development and standardization, it is expected to become a widely adopted design method for tunnels, characterized by its remarkable technical and economic advantages.

Considerations of the coefficient of subgrade reaction forces on seismic response displacement method of a double-circular shield tunnel

Min Xu* & Takashi Manabe

Science Solutions Division, Mizuho Research & Technologies, Ltd, Chiyoda-ku, Tokyo, Japan

ABSTRACT: In this paper, we investigate the seismic analysis of the cross-section of a double-circular shield tunnel using the seismic response displacement method. In the seismic response displacement method, we consider the ground displacement during an earthquake as the displacement of the ground spring. We discuss the calculation method of the coefficient of subgrade reaction used in the seismic response displacement method by comparing it with the results obtained from 3D dynamic FEM analysis. Specifically, we effectively estimate the coefficient of subgrade reaction by thoroughly examining the ground deformation obtained from the 3D dynamic FEM analysis.

Keywords: Seismic response displacement method, Coefficient of subgrade reaction, Double-circular shield tunnel, 3D dynamic analysis, M-K method

1 INTRODUCTION

In the seismic response displacement method, the interaction between the shield tunnel segments and the ground during an earthquake is simulated by utilizing ground springs. However, there has been no established method for determining the ground spring constants, making it one of the significant areas of investigation until now.

The authors conducted an analysis using the 3D dynamic finite element method (FEM) and the 2D beam-spring model based on M-K method in the response displacement method for the cross-sections of a double-circular shield tunnel. In the case of the 2D beam-spring model based on M-K method^{1),2)}, they compared the results obtained using ground spring constants for cases where tangential shear stresses are not fully transmitted of the traditional shear Stress in the tangential direction and where they are fully transmitted. These ground spring constants were calculated from FEM analysis¹⁾. The results indicated that careful attention is required in determining ground spring constants for the double-circular shield tunnel.

This study focuses on the determination of ground spring constants using the FEM analysis model. It estimates ground spring constants for the general-section segment and the gull-section segment of the double-circular shield tunnel using respective methods. It then conducts analyses using the response displacement method and compares the results with those obtained through the 3D dynamic FEM analysis method. Regarding subgrade reaction forces, the study considers

four calculation methods, 1) The unit forced displacement method using the FEM analysis model (referred to as the $\delta=1\text{m}$ method); 2) The unit load method using the FEM analysis model (referred to as the $F=1\text{kN}$ method); 3) The theoretical solutions for cases where tangential shear stresses in the ground are not fully transmitted to the lining (referred to as the Full-slip method) based on 2D elastic theory¹⁾; and 4) Theoretical solutions for cases where tangential shear stresses in the ground are fully transmitted to the lining (referred to as the No-slip method) based on 2D elastic theory¹⁾. Furthermore, the shield tunnel model is implemented using the beam-spring model based on M-K method. The beam-spring model is a structural model that represents the segment body as a beam element, the segment joint as a spring with rotational components, and the ring joint as a shear spring. The rotational spring constant of the segment joint is calculated using the Murakami-Koizumi method (M-K method)²⁾. The interaction between the tunnel and the ground is expressed using ground springs. The schematic diagram is shown in Figure 1.

2 THE RESPONSE DISPLACEMENT METHOD FOR A DOUBLE-CIRCULAR SHIELD TUNNEL¹⁾

The seismic analysis of shield tunnels in semi-infinite horizontal layered ground often employs the response displacement method using the beam-spring model based on M-K method²⁾, which is

*Corresponding author: min.xu@mizuho-rt.co.jp

Figure 1. Schematic diagrams of the beam-spring model based on M-K method.

a relatively straightforward computational approach and widely used in the seismic design of underground structures. In this method, seismic ground displacements obtained from one-dimensional overlapping reflection theory, as shown in Figure 2, are input as ground spring displacements, the method directly applies circumferential shear forces and conducts the analysis. For a double-circular shield tunnel with an external diameter of 3.15m at a depth of 14.0m in semi-infinite horizontal layered ground, as illustrated in Figures 3 and 4, the authors have previously compared the results of the 3D dynamic FEM analysis and the 2D M-K method of beam-spring model's response displacement method. When comparing the results of both methods to those obtained from the 3D dynamic FEM analysis, it was found that the results of both methods are nearly identical for the general-section segment of the tunnel, excluding the gull-section segment. However, differences in sectional forces appeared in the gull-section segment.

Regarding the 2D M-K method of beam-spring model, the authors calculated subgrade reaction coefficients for the No-slip method, including previously established subgrade reaction coefficients for the Full-slip method, as shown in Figure 2. They conducted analyses using both sets of coefficients. When comparing the results of these analyses with the 3D dynamic FEM analysis results, it was observed that the differences in the gull-section segment were small, but the differences in the general-section segment were significant¹⁾. Based on the above findings, it is evident that in the analysis of the response displacement method for double-circular shield tunnels, different estimation methods are required for calculating the subgrade reaction coefficients for the general-section segment and the gull-section segment.

3 CALCULATION METHOD FOR SUBGRADE REACTION COEFFICIENTS

There are several methods to determine subgrade reaction coefficients. In this context, the four calculation methods were used, which are $\delta=1\text{m}$ method, $F=1\text{kN}$ method, Full-slip method and No-slip method. They are used to calculate subgrade reaction coefficients. These coefficients are then utilized in response displacement based analyses (Case 1 to Case 4). The results from these analyses are compared with the results from the 3D dynamic FEM analysis (Case 5) to assess the methods for calculating subgrade reaction coefficients.

3.1 $\delta=1\text{m}$ method (Case1)

Here, a finite element analysis (FEM) model of the cavity ground was created as shown in Figure 5³⁾. Unitary forced displacements were applied at various points within the cavity. Subsequently, ground spring constants around the segments in contact with the ground were determined from the resulting forces. In the previous analysis (Case 1), only horizontal forces (in the X-direction of the global coordinate system as depicted in Figure 5) were considered for subgrade reaction calculations. However, in this analysis, unitary forced displacements were applied in both horizontal and vertical directions (in the Y-direction of the global coordinate system shown in Figure 5), and subgrade reaction forces were calculated. The calculated subgrade reaction forces in the global coordinate system were transformed into the element coordinate system (tangential-normal direction) as shown in Figure 6.

Figure 5. Illustration of the FEM calculation model.

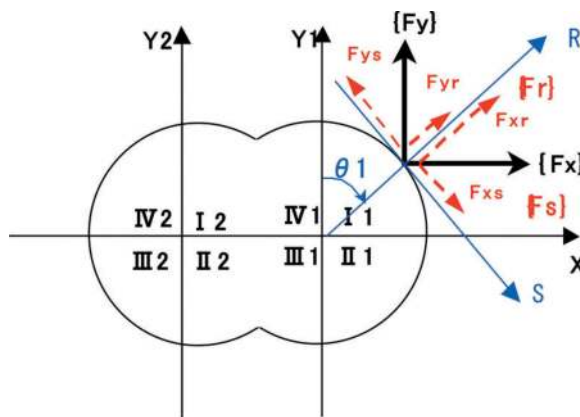

Figure 6. Illustrations depicting the global coordinate system and element coordinate system.

These subgrade reaction forces were used as the ground spring constants for Case 1, and analysis was conducted using the response displacement method.

The subgrade reaction forces, estimated using the $\delta=1\text{m}$ method for various points within the cavity, as presented in Figure 7, are depicted in Figures 8 and 9. Specifically for $\delta=1\text{m}$, the subgrade reaction forces for general-section segments of the double-circular shield tunnel increase with depth. In other words, the left and right subgrade reaction forces for general-section segments are symmetrical with respect to depth.

It may be assumed that the same ground spring constants can be set for segments at the same depth. However, the subgrade reaction forces for gull-section segments at the same depth differ from those of general-section segments, suggesting that different ground spring constants must be assigned.

Here, as for the ground spring constants in the response displacement method, the subgrade reaction forces in the X and Y directions were converted into segment element coordinate systems, and their absolute values were calculated. The distribution of the estimated ground spring constants is shown in Figures 10 and 11. As depicted in Figure 10, the shield tunnel is divided into five segments. The average values of subgrade reaction forces at various points within each segment were calculated. The ground spring constants were then determined based on these average values, and the response displacement method analysis was conducted. The calculated ground spring constants are presented in Table 1.

Figure 10. Distribution of tangential ground spring constants calculated by the $\delta=1m$ Method.

3.2 $F=1kN$ Method (Case2)

Next, as shown in Figure 12, a unit load was applied to each point within the cavity⁴⁾, and the values of ground displacement were calculated. The estimated ground displacements at various points within the cavity are illustrated in Figures 13 and 14.

Here, as for the ground spring constants in the response displacement method, the subgrade reaction forces in the X and Y directions were converted into segment element coordinate systems, and their absolute values were calculated. The distribution of the

estimated ground spring constants is shown in Figures 15 and 16. As in the case of Case 1, values from each point were used to divide the shield tunnel into five segments, and the average ground spring constants for each segment were calculated. The response displacement method analysis was then conducted using these calculated ground spring constants. The results are presented in Table 2.

3.3 Full-slip Method (Case-3) and No-slip Method (Case-4)

In 2D elastic theory, the relationship between the lining and the surrounding ground is depicted in the Figure 17.⁵⁾

Here, the variables and parameters mentioned are,
P: Load(kN);

λ : Side pressure coefficient;

σ_R : Radial stress acting on the lining (N/mm^2);

$\tau_{R\theta}$: Tangential stress acting on the lining (N/mm^2);

u_S : Radial displacement of the lining (m);

v_S : Tangential displacement of the lining.(m);

E: Deformation modulus of the ground (kN/m^2);

E_S : Elastic modulus of the tunnel lining (kN/m^2);

ν : Soil's Poisson's ratio;

ν_S : Tunnel lining's Poisson's ratio;

I_S : Sectional second moment of area per unit width of the lining (m^4);

A_S : Cross-sectional area per unit width of the lining (m^2);

R : Outer radius of the lining (m)

calculations for the Full-slip method and related analyses. Additionally, the calculation formula for the No-slip method is shown in Equation (2) and (3).

By using the methods mentioned above, the ground spring constants obtained using the Full-slip method and No-slip method for the ground conditions as shown in Table 3 are presented in Table 4.

4 CALCULATION RESULTS AND DISCUSSION

We conducted an analysis using the response displacement method with the subgrade reaction coefficients determined for each case (Case1 to Case4). The resulting section forces at the positions shown in Figure 18 and the section forces from the 3D dynamic FEM analysis (Case5) are presented in Table 5 to Table 10. The section force distribution for Case1 is shown in Figure 19. The section force distribution trends for each case are nearly the same. From the analysis results presented in Table 5 to Table 10, it can be observed that the bending moments of the upper gull-section segment at position (1) are nearly the same as those from the 3D dynamic FEM, but differences appear in axial and shear forces. At position (2), where the upper gull-section segment connects to the general-section segment, differences in section forces are apparent. At positions (3), (4), and (5), the bending moments for the general-section segment are almost the same, but differences appear in axial and shear forces. At position (6), where the lower gull-section segment connects to the general segment, the section forces are almost the same.

the response displacement method for a shield tunnel with double-circular cross-sections. Analyses using the response displacement method with 3D dynamic FEM and a 2D beam-spring model based on M-K for the double-circular shield tunnel. For the 2D beam-spring model based on M-K method, we considered various cases, including applying unit displacements or unit loads in horizontal or vertical directions. We determined the ground spring constants for each case and compared the results obtained using the response displacement method with those from the 3D dynamic FEM analysis. As a result, it was found that the subgrade reaction forces for the general-section segments of the double-circular shield tunnel increase with depth. In other words, as the depth of the ground increases, the relative displacement responses become smaller, but the subgrade reaction coefficients become larger. Additionally, for general-section segments, the left and right subgrade reaction forces of the overlapping circular shape are symmetric. Therefore, it is

sufficient to set the same ground spring constants for segments at the same depth.

However, for segments at the same depth, the subgrade reaction forces for the gull-section segments and the general-section segments are different, requiring the use of different ground spring constants. This study verifies the possibility of calculating ground spring constants from the response displacement method for the overlapping circular shield tunnel, but it is important to analyze and understand the characteristics of these springs with precision.

Analysis of key technologies in structural design of prefabricated station of Shenzhen Metro

Zhuang Xu, Dong Meng & Renpu Liu
Shenzhen Metro Group Co., Ltd., Shenzhen, China

Mengting Li
Beijing Urban Construction Design and Development Group Co., Ltd., Beijing, China

ABSTRACT: This paper takes the prefabricated station under the inner support system of Shenzhen Metro as the engineering background. The key design techniques for prefabricated middle plate, beams and columns in station were proposed. And the influence of geological conditions on the deformation, stress, and joints internal forces of the station structures was analyzed. Research shows that the design of prefabricated middle plates, beams and columns in station includes three key techniques: overall flow assembly process, stress analysis of prefabricated middle plate, and design of large open pore in the precast middle plates, beams and columns system. Among them, the overall flow assembly process of prefabricated station needs to solve the problem of continuous flow assembly in the vertical direction of the foundation pit and the longitudinal direction of the station. The stress of prefabricated middle plates mainly includes three stages: factory prefabrication, lifting and transportation, on-site assembly, and normal use. The design of large pore in prefabricated middle plates needs to consider the shear effect between the prefabricated plates, so that the prefabricated plate, the laminated layer, and the longitudinal beam form an overall bearing horizontal force in the plane of the middle plate. For the overall structure of prefabricated subway station, the geological conditions have a significant impact on the internal forces of the roof span, arch foot support, and top corner joints, while the impact on the internal forces of the side walls is relatively small. The top corner joints of a prefabricated subway station are the weak part. When the station is located in a fill layer, the top corner joints need to be strengthened in design, and when the station is located in a hard plastic layer, the safety reserve of the top corner joints is sufficient.

Keywords: Shenzhen Metro, prefabricated station, key design techniques, geological conditions, internal forces and deformation analysis

1 INTRODUCTION

In recent years, prefabricated subway station technology has been promoted nationwide. Since the first prefabricated station in China was applied at Yuanjiadian Station on Changchun Metro Line 2 in 2012, prefabricated station technology has been applied in cities such as Jinan, Shanghai, Guangzhou, Harbin, Qingdao, Shenzhen, and Wuxi in China. The construction process of prefabricated stations involves prefabricating components in the factory and using “building blocks” on site to assemble each component into a whole using connecting joints. Compared with cast-in-place stations, this construction method has advantages such as high production efficiency, good construction quality, less labor, and minimal environmental impact. The research work related to prefabricated subway stations is the theoretical and technical support for its promotion and application.

Yang^[1-7] conducted a systematic study on the design, calculation methods, component partitioning, joint types, joint mechanical properties, stiffness characteristics, structural static and dynamic characteristics, and station waterproofing of prefabricated stations. Ding^[8-9] analyzed the stress and deformation mechanism of a single ring structure of a prefabricated station after being assembled into a ring, and studied the horizontal and vertical seismic responses of the prefabricated station, which showed that the prefabricated station structure has excellent seismic performance under earthquake and meets seismic requirements. Peng et al.^[10] analyzed the entire construction process of prefabricated station structures through a combination of numerical simulation and on-site measurement. Tao et al.^[11] established a three-dimensional solid model to study the effects of different support methods on structural internal forces, stresses, and deformations.

The prefabricated station in Changchun is based on an anchor cable support foundation pit system, where the floor slab and beam columns adopt a cast-in-place plan. The existing literature on prefabricated stations mainly focuses on the stress characteristics of joints and prefabricated peripheral lining structures, while there is less research and application on the mid floor structure system under the internal support foundation pit support system. This article takes prefabricated stations in Shenzhen as the research object, and conducts research on the key structural design of prefabricated middle plate beams and columns. Subsequently, the influence of geological conditions on the force deformation of prefabricated stations was analyzed. Through the study of prefabricated middle plates in prefabricated stations, the full section assembly of subway stations has been achieved, which improve the assembly rate of subway stations and the efficiency of on-site flow assembly. This provides valuable experience and methods for the subsequent design of prefabricated station structures.

2 PROJECT OVERVIEW

The prefabricated station section of Shenzhen Metro adopts a column arched structure section without column platform in the station hall. The total length of the station is 260 m. The two ends of the station are reinforced concrete cast-in-place structures, and the middle section of the station is 194 m long and adopts a prefabricated structure. The prefabricated station is an underground two-story structure with a single arch and large span structure, as shown in Figure 1. The structural dimensions of the station include a total width of 22.3 m, a height of 17.35 m, a top plate thickness of 1.2 m, a side wall thickness of 0.8 m, a bottom plate thickness of 1 m, a middle plate thickness of 0.45 m, and a station ring width of 2 m.

The first ring structure, using prefabricated components, consists of bottom plate A, side wall block B, top plate C, middle plate, and middle column. The joint between the bottom plate and the side wall is called the AB joint, and the joint between the side wall and the top plate is called the BC joint. The fertilizer trough between the main structure and the enclosure is transmitted through screws and concrete.

Figure 1. Cross-section of prefabricated station.

According to the structural characteristics of prefabricated stations, the design of prefabricated middle plate beam column structures has the following key and difficult points:

- 1) Adopting a prefabricated middle plate beam column system. The research on the assembly process of the entire prefabricated station is a key focus.
- 2) The design of the middle plate needs to meet the stress requirements of lifting construction, assembly construction, foundation pit stress conversion, normal use, and other working conditions, which are significantly different from cast-in-place structures. The stress analysis of the middle plate is the focus of the middle plate design.
- 3) There are large holes in the middle board. The design and stress analysis of large openings using a prefabricated middle plate beam column system is a difficulty in middle plate design.

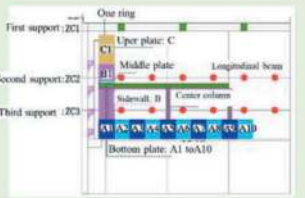

3 RESEARCH ON KEY TECHNOLOGIES FOR DESIGN OF PREFABRICATED MIDDLE PLATE BEAMS AND COLUMNS

3.1 Research on assembly steps

The difficulties in the assembly process of assembled stations under the prefabricated middle plate beam column system need to solve the vertical and vertical continuous flow assembly problems of the foundation pit and the station. The key to vertical flow assembly of foundation pits is to combine the dismantling and replacement of the support system within the foundation pit. The prefabricated structural plates assembled first are used to form the replacement support of the foundation pit, and then the support of adjacent foundation pits is removed, providing installation conditions for the subsequent assembly of prefabricated plates; The key to the vertical continuous flow assembly of the station is to use the support spacing to advance the assembly of the bottom plate, center column, and center beam in the station, providing conditions for the vertical ring assembly of prefabricated components in the foundation pit. By connecting the vertical components of the foundation pit with the vertical assembly of the station, a flow assembly process for the full section prefabricated station under the open excavation and internal support foundation pit support system is formed. The vertical flow construction sequence of prefabricated stations is shown in Table 1.

Compared with the cast-in-place subway station foundation pit, the horizontal spacing of the support and the width of the diaphragm wall of the prefabricated station have been increased (the steel support spacing of the cast-in-place station foundation pit is generally 3 m, and the width of the diaphragm wall is generally 6 m). To ensure the stress feasibility of foundation pit support, finite element modeling

Table 1. The longitudinal construction steps.

Construction steps	Step 1	Step 2	Step 3

Content	Dismantle the second and third supports, assemble side wall blocks and middle plates	Assembly of remaining side walls and middle plates	Enter the next cycle of assembly

analysis was conducted on the stress of the support before and after the assembly of the middle plate, as well as the deformation of the retaining structure, as shown in Figure 2. The concrete grade of the enclosure structure is C35, the wall thickness is 0.8 m, the maximum size of the plate shell unit used is 0.8 m, the soil volume weight is 19.5 kN/m^3 , and the lateral pressure coefficient is 0.55. The calculation results are shown in Table 2. The calculation analysis shows that the horizontal displacement of the retaining structure in the above working conditions is less than the control value (30mm), meeting the requirements for deformation control of the foundation pit. The Q345 steel support for foundation pit support has an outer diameter of 800 mm and a wall thickness of 16 mm. The calculated stable stress ratio is 0.68 (less than 1), and the bearing capacity meets the requirements. Therefore, increasing the horizontal spacing of the prefabricated station foundation pit support and the width of the ground connecting wall, as well as meeting the stress requirements of the flow assembly process for the enclosure and middle plate.

Figure 2. Load-structure finite element calculation model.

3.2 Stress analysis of prefabricated middle plate under different working conditions

There are differences in the design of prefabricated mid slabs between subway stations and cast-in-place stations, and prefabricated middle slabs need to cover various stress conditions during the design stage. The prefabricated middle

Table 2. Axial force of support at middle plate and deformation of retaining structure.

Construction conditions	Condition 1	Condition 2	Condition 3	Condition 4
Description	Excavation of foundation pit	Replace the bottom plate and remove the third support	Assemble the first middle plate and remove the second steel support	Subsequent middle plate assembly
Deformation of enclosure (mm)	3.41	7.22	7.94	7.72
Support/Replacement axial force (kN)	2267 (Second support)	2450 (Second support)	3342 (Middle plate support)	3455 (Middle plate support)

plate undergoes three stages: factory prefabrication, lifting and transportation, on-site assembly, and normal use. For the above stress stages, the calculation conditions are as follows: lifting construction, assembly, foundation pit stress conversion, pouring of composite layer construction, decoration, equipment installation construction, short-term low water level during normal use, and long-term high water level during normal use. Considering that the equipment load borne by the middle plate in the equipment room area is greater than the crowd load borne by the public area, the middle plate in the equipment area is selected for calculation, as shown in Figure 3. The calculation results for each working condition are shown in Table 3. From Table 2, it can be seen that the axial force of the middle plate support replacement is 1671 kN-1727.5 kN per linear meter. In addition, in the first stage (condition 1 to condition 3), the internal force control condition of the prefabricated middle plate is the pouring middle plate composite layer, and its reinforcement ratio meets the requirements of bearing capacity and crack control. In the second stage (condition 4 to condition 6), the control condition is the high water level during the use stage, and the reinforcement ratio also meets the requirements for bearing capacity and crack control. The deformation calculation shows that the deformation of each working condition meets the stiffness requirements, and the maximum deflection of the prefabricated middle plate during the construction stage is the pouring composite layer working condition.

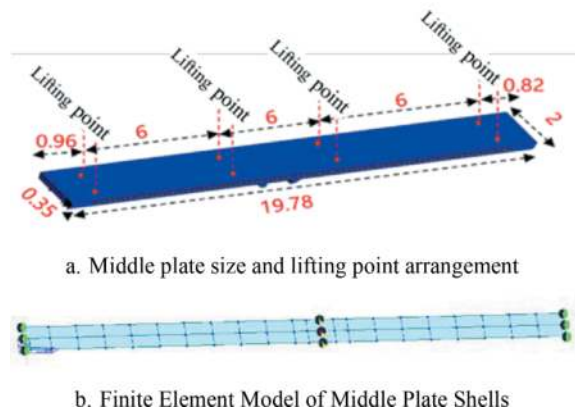

Figure 3. Middle plate size and graphic calculation model.

3.3 Design and stress analysis of large holes in middle plate

The stairs, escalators, and equipment in the station need to have large holes in the middle plate, such as the size of the hole in the escalator is 12m × 6m. In prefabricated stations, the opening design of the middle plate not only needs to meet the stress requirements during the use stage, but also needs to meet the stress requirements during construction stages such as transportation, lifting, and assembly. The design plan diagram of the large hole position in the middle plate during the construction and application phase is shown in Figure 4.

According to the force analysis results of the standard middle plate, the most unfavorable

Table 3. Results of middle plate's internal force under various working conditions.

Construction conditions	Condition 1	Condition 2	Condition 3
Description	Hoisting construction	Assembly and force conversion of foundation pit	Pouring laminated layer
Bending moment of support (kN·m)	45	202	243
Bending moment in the span (kN·m)	32	195	235
Shear force (kN)	39.5	130	166
Deformation in the span (mm)	0.56	11	13
Construction conditions	Condition 4	Condition 5	Condition 6
Description	Decoration and equipment installation	Normal use under low water levels	Normal use under high water levels
Bending moment of support (kN·m)	284	315	392

working condition (pouring composite layer working condition) is selected for the construction stage analysis of the middle plate opening large hole. The finite element models were established to analyze the stress of single mid plate and steel support. Figure 5 shows the finite element model of prefabricated mid plate and section steel support at each stage, and the calculation results are shown in Table 4. The results indicate that the composite component composed of prefabricated middle plate and section steel support during the construction stage can meet the requirements of bearing capacity and crack control by reinforcing according to the standard plate. During normal application stage, the reinforcement of the longitudinal beam and crossbeam at the hole edge meets the requirements for bearing capacity and cracks.

4 ANALYSIS OF THE INFLUENCE OF GEOLOGICAL CONDITIONS ON THE INTERNAL FORCES OF PREFABRICATED STATION STRUCTURE

4.1 Station structural model

The assembled station strata model is shown in Figure 6. Considering the influence of boundary effects on the structural model, the depth of the soil in the model needs to be selected at least 3 times the height of the station, and the horizontal boundary needs to be selected at least 5 times the width of the station. The horizontal and vertical sizes of the model are 162 m and 54 m, respectively, with a longitudinal length of 2 m. Fixed constraints are set at the bottom and surrounding boundaries of the soil, while the upper boundary is free. The elastic constitutive model is used for concrete materials, and the Mohr Coulomb constitutive model is used for soil materials. The main structure adopts C50 concrete material, and the ground connecting wall adopts C35 concrete material. The model joint adopts the joint mode proposed by Lin [12], which uses beam spring element simulation and multiple joint stiffness iterations to obtain accurate joint stiffness.

Figure 6. Stratum-structure calculation model.

In order to better analyze the impact of different geological conditions on the station structure, representative soft and hard soil layers are selected for analysis. Four types of strata, namely fill soil, soft plastic silty clay, hard plastic silty clay, and completely weathered sandstone, were studied. The selection of elastic modulus and Poisson's ratio for different soil properties is shown in Table 5.

Table 5. Strata parameters.

Strata	Elastic modulus E/ (MPa)	Poisson's ratio ν
Fill soil	15	0.4
Soft plastic silty clay	30	0.35
Hard plastic silty clay	45	0.3
Completely weathered sandstone	60	

4.2 Analysis of internal force and deformation of prefabricated station structure

Figure 7 shows the horizontal displacement deformation of the station in a completely weathered sandstone formation. For the prefabricated station structure studied in this paper, the BC joint is relatively close to the arch foot, which is the weak point of structural deformation. Therefore, the horizontal displacement of the arch foot needs to be focused on.

Figure 8 shows the vertical displacement deformation of the station in a completely weathered sandstone formation. The vertical settlement of the top plate is greater than that of the bottom plate. Excessive deformation of the structure can affect the stability of the station and result in displacement exceeding the limit. Therefore, this paper selects the horizontal displacement and mid span settlement of the top plate at the arch foot support as the analysis objects for structural deformation.

Figure 7. Horizontal displacement of station.

Figure 8. Vertical displacement of station.

Figures 9 and 10 show the distribution of bending moment and axial force at stations in completely weathered sandstone formations. It can be seen that the position where the larger bending moment is located is the mid span of the top plate, the arch foot support and bottom plate support, and the mid span of the bottom plate. The extreme bending moment occurs in the span of the top plate. The larger values of axial force are concentrated at the supports of the top and bottom plates. The extreme value of axial force occurs at the position of the arch foot support of the top plate. Therefore, this paper selects the arch span and arch foot support for analysis.

Figure 9. Bending moment of station.

Figure 10. Axial force distribution of station.

4.3 The influence of geological conditions on the stress of station structure

Figure 11 shows the curves of the settlement of the arch crown and the horizontal displacement of the arch foot support in different strata. It can be seen that as the stratum hardens, the horizontal displacement of the arch foot support and the settlement of the arch crown decrease. For the mid span of the top plate, the settlement of the arch crown in fully weathered sandstone is 10.42 mm smaller than that of the fill, and the horizontal displacement of the arch foot support is reduced by 2.56 mm.

Figure 12 shows the bending moment values at the arch and support under different geological conditions. The axial force values at the arch and support under different geological conditions are shown in Figure 13. For the mid span of the top slab, the bending moment of completely weathered sandstone has decreased by 1640 kN·m compared to that of the filled soil, and the axial force has increased by 428 kN. For

Figure 11. Horizontal displacement of bearing and settlement curve of vault for different soil.

the arch foot support, the bending moment of completely weathered sandstone has decreased by 337 kN·m compared to that of the filled soil, and the axial force has increased by 853 kN.

It can be concluded that the geological conditions have a significant impact on the structural stress. The harder the formation, the more favorable the structural stress. When the elastic modulus E of the soil layer is 15 MPa, the mid span bending moment of the top plate reaches 5536 kN·m. It is recommended to strengthen the structural design in this formation. In relatively hard soil layers ($E > 60$ MPa), the bending moment value is small, the axial force value is large. The slightly hard strata are favorable for structural stress, and are suitable for the structural cross-section form presented in this article.

Figure 12. Bending moment of bearing and arch crown of different soil.

By comparing the redundancy of bending moment and shear force values, it is possible to compare the redundancy of joint stiffness under different geological conditions. The joint redundancy of structures under different geological conditions is shown in Table 6. The following conclusions can be drawn: 1) As the soil layer hardens, the redundancy of bending moment and shear force of the BC joint and the AB joint increases, indicating that the hardening of the soil layer has a positive impact on the structural stress. 2) The change of soil layer has a significant impact on the redundancy of the BC joint, while it

Figure 13. Axial force of different soil.

has a smaller impact on the redundancy of the AB joint. When the formation changed from fill soil to completely weathered sandstone, the bending moment redundancy of the BC joint increased from 5.7% to 40.74%, which increase 35.04%. While the AB joint increased from 48.04% to 49.78% as the formation becomes hard, only an increase of 1.74%. 3) The redundancy of the BC joint in the fill layer is very small, only 5.7%. In this soil layer, measures such as increasing the size of the tenon can be taken to enhance the joint stiffness, such as joint reinforcement design or soil improvement.

Table 6. Connector redundancy of bearing of different soil.

Formation condition	BC joint	BC joint	AB joint	AB joint
	Bending moment	Shear force	Bending moment	Shear force
Fill soil	5.70%	57.59%	48.04%	38.18%
Soft plastic silty clay	25.29%	60.35%	48.34%	41.49%
Hard plastic silty clay	34.04%	67.61%	48.38%	51.93%
Completely weathered sandstone	40.74%	75.30%	49.78%	54.37%

5 CONCLUSION AND SUGGESTIONS

Taking the prefabricated subway station project in Shenzhen as the engineering background, the key and difficult problems in the prefabricated middle plate, beam, and column scheme of the prefabricated subway station were studied. The mechanical properties of station structures under different geological conditions were analyzed, and the main conclusions are as follows:

- 1) A flow assembly sequence under the open excavation of the internal support system is proposed for the prefabricated middle plate of prefabricated stations, which improves the section assembly rate and assembly efficiency. At present, the assembly

efficiency of this process in Shenzhen is 2 days to complete 3 complete rings.

- 2) The prefabricated middle plate is used in the prefabricated station. The design of prefabricated middle plate needs to be combined with factors such as the force conversion requirements of open excavation of foundation pits, the lifting of prefabricated components, and the assembly process of stations.
- 3) The deformation of the single arch large span non-column arch roof station structure is mainly reflected in the top plate support and bottom plate support. Both undergo outward horizontal displacement, but the horizontal displacement is relatively small. The top and bottom plates mainly experience downward settlement, and the vertical settlement of the top plate is greater than that of the bottom plate.
- 4) As the stratum hardens, the redundancy of bending moment and shear force of the BC joint and the AB joint increases, but the influence of stratum change on the BC joint is greater than that of AB joint. When designing prefabricated station joints, the BC joint between the roof and side wall should be given special attention.

Addressing design challenges in large diameter tunnels with big openings in deep soft ground: Innovative solutions and analysis techniques

Jinrong Yuan*, Vince Chee Siong Goh & Claudia Maxcia
COWI Singapore Pte Ltd. Singapore, Singapore

ABSTRACT: This paper discusses the design challenges and innovative solutions of segmental lining for a large diameter bored tunnel with big opening in soft ground at a depth of 50m. One of the main challenges in the design is to design a temporary support system for the opening that would not disrupt concurrent tunnelling works. To achieve this, it was necessary to transfer the maximum ground load applied on the cutting rings to the adjacent rings and minimize the temporary support. Therefore, 3D structural FEM analysis was carried out to simulate the load transfer and tunnel lining behaviour as well as the stress states of all radial and circumferential joints. In addition, investigation on the ground loading applied on tunnel lining with different tunnel depth was carried out using 2D/3D Plaxis. The analyses results show that the circumferential dowels and bicone significantly contributed to load transfer between the cutting and adjacent rings, the soil arching effect may reduce the ground loading applied on the tunnel lining by 20~30%, which allow for a reduction in the required reinforcement and a smaller temporary support system. The study provides valuable insights into the design and analysis of a segmental lining for a large diameter bored tunnel in soft ground with openings. The findings can be applied to similar tunnel projects in soft ground conditions.

1 INTRODUCTION

Global cities are experiencing rapid urbanization as rural populations migrate to urban areas. According to the United Nations 2022 World Cities Report (UN-Habitat, 2022), the world's cities are projected to add 2.2 billion people by 2050, with nearly 90% of this growth occurring in Asia and Africa (S. Vardakos, S. Zlatanovic, S. M. Wongkaew & A. Bauer, 2023).

Large diameter tunnels, particularly single bores for transit, rail, and roadway applications, are well-suited to meet the demands of high-capacity transportation projects, especially in densely populated urban areas where surface and right-of-way space is at a premium. It is capable of accommodating multi-lane roadway traffic or multi-modal services, thereby eliminating the need for multiple tunnels with cross connections. In comparison to dual bored tunnel, which typically necessitate the construction of cross-passages at specific intervals, a single bored tunnel offers the flexibility to incorporate cross passages, thereby reducing evacuation times in the event of an incident within the tunnel.

Current practice in tunnel design tends to vary a great deal, depending on national or owner-imposed design requirements, local tradition and practice and the experience of the tunnel designer. There are no universally accepted guidelines on how to assess the safety of a tunnel or the acceptability of a design and this means that engineering judgement and experience play a very large role in the design of tunnel.

2 CHALLENGES OF LARGE DIAMETER BORED TUNNEL

The benefits of large diameter tunnels are counterbalanced by challenges in their design and construction, necessitating careful planning, alternative analyses, and innovative, performance-based engineering solutions.

2.1 *Non-uniform ground conditions within the advancing face*

Large diameter tunnels frequently encounter intricate and demanding ground conditions. The expanded

*Corresponding author: jiyu@cowi.com

excavation size increases the likelihood of encountering various geological formations, thereby presenting a substantial challenge. These ground conditions may encompass soft soils, rock formations, mixed face conditions, weak rock masses, fault zones, and more. Understanding the geotechnical properties of the ground and devising suitable support systems to maintain stability becomes imperative.

2.2 *Ground control and settlement risks*

Impacts to adjacent buildings/utilities due to settlement are key risks associated with large diameter tunnel. It is very important to recognize that the volume loss will be smaller and does not scale with the square of the tunnel diameter, as is often the case with smaller diameter tunnels. Volume losses in such cases are often found to correlate better with the diameter of a large tunnel (S.Vardakos, S.Zlatanovic, S. M. Wongkaew & A. Bauer., 2023)

2.3 *Higher hood force and thrust force in the segmental lining*

The increased size of these tunnels presents new technical challenges to both designers and contractors, such as increased pressure due to soft ground or weak rock, will significantly increase hoop force and TBM thrust force in the tunnel segmental lining, which pose challenges in the design of segmental lining, especially for radial joints and circumferential joints.

2.4 *Provision of internal structures*

Large tunnels often necessitate the inclusion of internal structures for functional purposes, which can adversely affect the structural integrity of the lining. For instance, consider a TBM road tunnel requiring a ventilation slab with supports at shoulder level, potentially leading to unacceptable localized loading of the lining. The design of the segments must carefully address such concerns. In the case of larger TBM tunnels, solutions may need to account for significant internally induced forces.

2.5 *Opening in the segmental lining*

Another challenge for designers to consider is the provision of structural openings to accommodate future underground infrastructure or other purpose. The presence of these openings can have a substantial impact on stress distribution within the segmental lining of large diameter tunnels. Consequently, strengthening work is typically required around the openings for both temporary and permanent cases in order to maintain the overall integrity of the tunnel structure. Advanced analysis techniques can be used to optimise the structural designs in these areas to ensure cost effective solutions.

2.6 *Greater risks of lining uplifting, stepping and ovalisation*

Large tunnels passing through poor ground with rich underground water content entail greater risks of lining uplifting, stepping, and ovalisation due to buoyancy during segment erection. In the case of larger diameter tunnels, increasing the number of segments per ring is a common practice to reduce their size and weight for ease of delivery and handling within the TBM during erection. While having more segments per ring allows for greater flexibility and lining deformation, it also increase the risks affecting the lining's integrity.

3 GROUND LOADING CONSIDERATION FOR LARGE DIAMETER BORED TUNNEL

A tunnel can be expected to experience permanent loads (i.e. dead loads, earth pressure, surcharge loads, etc.), live loads (i.e. vehicular loads, live load surcharges, etc.), or transient loads (i.e. earthquake, superimposed deformations, blast, fire, construction loads, etc.).

Ground movements due to tunnelling, either TBM or sequential excavation are inevitable and can be attributed to: (1) Ground movement towards the face; (2) Radial movement towards the shield; (3) Ground movement towards the tail void; and (4) Deformation of the lining.

Deformation of the tunnel lining results in a reduction in ground stress acting on the tunnel linings. After excavation, the ground requires time to redistribute, and even longer for consolidation to reach the final stress state.

The ground loadings imposed on the tunnel lining are a function of the stress variation with tunnel depth, ground-lining relative stiffness, tunnel geometry, and construction sequence. As Per AASHTO-LRFDTUN-1 (2017), the vertical earth pressure for tunnels in soft ground may be taken as the pressure resulting from the total height of ground directly over the tunnel crown, if the height of ground over the tunnel crown is two times or less the excavated width of the tunnel. If the height of ground directly over the tunnel crown is greater than two times the excavated width of the tunnel, the arching action of the soil should be evaluated to determine if an increase in pressure is necessary. Similar, ITA working group 2 recommends that reduced earth pressure for bored tunnel can be adopted in accordance with Terzaghi's formula (WG2 ITA (2000)).

Peck (1969) defined the two principal requirements of a tunnel lining and illustrated the factors influencing the development of ground loading on the lining. The key points are summarized as follows (R. J. Mair & R. N. Taylor (1997)):

- By the time the lining is installed, soil displacements have inevitably occurred (the ground

having moved radially towards the tunnel and axially towards the face).

- The short-term ground loading experienced by the tunnel lining is inversely proportional to the magnitude of soil displacements that have occurred prior to its installation.
- The circumferential flexibility of the lining may allow a further reduction in the loading, although this is generally small since most completed rings are generally relatively stiff circumferentially.
- The short-term ground loading acting on the tunnel lining can be taken to correspond to when the tunnel face has moved away from the lining by approximately 2 tunnel diameters, i.e. when the three-dimensional effects of the tunnel heading are no longer evident.
- Any further increase in ground loading on the lining depends on the soil type. In the case of sandy soils, tunnel excavation and lining erection take place under drained conditions, and hence little or no increase in ground loading would be likely (unless caused by additional grouting). In clays, however, the ground loading will increase as excess pore pressures dissipate.

Arching effect is one of the most universal phenomena encountered in soils both in the field and in the laboratory (Terzaghi, 1943). This effect is most recognized in underground structures, for example, underground conduits. Underground openings can be built utilizing the arching action to account for the reduction in the overburden pressure.

Hsien-Jen Tien (1996) carried out a literature study on the arching effect and summarized the arching effect as follows:

- (1) Arching is a phenomenon existing widely in nature and man-made construction. It is an important issue for geotechnical engineers and researchers to comprehend and recognize in their studies and design.
- (2) The arching effect can be defined as follows: "If a portion of an otherwise rigid support of a geomaterial mass yields, the adjoining soil moves with respect to the remainder of the soil mass. This movement is resisted by shearing stresses which reduce the pressure on the yielding portion of the support while increasing the pressure on the adjacent rigid portions." Arching can also occur when one portion of a yielding support moves more than adjoining parts. Generally speaking, arching is stress redistribution occurring in a geomaterial mass.

Practice and literature show that moderate changes in earth loads may be responsible for large changes in predicted lining loads. This becomes especially critical for large diameter tunnels. Gröbl (2012) highlights that for large diameter tunnels with segmental lining, a marginal change of lateral pressure leads to notable changes of ring bending moments. As soil-structure interaction models can

capture soil arching and redistribution of ground stresses, they can be a practical method in estimating ground loads acting on lining. The Orlovsky-Tunnel study showed through FE calculations that a 25% reduction of earth loads should be possible versus conventional methods (Gröbl, 2012).

When numerical analyses are performed for the design of a tunnel lining the designer should consider the different stress states that the tunnel lining needs to accommodate starting from the initial ground stress regime, the change in stress during excavation, and the change in groundwater pressure. The estimation of ground loads becomes more complicated as the tunnel diameter increases and the probability of encountering ground of mixed stiffness becomes higher compared to smaller diameter tunnels. In that context, the use of geotechnical numerical models versus the conventional practice of empirically derived stress reduction due to arching, becomes more relevant than before. Further research should be performed to identify the instances when the use of numerical modelling for calculation of earth loads is necessary and provide the designers practical information for the application of this methodology.

The Convergence Confinement Method (CCM) (Marc Panet, Jean Sulem, 2022) is a design principle used for tunneling in soft ground conditions. The method aims to control and manage ground movements and deformations by achieving a balance between convergence (deformation) and confinement (support).

Convergence refers to the inward movement or deformation of the ground around the tunnel. The CCM recognizes that some level of convergence is inevitable in soft ground tunneling. However, excessive convergence can lead to instability and potential failure. The goal is to control and manage the convergence to ensure it remains within acceptable limits.

Confinement refers to the support provided to the tunnel lining to resist the pressure exerted by the surrounding ground. The CCM emphasizes the need for a robust and effective support system, typically achieved through the use of segmental lining, shotcrete, or other forms of structural support. The support system should be designed to provide sufficient stiffness and strength to prevent excessive deformations and maintain stability.

The key principle of the CCM is to achieve a balance between convergence and confinement. By carefully designing the support system and controlling ground movements, a state of equilibrium can be achieved where the deformations are controlled within acceptable limits, and the stability and integrity of the tunnel are maintained.

The CCM emphasizes the importance of continuous monitoring of ground and tunnel behavior during and after construction. Monitoring techniques such as instrumentation, geodetic measurements, and ground surface surveys are used to assess

convergence, ground settlements, and other relevant parameters. This information allows for real-time adjustments to the support system, if necessary, to ensure the desired balance between convergence and confinement is maintained.

Overall, the Convergence Confinement Method provides a systematic approach to tunnel design in soft ground conditions. It focuses on achieving a controlled and balanced interaction between the tunnel lining and the surrounding ground to maintain stability, control deformations, and ensure the safety and functionality of the tunnel structure.

4 SEGMENTAL LINING DESIGN AT OPENING LOCATION

Design of railway or road bored tunnels always calls the need for opening in the segmental lining, for instance, for cross passage or future underground infrastructure, design of opening in the bored tunnel segmental lining especially in large diameter bored tunnel in soft ground with deep overburden under high groundwater table proves to be a challenging task.

In order to construct opening, the tunnel segmental lining at opening location is required to be removed and temporarily supported during construction stage and connected to the cross passage in permanent stage.

Figure 1. Support for tunnel opening. left: temporary right: permanent.

The relevant tunnel rings are opened by removing the filling segments so that they no longer act as a closed structural system. The hoop forces must be supported temporarily during construction and permanently after completion by other structural elements. This can be accomplished either by using steel segments, which remain in the structure permanently and form part of the tunnel lining, or with special concrete segments. In case of special concrete segments these either must be temporarily supported with a suitable structure during construction, or permanently coupled during and after construction. Temporary support can be provided by, for example, an appropriate steel structure or by using dowels to couple the segments. In the final stage, a concrete frame which forms part of the permanent cast-in-place lining will carry the forces around the opening (See Figure 1).

Figure 2. Temporary steel support for tunnel opening (left: Hamster cage Right: Half-moon).

Various methods, such as steel support frames of hamster cage, half-moon (See Figure 2), or steel segments, can be used to provide the rigidity to bear the loads which need to be conducted around an opening in a segment-lined tunnel. Each solution has advantages and disadvantages, and some methods have limits with regard to their applicability.

In Singapore MRT tunnel, the hamster cage temporary support was commonly adopted as temporary support for opening in the past. One of the disadvantages of this solution is that these steel structures extend into the tunnel space and, thus, could disrupt construction work in the main tunnel. The time required to install and remove, the construction and the cost of the steel components are also disadvantageous. In order to overcome the disadvantage, some of the projects proposed different steel frame of half-moon or/curved steel frame for the opening with innovative design approach considering the load transfer to adjacent ring through the circumferential joints of dowel or/and bicone.

This half-moon/curved steel frame eliminate risks associated with the traditional “Hamster cage” internal bracing, difficult and potentially dangerous to build due to having to lift heavy steel structure and provide sufficient working platform for concurrent activities in the bored tunnel and therefore significantly improved the construction progress.

For permanent stage, the permanent collar will be designed to carry the loads from the cut segment lining from the time when the temporary steel frame is removed until permanent stage. These loads will be carried by bending and torsion in the beam and column members of the rectangular frame and the design actions will be locked into the structural members for the entire design life.

5 CASE STUDY

A case study was carried out to study on the design and analysis of the large diameter bored tunnel with large opening in the segmental lining to be built in soil conditions of old alluvium (OA) at depth of 50 m from ground level in Singapore. This study involves discussion of the magnitude of ground loads on the tunnel lining and its influence on the opening set design of the segmental lining with 3D geotechnical and structural analysis.

Figure 3. Soil profile for large diameter tunnel analysis.

The proposed segmental lining with 11.3 m internal diameter comprises 9 standard segments and 1 key segments (9+1). The segment thickness is 450 mm thick and steel fibre reinforced (sfrc).

Th ground conditions of the studied section is illustrated in Figure3, based on the geological information, the large diameter tunnel at this section is envisaged to be driven through Old Alluvium overlain by Fill materials. Old Alluvium consists of ill-assorted masses of semi-consolidated sand, gravels, pebble beds and silty clay beds. Old Alluvium was categorized and divided into 5 sub-layers (OA(A) to OA(E)), according to its weathering grade and strength based on SPT N-Values with OA(A) being unweathered and OA(E) as residual soil.

A series of openings of 4.0m wide x 5.6 m height will be created on the segmental lining to facilitate the future connection with the future underground infrastructure (see Figure 4), the tunnel horizon at openings will be in OA(B) or better with about 4 times tunnel diameter ground cover to the tunnel crown.

According to the project requirement, the proposed design of load transfer elements and associated temporary support systems at the opening locations shall allow concurrent TBM tunnelling work. Hence, the stability of the cut ring will be maintained by

Figure 4. Large diameter tunnel section with opening.

transfer of axial load to adjacent segments through special segments(steel-concrete grout composite segments and SFRC-rebar reinforcement hybrid precast segments) as well as high shear capacity dowels and bicones for the circumferential joints during construction period between the breaking of the segment to form an opening, and the installation of the permanent reinforced concrete collar.

Both short-term construction and long-term permanent stages considered in the analysis.

During construction stage, the special segments in conjunction with bolts, shear bicones and high strength dowels along the circumferential joints to ensure the axial load transfer mechanism to be achieved.

To further enhance the stability of the system, additional steel temporary props will be installed in conjunction with all the aforementioned measures.

During the long-term permanent stage permanent RC collar will be carrying the permanent loads induced onto the segmental lining over time.

5.1 Ground relaxation in the segmental lining design

As discussed in section 3 above, tunnel excavation necessarily results in direct stress release towards the excavation accompanied by arching of the ground around it before ground supports are installed. For deep tunnel excavation the eventual load for which supports need be designed can be far less than the load corresponding to original ground stresses before excavation. Theories for assessment of arched loading may be used to establish appropriate loading for design of supports in granular materials. For excavations in clay soils with lower permeability, pore water pressures changing towards equilibrium values with time bring about gradually increasing load on excavation supports.

Figure 5. Recorded time related loading on tunnel in London clay (London Underground, 2007).

Figure 5 shows the measurement of ground load on London Underground tunnel linings in London Clay (London Underground, 2007), which shows that the actual load on the tunnel at 1000 days is less than 65% overburden. These measurements confirm the important point highlighted by Peck (1969) that in reality the tunnel lining is not subjected to the original in-situ ground stresses as if it had been “wished into

Table 1. Comparison of soil parameters for OA(B) and London Clay.

Soil Type	Unit weight [kN/m ³]	Drained modulus [MPa]	Undrained modulus [MPa]	Undrained shear strength [kPa]	Friction angle [°]	Cohesion [kPa]
London Clay	20	Min. 36.4	Min. 45	Min. 65	23	0
OA(B)/OA(A)	20.5	200	230	250	34	20

place”. The soil displacements that occur prior to installation of the lining clearly have a major influence in reducing both the short-term and long-term ground loading to much lower values than the original in-situ stresses. Particularly in the case of highly over-consolidated clays.

Comparing with London clay, OA(B)/OA(A) is cemented stiff material similar to London Clay (see Table 1), the ground load on the tunnel for the case study is expected not more than that in London clay (65%).

Plaxis 2D and 3D analysis were carried out to study on the ground-structure interaction and ground relaxation. In Plaxis 2D model, different overburden of bored tunnel were assumed to study the effective stress influence height above the tunnel versus overburden, the bored tunnel lining was only considered as “Wished-in-place” without construction sequence considered, the soil relaxation is only result from the soil-structure interaction due to the differential stiffness. Refer to Figure6 for the total displacement around the tunnel.

Figure 6. Plaxis 2D model for tunnel overburden at 4D.

From the Plaxis 2D analysis, following findings are observed:

- Ground cover lesser than 2D (D is the tunnel external diameter), the soil arching effect is insignificant. The soil pressure acts on the tunnel is close to in-situ stress.
- Ground cover greater than 2D, the soil arching effect tends to more notable. In this study of 4D ground cover, approximately 20% of soil relaxation is expected (See. Figure 7).
- Influence height of effective stress increase with tunnel overburden, but not more than 2D (See Figure 8), which indicates the extent of soil relaxation and disturbance of soil is about 2D, the stress beyond 2D will not be affected.

Figure 7. Soil pressure over in-situ stress for different tunnel overburden.

Figure 8. Influence height of effective soil pressure for different tunnel overburden.

Plaxis 3D analysis was adopted to simulate the future underground infrastructure excavation and tunnel boring works to obtain the relevant ground stresses that serves to be the input in the tunnel structural model.

Figure 9. Plaxis 3D model for bored tunnel with openings.

The Mohr-Coulomb constitutive model is used for various soil strata. Only undrained analysis is conducted due to the short completion time of the openings. Undrained (B) is adopted for analysis which does not have a cap and yield surface. Linear-elastic and perfectly plastic conditions are used in the analysis; hence deformations and effective stresses were used to ensure that the overall results make sense and do not stray far from initial conditions.

Figure 9 shows the idealised finite element model. The future underground infrastructure have been split into 2 phases (1 & 2) to show the relative sequence of excavations. This is in correspondence to carrying out excavation only in alternative opening to mitigate the risk of concurrent excavation within close proximity. The opening excavation is simulated with wished-in-place techniques to conservatively estimate the ground stresses for bored

tunnel lining design. The envisaged construction sequence as follows:

- Apply surcharge
- Apply ground volume Loss
- Install bored tunnel lining & deactivate soil clusters
- Phase 1 Excavate & install primary lining
- Phase 1 Install permanent lining
- Phase 2 Excavate and install primary lining
- Phase 2 Install permanent lining

Figure 10. Ground load generated from Plaxis 3D.

Equivalent moment of inertia of segmental lining has considered Muir Wood Tunnel lining reduction to account for the segmental radial joints (Refer to Equation (1)).

$$I_{eq} = I_{joint} + I_{full} \left(\frac{4}{n} \right)^2 \leq I_{full}. \quad (1)$$

Where I_{eq} is the equivalent moment of segment
 I_{joint} is the moment of inertia of segment radial joint

I_{full} is the moment of inertia of full segment thickness

n is the number of main segments (excluding key segment)

Plaxis 3D analysis shows that the ground load on the bored tunnel is only 65%~70% of the in-situ stress in the temporary stage (see Figure 10).

Based on Plaxis 2D and 3D analysis, arching ground load of 80% of full overburden (i.e 20% ground relaxation) was considered for short-term temporary construction stage is deemed to be appropriate.

For permanent stage, full overburden ground load will be considered in segmental lining design.

5.2 3D structural analysis with opening for temporary stage

Bedded-shell spring models have been set up in LUSAS (version 19.1) to derive the structural forces, i.e. the bending moments, hoop forces and shear forces in the segmental tunnel lining as well as the shear force and tension force in the joints.

The soil load derived from Plaxis analysis together with all temporary and permanent loadings

Figure 11. 3D bedded-shell spring model setup.

are applied to the structural model (see Figure11) with different load combinations, at temporary stage, no soil and water pressure loads have been applied at all the excavated regions to simulate the loss of confinement.

The soil-structural interaction is modelled with a set of ground radial and tangential springs. The radial ground reaction spring value K_r is derived with Duddeck and Erdmann's empirical formulas:

$$K_r = \frac{E_c(1 - \nu)}{(1 + \nu)(1 - 2\nu)R}$$

Where E_c is the drained Young's modulus of the surround ground;

ν is the Poisson ratio of the surround ground;

R is the extrados radius of the tunnel.

The tangential stiffness has considered as one third of radial springs stiffness as per Dixon (1971) for soft ground.

The rotational springs with spring stiffness magnitude derived according to Leonhardt (1966) have been adopted to model the radial joints between the segments.

At the circumferential joints, connection has been modelled via coupled-shear springs without rotational stiffness (thus no moment transfer). The shear force-displacement curves of the connectors have been input based on the direct shear test carried out in the laboratory by the suppliers.

Additional internal temporary propping system consist of two vertical steel props connected to the non-standard segments have been modelled as beam elements connected to the shell elements of the ring (See Figure12).

5.3 3D structural analysis with opening for Permanent stage

In the permanent stage, the hoop load from the cut segments will be transferred to the permanent RC collar upon the removal of the temporary prop. The stability of the tunnel will be improved at this stage as the permanent

Figure 12. Temporary support for opening.

concrete collar and adit structures provide additional lateral restraint to the tunnel. The regions where the ground support was lost during the temporary stage has been casted with concrete at this stage (See Figure13).

Figure 13. Load path of opening (elevation and section view).

The RC collar is modelled with as a volume element using LUSAS v19.1. Due to the line of symmetry, only half the collar is modelled and it is fixed along the Global Y axis at the axis of symmetry. Only the permanent lining is modelled for this permanent case model and it is assumed that the full ground load will be transferred to this permanent lining in the long-term

Figure 14. Permanent RC collar model geometry.

Figure 15. General ring arrangement for opening.

case. A tetrahedral mesh with quadratic interpolation is used. The model geometry is shown in the Figure 14.

5.4 Analysis results and segmental lining design

The results of 3D structural analysis of the tunnel opening segmental lining (temporary stage and permanent stage) have been evaluated and studied carefully due to the presence of singularities in finite element analysis (FEA) especially at sharp corners or sudden change in boundary conditions that does not represent the reality.

The structural design of segmental lining and check for the joints were carried out based on Euro-codes and Singapore codes and specifications.

The segment types and joints connection details are shown in Figure15.

6 CONCLUSIONS AND RECOMMENDATIONS

Design of openings in segmental linings for large diameter tunnels, particularly in soft ground with substantial overburden and high groundwater tables, presents intricate challenges, the need for concurrent tunnelling works during opening construction further complicates the design process.

There are no generally accepted standards or guidelines for the detail design of precast segmental lining, especially for ground loading consideration in deep tunnel, which depends on geological conditions, tunnel stiffness, tunnel depth, excavation method etc., hence, experience of the tunnel designer with engineering judgement is important.

Arching is an important issue for geotechnical engineers and researchers to comprehend and recognize in their studies and design.

The case study shows that the ground relaxation increase with overburden, for 4 times tunnel diameter overburden, 20% soil relaxation is expected, while soil arching effect is not significant when overburden is less than 2 times tunnel diameters, the influence height of effective stress increase with tunnel depth, but not more than 2 times tunnel diameter, which means soil arching can be considered if tunnel overburden is deeper than 2 times tunnel diameters, this is in line with studies of previous researchers (e.g. Terzaghi, 1943).

Effective load transfer mechanisms are critical to maintaining structural stability. Various methods, such as steel support frames, bicones, shear dowels, and bolts, play vital roles in transferring hoop forces around openings. Careful selection and design of these elements are essential for safe and robust construction. Hybrid and composite segments, incorporating steel reinforcement and specialized connections, prove effective for opening creation. These segments enhance load transfer capabilities and overall structural integrity.

Tunnel hoop force around the opening may be transferred to adjacent rings through circumferential joints and significantly simplify the temporary support for the opening during construction stage and therefore eliminate the obstruction of concurrent tunnelling works. Sophisticated 3D structural analysis modelling with appropriate software, realistic boundary condition assumptions, and correct inputs, and interpretation, post-processing of the outputs by experienced engineer are critical to successful design of the segmental lining and joints connections.

The design of permanent collar requires to consider the hoop force transferring during the design life, the permanent collar significantly contributes to long-term stability of the tunnel at opening location.

ABSTRACT: The longitudinal seismic response of a tunnel during an earthquake cannot be ignored aspect same as the transversal seismic response. A novel laminated shear energy dissipation (LSED) structure is proposed for the longitudinal aseismic design in this paper. The LSED structure is composed of thin steel plate and rubber layer bonded alternately aiming at improving the longitudinal seismic performance of the tunnel by changing the connection mode between the linings. The laboratory compression-shear test on the LSED structure is carried out. Results show that a better deformation capacity in the horizontal direction because of the small horizontal stiffness of the rubber layer in the structure, and a larger vertical bearing capacity in the vertical direction because of the rigidity of the thin steel plate. A three-dimensional refined numerical model of LSED structure-tunnel lining-surrounding ground is established using the finite element software ABAQUS. The seismic response analysis is carried out by using the dynamic time history method. The research results showed that the installation of LSED structure could effectively reduce the seismic response of the lining with the seismic mitigation rate of more than 45%.

1 INTRODUCTION

Statistics on earthquake damage to underground structures indicate that tunnels and other underground engineering are not entirely resistant to seismic forces. Numerous historical earthquakes, such as the 1923 Kanto earthquake, the 1996 Kobe earthquake, the 1999 Chi-Chi earthquake, the 2008 Wenchuan earthquake, the 2016 Kumamoto earthquake, and the 2022 Menyuan earthquake, have caused varying degrees of damage to tunnel structures (Asakura et al., 1996; Sayed et al., 2019; Shen et al., 2014; Yu et al., 2016; Zhang et al., 2018; Wang et al., 2021; Chen et al., 2023). These global instances of tunnel seismic performance emphasize

the importance of focusing on the seismic safety and aseismic design of underground structures, particularly in seismically active areas.

The primary objective of aseismic design, as pursued in various studies, is to reduce the stress induced by earthquakes on tunnel linings or release seismic energy by implementing mitigation measures at the connections between the lining and ground or between lining spans. Presently, two main approaches—seismic isolation technology and seismic reduction technology—are used to protect underground structures from earthquake damage. Seismic isolation technology involves incorporating an isolation system between the tunnel lining and the ground to reduce the transfer of seismic energy from the

*Corresponding author: zhangxuepeng0722@126.com

ground to the tunnel structure (Li, 2012; Providakis, 2009; Xin et al., 2019). The use of an isolation layer, frequently employing foam, concrete, rubber, and similar materials, has proven effective in reducing seismic damage to underground structures through theoretical and experimental studies (Konagai et al., 2001; Xu et al., 2016; Hasheminejad et al., 2008; Li et al., 2019). Seismic reduction technology involves incorporating structures such as flexible joints between tunnel segments or at lining connections (Ding et al., 2006; Yu et al., 2013; Kawamata et al., 2016; Yu et al., 2017). While seismic reduction technology is primarily used in subway tunnels, it is seldom applied in mountain tunnels. However, recent seismic investigations of ring crack damage in tunnels resulting from the 2016 Kumamoto earthquake and the 2008 Wenchuan earthquake have highlighted the significance of considering longitudinal performance in mountain tunnels, which mainly experience axial compression and tension during earthquakes. As a result, longitudinal seismic mitigation technologies are crucial for improving the seismic performance of mountain tunnels, particularly for long tunnels constructed in recent years, to protect the lining from severe damage (Atsushi et al., 2009; Cui et al., 2015; Yu et al., 2016; Zhang et al., 2018; Savigamin and Bobet, 2021).

Flexible joints for mountain tunnels can be installed at the primary or secondary lining connections. However, research on longitudinal flexible joints is still in its initial stages, with current studies primarily focused on the tunnel portal section (Cui et al., 2013, 2020; Ma, 2018). Ding et al. (2019) have also noted that there are few countermeasures for tunnel longitudinal deformation, with existing tunnel engineering only considering individual cases. It should be mentioned that the stiffness of flexible joints made with isotropic materials like rubber or foam concrete may be weakened, leading to larger local deformations and potential leakage due to differential surrounding pressure (Yu et al., 2013; Zhang et al., 2022). Therefore, seismic design of tunnels with flexible joints needs careful consideration, allowing for differential movements, resisting static and dynamic loads, and ensuring the integrity of the entire lining structure in the axial direction. To enhance the overall seismic performance of tunnel structures, it is necessary to conduct aseismic optimization designs of existing tunnel lining connections. In light of these challenges, a new type of laminated shear energy dissipation (LSED) structure is proposed to modify the connection mode of the lining and improve the aseismic performance of tunnel structures. The LSED structure's energy absorption body consists of both an elastic layer and alternating steel plates. In the radial direction of the tunnel cross-section, the LSED structure remains nearly rigid to avoid compromising the radial stress-bearing capacity provided by the surrounding rock. With the implementation of the LSED structure, the tunnel lining gains flexibility in the longitudinal

direction. The aseismic efficacy of this proposed structure requires further investigation before its application in underground structures.

Hence, a fine three-dimensional (3D) finite element model is developed using numerical methods to investigate the aseismic longitudinal performance of the LSED structure in conjunction with the tunnel lining and surrounding rock. In this study, 18 cases are considered to analyze the structure's aseismic mechanism, considering both internal influencing factors such as the rubber shear modulus, steel plate dimensions, structure number, and structure installation location, as well as external influencing factors including seismic wave parameters and surrounding rock grade. These cases provide a comprehensive evaluation of the LSED structure and its effectiveness in mitigating seismic effects on the tunnel system.

2 MECHANICAL PRINCIPLE OF LSED STRUCTURE

2.1 Design of LSED structure

Figure 1 illustrates the schematic design diagram of the LSED structure, which comprises two main components: the energy absorption body (A in Figure 1) and the connecting parts (B in Figure 1). The energy absorption body is composed of an elastic rubber layer (A1 in Figure 1) that provides deformation capability and a steel plate (A2 in Figure 1) that offers high rigidity. These layers are stacked alternately to form the energy absorption body. The connecting parts are constructed using L-type steel-reinforced concrete slabs. The energy absorption body is connected to the L-type connecting parts through flange plates (C in Figure 1).

The horizontal equivalent stiffness, denoted as K_h , is a crucial parameter for evaluating the anti-shear characteristic of the LSED structure. The stiffness is influenced by various factors, including the rubber shear modulus, rubber layer thickness, rubber layer number, and steel plate dimensions. To calculate this stiffness, a method similar to the approach used for natural laminated rubber bearings in building structures can be employed (Liu et al., 2022), as illustrated in Equation (1).

$$k_h = \frac{GA}{T_r} \quad (1)$$

where G is the shear modulus of rubber, A is the effective area of rubber inside, and T_r is the total thickness of rubber inside.

2.2 Aseismic principle of LSED structure in tunnel

Figure 2 depicts three models of tunnel lining connections, illustrating the presence or absence of longitudinal aseismic measures. In these models, the lining is simplified as a spring-mass system with circumferential stiffness (k_s) and

Figure 1. Schematic design diagram of the laminated shear energy dissipation structure (Symbol A denotes energy absorption body; symbol A1 denotes elastic rubber layer; symbol A2 denotes steel plate; symbol B denotes L-type steel-reinforced concrete slab; and symbol C denotes flange plate).

axial stiffness (k_t). The static and dynamic forces acting on the lining can be decomposed into axial force $H(t)$ and vertical force $V(t)$.

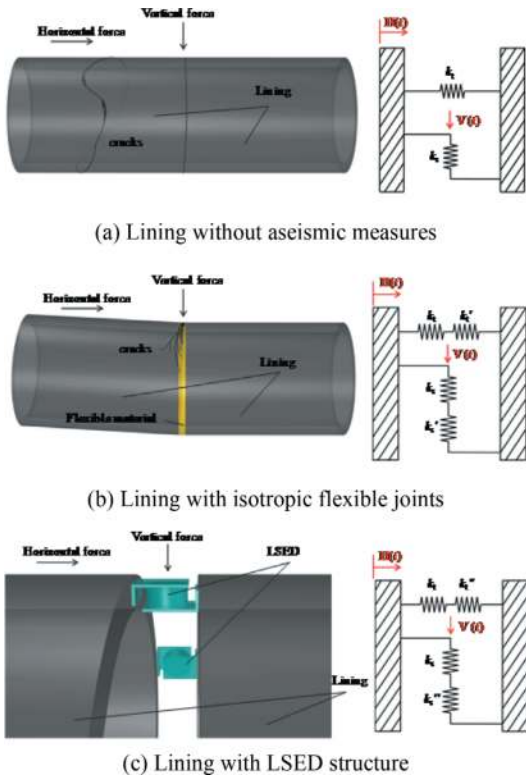

Figure 2. Lining connection models with/without longitudinal aseismic measures.

In Figure 2a, the connection between the tunnel linings is rigid, without any aseismic measures. In this case, the lining's axial and circumferential stiffness values are solely determined by the lining k_t and the lining circumferential stiffness k_s .

To mitigate the negative effects of rigid connections, flexible joints with isotropic characteristics, such as rubber or foam concrete, are commonly used in current longitudinal seismic design between tunnel linings (Hasheminejad et al., 2018; Xu et al., 2011; Li et al., 2019), as shown in Figure 2b. In this case, the mechanical model can be simplified as two springs connected in series, considering both the horizontal and circumferential directions. Due to the flexible characteristics of the joint, a significant amount of energy can be absorbed by the flexible joint along the axial direction of the tunnel, effectively mitigating seismic damage. However, it should be noted that the elastic deformability of the flexible joint is much greater than the rigidity of the lining. This increased deformation has the potential to compromise the integrity of the entire tunnel structure, including the functionality of the waterproof layer.

To mitigate the isotropic effect of the flexible joint, a transversely isotropic model is proposed, as depicted in Figure 1. This structure exhibits different stiffness properties in the horizontal and vertical directions. The thin steel plate provides significant vertical bearing capacity, while the rubber component maintains good deformation allowance in the horizontal direction. The aim is to ensure that the structure can withstand large vertical loads while allowing for deformations in the horizontal direction. Figure 2c illustrates the lining connection model incorporating the LSED structure. The orientation of the laminated layers aligns with the circumferential direction of the tunnel, while the horizontal direction runs parallel to the axial direction of the tunnel. By implementing the LSED structure, the aim is to achieve improved seismic performance by effectively managing both vertical load-bearing capacity and horizontal deformation allowances. The mechanical model with the LSED structure can be expressed as

$$\begin{cases} H(t) = k_t'' u_t'' = k_t u_t = k_{tL} u_{tL} \\ k_t'' = \frac{k_t}{k_t + k_{tL}} \\ V(t) = k_s'' u_s'' = k_s u_s = k_{sL} u_{sL} \\ k_s'' = \frac{k_s}{k_s + k_{sL}} \end{cases} \quad (2)$$

where k_t'' and k_s'' are the equivalent horizontal and circumferential stiffness of lining and the LSED structure in series; u_t'' and u_s'' are the overall horizontal and circumferential displacement of lining and the structure in series; k_{tL} and k_{sL} are the horizontal and circumferential stiffness of the LSED structure; u_{tL} and u_{sL} are the horizontal and circumferential displacement of the LSED structure. The LSED structure, with its flexible rubber component in the horizontal direction, exhibits similar energy absorption capabilities as a flexible joint. However, what sets it apart from a flexible joint is its ability to maintain circumferential rigidity due to the increased stiffness of the steel plate. This circumferential rigidity ensures the integrity of the entire tunnel structure and protects the waterproof layer.

By combining the energy absorption performance of the rubber component and the circumferential rigidity provided by the steel plate, the LSED structure offers a balanced solution that effectively mitigates seismic damage while preserving the overall structural integrity of the tunnel system.

3 NUMERICAL SIMULATION ON ASEISMIC PERFORMANCE OF THE LSED STRUCTURE IN TUNNELS

3.1 Numerical model establishment of the lining – ground - LSED structure system

The seismic response of the LSED structure-tunnel-ground system is analyzed using the full dynamic time history analysis method with the finite element analysis software ABAQUS. The numerical model of the system is illustrated in Figure 3. In the model, the upper and lower L-type slabs of the LSED structure (highlighted in red in Figure 3) are connected to the left and right sides of the lining cross-section, respectively. The LSED structure is distributed along the circumference of the lining, and the remaining

joint area is filled with elastic material. The numerical model has dimensions of 80 m in width (cross-sectional direction), 60.996 m in length (axial direction), and 80 m in depth (vertical direction), with a buried depth of 36.4 m. To eliminate boundary effects on the tunnel response, the distance between the ground boundary and the lining is more than five times the tunnel diameter. The tunnel cross-section is circular, with inner diameters of 3 m and a thickness of 0.6 m. Construction joints occur at regular intervals of 10 m along the axial direction of the tunnel. In the numerical model, the LSED structure is only installed at the middle construction joint to highlight its seismic performance.

The proposed structure has dimensions of 0.996 m in length, 0.6 m in width, and 0.421 m in thickness to meet the requirements for tunnel lining thickness. The energy absorption body consists of 19 steel plates and 20 rubber layers, each with dimensions of 0.6 m in length, 0.6 m in width, and 0.2355 m in thickness. The steel plates and rubber layers are generated by establishing the overall model before assigning parameters in different regions. This approach reduces the number of node elements in the model, improving convergence and

Figure 3. Model sketch for the LSED structure - lining - ground system.

minimizing errors compared to establishing separate steel plates and rubber layers and setting binding contacts between them. To simplify the contact between the LSED structure and the filling material, the cross-section shape of the energy absorption body is designed as a square, and the rubber protective layer is not included in the numerical model as it has a negligible influence on the tunnel response.

The meshing of the model is shown in Figure 4. The size of soil elements is chosen to be less than 1/6 to 1/8 of the minimum wavelength to ensure proper wave propagation through the elements (Kuchlemeyer et al., 1973). Mesh refinement is performed near the contact areas between the surrounding rock and the lining, as well as between the LSED structure and the lining.

Figure 4. Meshing of model.

3.2 Material model

The surrounding rock is discretized using a 3D 8-node reduced integration element (C3D8R) with the Mohr-Coulomb model, where the damping ratio of the rock is set as 0.05. The tunnel lining and filling at the joint are also discretized using a 3D 8-node reduced integration element (C3D8R) and

assumed to have an elastic behavior. Detailed properties of the ground-lining system are provided in Table 1. For the LSED structure, the rubber material is considered almost incompressible and characterized using the 3D 8-node hybrid element (C3D8H) with the first-order strain energy function constitutive model (Mooney-Rivlin). This model accurately describes the mechanical properties of rubber materials with deformations below 150%. The constants C_1 and C_2 in the Mooney-Rivlin model can be calculated based on the rubber shear modulus, while the coefficient D_1 , which affects the compressibility of the rubber, is set to zero (Du et al., 2006). The steel plate material is discretized using the 3D 8-node element (C3D8) and assumed to follow an elastic behavior with a density of 7850 kg/m³, an elastic modulus of 206 GPa, and a Poisson's ratio of 0.3. To simulate the bolt connection, the L-type steel-reinforced concrete slab is set to have a binding contact with the lining end face. Surface-to-surface contact with finite sliding is established at the connections between linings at the construction joint, between the ground and the lining, and between the ground and the filling. The contact is modeled using tangential penalty friction and normal 'Hard' contact conditions (Wang et al., 2022). Please refer to Table 1 for more detailed properties of the ground-lining system and the LSED structure.

3.3 Boundary condition

To simulate free field motion and account for the elastic recovery performance of the semi-infinite media outside the artificial boundary, a viscous-spring artificial boundary is applied to all boundaries except the upper boundary of the model. This boundary condition involves the application of a viscous damper and a spring to the boundary node of the finite element model. The viscous-spring artificial boundary is designed to maintain good stability at both high and low frequencies (Du, 2006). It effectively mimics the behavior of the surrounding media beyond the artificial boundary and allows for

Table 1. Properties of the LSED-tunnel-ground system for numerical simulation.

accurate simulation of the elastic recovery response. By implementing this boundary condition, the model can effectively reproduce the dynamic characteristics of the free field and ensure that the seismic response analysis captures the realistic behavior of the system.

The input motion of the shear wave is vertically applied at the bottom boundary of the model. Figure 5 displays the seismic wave from the Trinidad earthquake. To simplify the calculations, the acceleration concentration portion between the 7th and 10th seconds is selected as the input wave. In ABAQUS, instead of directly applying the seismic wave, an equivalent node force is applied at the bottom node of the artificial boundary surface. This equivalent node force is determined based on the velocity and displacement time history of the seismic waves (Huang, 2015), allowing for a realistic representation of the input motion. By using this approach, the seismic response can be accurately captured while reducing computational complexity and simplifying analysis process.

Figure 5. Trinidad seismic wave.

3.4 Seismic response result

In this study, the monitoring surface is chosen as the right end face of the third lining section. Considering the model's geometry and boundary conditions, the seismic response of the cross-section exhibits axisymmetric behavior. To analyze the seismic response, five monitoring points are strategically placed, namely the crown, spandrel, haunch, springing line, and invert, as depicted in Figure 6. Using a finite element model, we obtained the seismic responses of the tunnel-ground system with and without the LSED structure. We evaluated the differences between these responses by examining the maximum principal stress and strain energy within the tunnel lining structure.

Figure 6. Monitoring points arrangement of the lining.

Figure 7 illustrates the time histories of the maximum principal stress and strain energy at the five monitoring points. A comparison between the model with and without the LSED structure is shown, represented by the dotted line and solid line, respectively. The results indicate a significant reduction in both the maximum principal stress and strain energy for the model with the LSED structure, accompanied by a smaller variation in amplitude. This highlights the effectiveness of the LSED structure in reducing the seismic response of the tunnel lining under earthquake forces. Further evidence supporting the good seismic performance of the structure can be observed from Figure 8, which displays the maximum principal stress contour of the third and fourth lining sections. To quantify the seismic mitigation achieved by the LSED structure, we define the seismic mitigation rate as the percentage change between the seismic response of the tunnel lining with the LSED structure and that without it. Figure 9 presents the seismic mitigation rates at the various monitoring points: 46.09% at the crown (Point 1 in Figure 7), 46.94% at the spandrel (Point 2), 45.07% at the haunch (Point 3), 46.75% at the springing line (Point 4), and 46.72% at the invert (Point 5). These findings highlight the excellent aseismic performance of the LSED structure in tunnel seismic design.

4 CONCLUSIONS

This paper proposes a laminated shear energy dissipation (LSED) structure to enhance the axial aseismic performance of tunnel structures. As tunnels are susceptible to longitudinal seismic response, the LSED structure, composed of alternating thin steel plates and rubber layers, is installed at the cross-section boundary of the secondary lining to improve deformation ability and rigidity resistance. The mechanical properties of the LSED structure are verified using a spring-mass model, and a three-dimensional numerical model of the LSED structure-tunnel lining-surrounding rock system is developed for seismic response analysis. The research results show that the LSED structure exhibits high vertical bearing capacity due to the rigidity of the thin steel plate, while maintaining good deformation allowance in the horizontal direction through the elastic characteristics of the rubber component. Seismic response analysis shows that the LSED structure significantly reduces the maximum principal stress and strain energy of the tunnel compared to the case without the structure. Subjected to Trinidad seismic waves, the seismic mitigation rate exceeds 45%.

An improved simplified solution for the characteristic line of tunnels in strain-softening rocks

M. Anthi*, Th. Pferdekämper & G. Anagnostou
ETH, Zürich, Switzerland

ABSTRACT: We present an analytical solution for calculation of the characteristic line for tunnels excavated in strain-softening rock masses obeying the Mohr-Coulomb criterion, with linear uniaxial compressive strength decay. The derivation is based on the simplifying assumption that the strains inside the plastic zone are completely plastic. This significantly simplifies the mathematical formulation, enabling the derivation of closed-form solutions. The accuracy of the simplified solutions is evaluated by comparing their predictions with rigorous solutions obtained by numerical finite-difference analyses.

Keywords: ground response curve, tunnelling, strain-softening, Mohr-Coulomb

1 INTRODUCTION

The characteristic line in strain-softening rock masses can be determined by numerical methods with rigorous treatment of the deformations in the plastic zone, or by analytical or semi-analytical methods involving certain simplifications (for comprehensive reviews see, e.g., Guan *et al.* 2020, Ghorbani and Hasanzadehshooili 2019). From a theoretical perspective, the rigorous methods are robust. However, in general, these are too complex for practical use, due to the need to solve differential equations. The mathematical treatment can be significantly simplified by neglecting the elastic strains that develop during yielding (Egger 1974, Panet 1976), but Guan *et al.* (2007) showed that this simplification underestimates the tunnel wall displacement by 20-40% compared to rigorous methods (Alonso *et al.*, 2003).

In this paper, we propose an improved simplifying solution for the characteristic line, adopting Kovári's (1985) approach, which derived characteristic lines for perfectly plastic rocks (no softening) completely neglecting the elastic strains within the plastic zone. The improvement achieved by the new solution is illustrated by means of comparative analyses considering older approximate solutions as well as numerical results obtained for the rigorous formulation by the finite differences method presented by Lee and Pietruszczak (2008). Furthermore, the paper discusses some interesting features of the characteristic line in addition to aspects of the stability in the case of strain softening.

2 PROBLEM STATEMENT

We consider a deep cylindrical tunnel with radius a , crossing homogeneous and isotropic rock under a hydrostatic *in-situ* stress field (Figure 1). The tunnel is supported by a uniform pressure σ_a , while the far field stresses are equal to the *in-situ* stress σ_0 . Under these assumptions the system fulfils rotational symmetry. We are looking for the relationship between the support pressure σ_a and the radial displacement u_a of the tunnel wall.

The rock mass is taken as a linearly elastic, softening plastic material obeying the Mohr-Coulomb yield criterion. A linear decrease in the uniaxial compressive strength f_c with the deviatoric plastic strain γ^{pl} will be assumed (Figure 2):

$$f_c(\gamma^{pl}) = \begin{cases} f_c^p - (f_c^p - f_c^r) \frac{\gamma^{pl}}{\gamma^r}, & \text{if } \gamma^{pl} \leq \gamma^r \\ f_c^r, & \text{if } \gamma^{pl} \geq \gamma^r \end{cases} \quad (1)$$

where f_c^p and f_c^r denote the peak and residual strength values, respectively; γ^r is a material constant representing the deviatoric plastic strain at which the residual strength is attained; and γ^{pl} is the deviatoric plastic strain.

Following Alonso *et al.* (2003), the latter is defined as follows:

$$\gamma^{pl} = \varepsilon_t^{pl} - \varepsilon_r^{pl}, \quad (2)$$

where ε_t^{pl} and ε_r^{pl} represent the tangential and radial plastic strains, respectively. For the sake of simplicity, we assume that the friction angle is constant.

*Corresponding author: maria.anthi@igt.baug.ethz.ch

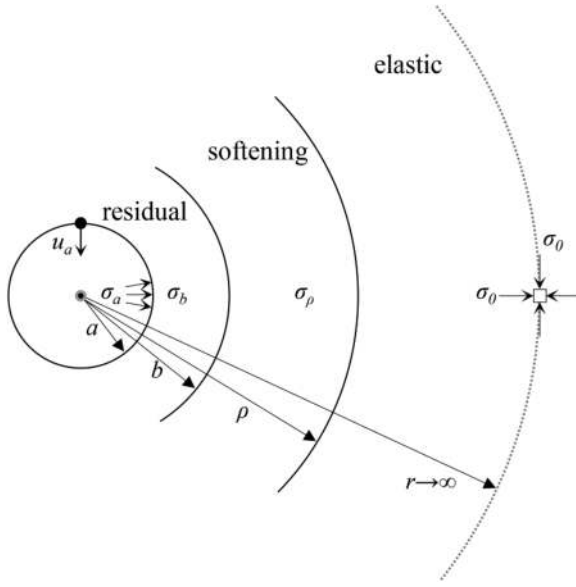

Figure 1. Problem setup and zones of the stress field in a strain softening rock mass.

Figure 2. Strength over deviatoric plastic strain.

Furthermore, considering that in most cases the dilatancy angle is small, a non-associated flow rule with zero plastic volumetric strains will be considered.

3 DERIVATION

We will determine the radial displacement of the tunnel wall that occurs when the radial stress at the tunnel wall decreases from its *in-situ* value σ_0 to the support pressure σ_a . With decreasing radial stress, the rock mass initially remains elastic and, at a certain support pressure σ_ρ , starts experiencing plastic deformations. Further radial stress reduction results in the formation of a zone of radius ρ where the rock mass experiences plastic shearing, and its strength decreases according to the softening law of Figure 2. The deviatoric plastic strain at the excavation boundary may reach γ^r at a certain support pressure σ_b ; in this case, a further decrease in the support pressure ($\sigma_a < \sigma_b$) will result in the formation of an inner plastic zone up to a radius b , where rock strength equals residual strength. So, the system consists in general of three zones, hereafter

referred to as the elastic zone (an infinite body with a cylindrical hole), the softening zone and the residual zone (thick-walled cylinders) (Figure 1). The characteristic line can be determined by considering these three system components separately, taking account of the radial stress and radial displacement continuity conditions at their interfaces.

For simplicity, the abbreviation

$$\bar{\sigma} \dots = \sigma \dots + f_c^p / (m - 1), \quad (3)$$

where m is a function of the friction angle ($m = (1 + \sin\varphi)/(1 - \sin\varphi)$), will be used below for all stresses. The elasticity solutions for a cylindrical tunnel in combination with the condition that the stress state at the boundary ρ of the plastic zone fulfils the yield condition with the peak strength parameters leads to the following expressions for the radial stress σ_ρ and for the radial displacement u_ρ (cf., e.g., Vrakas and Anagnostou, 2014):

$$\bar{\sigma}_\rho = \frac{2\bar{\sigma}_0}{m + 1}, \quad (4)$$

$$u_\rho = \rho \frac{\bar{\sigma}_0 (1 + \nu)(m - 1)}{E (m + 1)}, \quad (5)$$

where E and ν denote the Young's modulus and the Poisson's ratio, respectively.

Under the assumptions made (negligible elastic strains in the plastic zone and negligible plastic volumetric strains), the volume of the plastic zone is constant and consequently the radial displacements fulfil the following condition (Kovári 1985):

$$u_a a = u_\rho \rho = u(r)r = \text{constant}. \quad (6)$$

Introducing u_ρ from Eq. (5) into Eq. (6) leads to the following expression for the radius ρ of the plastic zone as a function of the displacement u_a of the tunnel boundary:

$$\frac{\rho}{a} = \left(\frac{m + 1}{(1 + \nu)(m - 1)} \frac{u_a E}{a \bar{\sigma}_0} \right)^{1/2}. \quad (7)$$

The tangential stress σ_t fulfils the yield condition $\sigma_t = m\sigma_r + f_c(\gamma^{pl})$, where σ_r is the radial stress and $f_c(\gamma^{pl})$ and γ^{pl} are given by Eqs. (1) and (2), respectively, whereby the strains on the r.h.s. of Eq. (2) are obtained from the kinematic relationships with u after Eq. (6). This leads to $\gamma^{pl}(r) = 2\rho u_\rho / r^2$; at the tunnel wall, $\gamma^{pl} = 2\rho u_\rho / a^2$.

Introducing σ_t from the yield condition into the equilibrium condition $d\sigma_r/dr = (\sigma_t - \sigma_r)/r$ results in a differential equation for the radial stress, the solution of which for the boundary condition $\sigma_r(a) = \sigma_a$ provides the stress field in the form $\sigma_r = f(r/\rho, \sigma_a)$. This equation in combination with the condition $\sigma_r(\rho) = \sigma_\rho$ results in a relationship between support pressure σ_a and radius ρ of the plastic zone. More specifically, considering the linear decay part of the softening relation (Figure 2), we obtain:

$$\frac{\bar{\sigma}_a}{\bar{\sigma}_0} = \frac{2}{m+1} \left(\left(\frac{\rho}{a} \right)^{1-m} + \frac{f_c^p - f_c^r (1+\nu)(m-1)}{\gamma^r E} \frac{1}{m+1} \left(\left(\frac{\rho}{a} \right)^2 - \left(\frac{\rho}{a} \right)^{1-m} \right) \right) \quad (8)$$

Eq. (8) holds provided that there is not yet a residual zone, which means that the plastic shear strain at the tunnel wall (which equals $2\rho u_\rho/a^2$ as mentioned above) is less than γ^r . This is the case as long as the radius of the plastic zone is less than a critical value ω :

$$\frac{\rho}{a} \leq \omega = \max \left\{ 1, \sqrt{\frac{\gamma^r E}{\bar{\sigma}_0} \frac{m+1}{2(1+\nu)(m-1)}} \right\}. \quad (9)$$

If the last r.h.s. term of this equation is less than 1, then $\omega = 1$ and a residual zone develops from the start of plastification (see Anthi *et al.*, 2024, for details). The support pressure at the onset of the formation of the residual zone (that is σ_b) can be obtained from Eq. (8) with $\rho/a = \omega$.

If $\sigma_b > 0$, then for $\sigma_a < \sigma_b$ (or, equivalently, for $\rho/a > \omega$) a residual zone develops. The outer radius of the residual zone (b) is such that the support pressure exerted by the residual zone upon the softening zone equals to σ_b and, consequently, $\rho/b = \omega$ or $b = \rho/\omega$. It can be obtained from the bearing capacity equation of a fully plastified thick-walled cylinder that exhibits a uniform strength (the residual strength f_c^r), is loaded at its outer boundary by σ_b and is supported at its inner boundary by σ_a (see, *e.g.*, Kovári 1985):

$$\frac{b}{a} = \frac{\rho/\omega}{a} = \left(\frac{\sigma_b + \frac{f_c^r}{m-1}}{\sigma_a + \frac{f_c^r}{m-1}} \right)^{\frac{1}{m-1}}. \quad (10)$$

Solving this equation with respect to σ_a provides the following expression for the support pressure in the presence of a residual zone, that is for $\rho/a > \omega$:

$$\frac{\bar{\sigma}_a}{\bar{\sigma}_0} = \left(\frac{\bar{\sigma}_b - \frac{f_c^p - f_c^r}{\bar{\sigma}_0} \frac{1}{m-1}}{\bar{\sigma}_0} \right) \left(\frac{\rho/a}{\omega} \right)^{1-m} + \frac{f_c^p - f_c^r}{\bar{\sigma}_0} \frac{1}{m-1}. \quad (11)$$

The non-trivial (plastic) part of the characteristic line can be computed analytically by considering the displacement as an independent parameter (observing the condition $u_a E/a/\bar{\sigma}_0 \geq (1+\nu)(m-1)(m+1)$ in order that $\rho \geq a$) and first computing ρ from Eq. (7). Subsequently, if ρ fulfils the inequality (9), then σ_a is determined from Eq. (8); else σ_b is computed first (from Eq. 8 with $\rho/a = \omega$) and introduced afterwards into Eq. (11), which finally provides σ_a . An inspection of the equations above readily reveals that the characteristic line can be expressed as follows:

$$\frac{\bar{\sigma}_a}{\bar{\sigma}_0} = f \left(\frac{u_a E}{a \bar{\sigma}_0}, \frac{f_c^p - f_c^r}{\bar{\sigma}_0}, \frac{\gamma^r E}{\bar{\sigma}_0}, \varphi, \nu \right). \quad (12)$$

The derivation outlined above can be applied for arbitrary softening laws as well as for Egger's (1974) and Panet's (1976) simplifying assumption regarding the elastic strains in the plastic zone (Anthi *et al.*, 2024).

4 ERROR

To assess the error of the proposed solution, we use Lee and Pietruszczak's (2008) numerical predictions as benchmarks. Figure 3 shows the error in the convergence of an unsupported cavity, calculated as follows:

$$\text{error} = \frac{u_{a,\text{simplified}} - u_{a,\text{exact}}}{u_{a,\text{exact}}} \cdot 100\% \quad (13)$$

The error is given as a function of the dimensionless parameter $\gamma^r E/\sigma_0$, which governs how rapidly the strength drops to its residual value, for two values of the normalised peak strength f_c^p/σ_0 , characterising

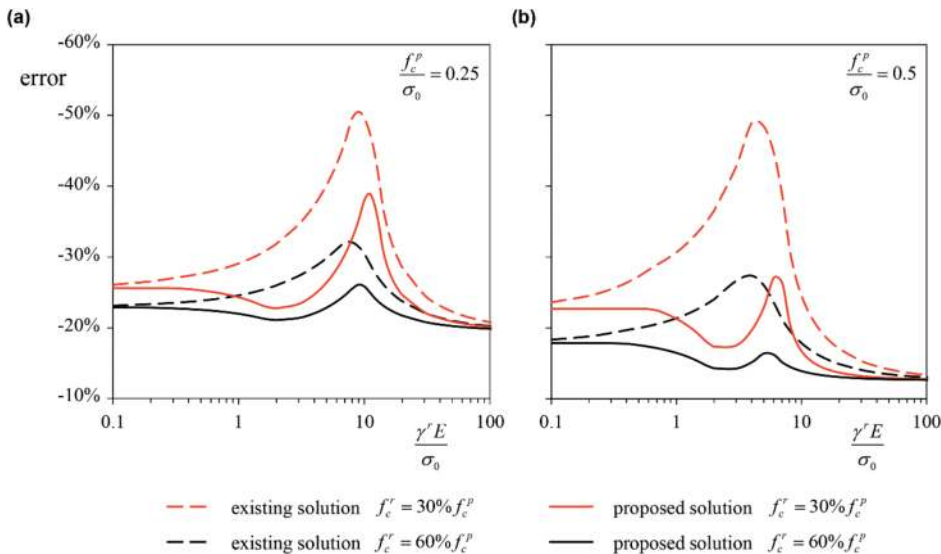

Figure 3. Error of the proposed and of the older analytical solution over the dimensionless factor $\gamma^r E/\sigma_0$ (unsupported tunnel, $\varphi = 30^\circ$, $\nu = 0.3$).

heavy and moderate squeezing conditions (Figures 3a and 3b, respectively), while comparing two values of the residual strength f_c^r as a percentage of the peak strength f_c^p , with red and black curves, respectively.

Each diagram presents two sets of curves. The continuous curves show the error of the simplified solution proposed in this paper, while the dashed curves hold for the former simplified solution. Both solutions underestimate the convergence of the unsupported tunnel, however, the proposed solution exhibits a smaller error. In general, the error increases with decreasing f_c^r and f_c^p/σ_0 . For materials with either low or high values of $\gamma^r E/\sigma_0$ (indicating rather brittle or rather perfectly plastic behaviour, respectively), the simplified solutions converge. For intermediate values of $\gamma^r E/\sigma_0$ (softening behaviour) the proposed solution outperforms the existing one significantly. While the existing simplified solution reaches an error of 50%,

the solution introduced in this paper maintains an error of less than 30% approximately.

5 CHARACTERISTIC LINES

Figure 4 illustrates the effect of the two softening parameters $(f_c^p - f_c^r)/\bar{\sigma}_0$ and $\gamma^r E/\bar{\sigma}_0$. It presents normalised characteristic lines for three values of the strength decay $(f_c^p - f_c^r)/\bar{\sigma}_0 = 0.75, 0.5, 0.25$ (black, blue and orange curves, respectively) and $\gamma^r E/\bar{\sigma}_0 = \infty, 12, 6, 3$ and 0 . The latter expresses how rapidly strength decreases with plastic deformations. The uppermost curve in each set of same colour ($\gamma^r E/\bar{\sigma}_0 \rightarrow 0$) holds for a brittle plastic material characterised by a sudden decrease in strength at the onset of yielding. The lowermost line ($\gamma^r E/\bar{\sigma}_0 \rightarrow \infty$) is common to all sets and holds for a perfectly plastic

Figure 4. Normalized characteristic lines ($\varphi = 30^\circ, \nu = 0.3$).

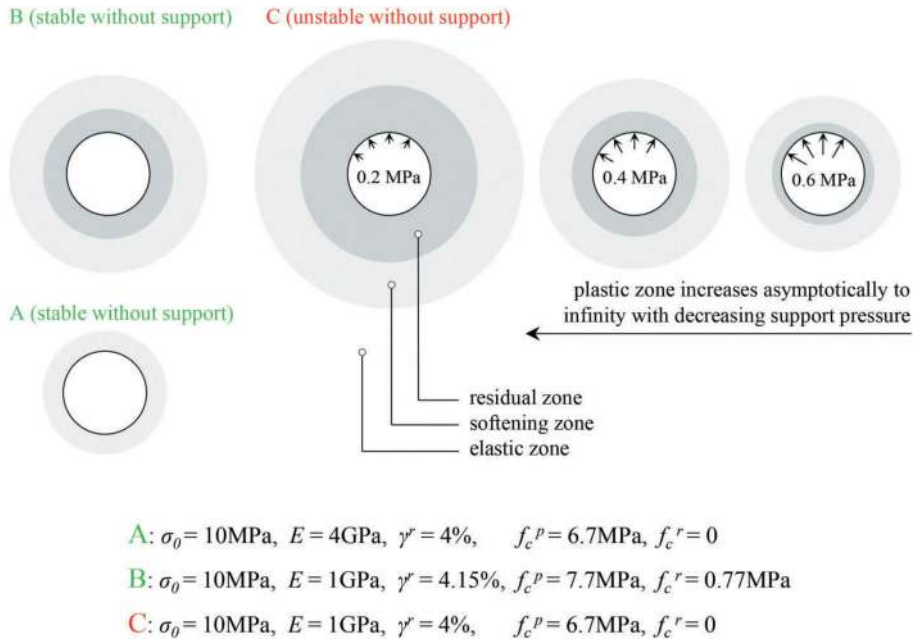

Figure 5. Characteristic lines illustrating stable and unstable conditions ($\varphi = 30^\circ$, $\nu = 0.3$). The presented plastic zones correspond to the marked points of the characteristic lines.

material; it is identical with Kovári's (1985) characteristic line, a straight line in the double-logarithmic diagram. Each characteristic line starts at $\bar{\sigma}_a/\bar{\sigma}_0 = (f_c^p - f_c^r)/\bar{\sigma}_0/(m - 1)$, which is the value of $\bar{\sigma}_a/\bar{\sigma}_0$ when $\sigma_a = 0$ and $f_c^r = 0$. Lower values are not considered because they correspond to negative support pressures and therefore lack physical meaning.

As expected, with decreasing $(f_c^p - f_c^r)/\bar{\sigma}_0$ -value, the effect of $\gamma^r E/\bar{\sigma}_0$ becomes smaller as all lines move towards that of the perfectly plastic material (lowest straight dashed line).

The convergence of an unsupported opening in a rock with zero residual strength stabilises to a finite value, despite the zero residual strength, if $\gamma^r E/\bar{\sigma}_0$ is so large that a residual zone does not form. In the cases of Figure 4, this is true for: $\gamma^r E/\bar{\sigma}_0 = 12$ and $f_c^p/\bar{\sigma}_0 = 0.25$; $\gamma^r E/\bar{\sigma}_0 = 12$ or 6 and $f_c^p/\bar{\sigma}_0 = 0.5$; $\gamma^r E/\bar{\sigma}_0 = 12, 6$ or 3 and $f_c^p/\bar{\sigma}_0 = 0.75$. Otherwise, *i.e.* if $\gamma^r E/\bar{\sigma}_0$ is small enough that a residual zone with zero uniaxial compressive strength develops, equilibrium is not possible and, therefore, the displacements increase asymptotically to infinity as the support pressure tends to zero (Panet, 1976).

To gain a better understanding of the dimensionless representation of the characteristic lines of Figure 4, we focus on the set of blue curves (*i.e.* $(f_c^p - f_c^r)/\bar{\sigma}_0 = 0.5$), examining three cases:

- complete strength loss ($f_c^r = 0$) and $\gamma^r E/\bar{\sigma}_0 = 12$, which is high enough that a residual zone is not formed around the unsupported opening (see characteristic line A and corresponding plastic zone in Figure 5);
- partial strength loss ($f_c^r = 0.10 f_c^p$) and $\gamma^r E/\bar{\sigma}_0 = 3$, which is low and allows residual zone formation around the unsupported opening (curve and plastic zones B in Figure 5); and
- complete strength loss ($f_c^r = 0$) with the same low $\gamma^r E/\bar{\sigma}_0$ of 3, leading to the formation of a zone with zero strength around the unsupported opening (curve and plastic zones C in Figure 5).

In cases A and B, the unsupported opening is stable, whereas in case C, equilibrium is impossible without support (displacements tend towards infinity).

Since curves B and C of Figure 5 correspond to the same normalised curve of Figure 4, one may say that the normalised diagram of Figure 4 presents characteristic lines for cases that are qualitatively different from the constructional viewpoint (stable vs. unstable unsupported openings).

The comparison of the case A (stable without support) with case C (stable without support), which are different only with respect to E (4 and 1 GPa, respectively) shows again that the stability of an unsupported opening also depends on Young's modulus.

6 CONCLUSIONS

An improved analytical solution was derived for assessing tunnel convergences in strain-softening rock masses obeying Mohr-Coulomb yield criterion with linear strength decay during softening.

The characteristic lines are expressed in a dimensionless form, which enables the analysis of qualitatively different cases, *i.e.* stable and unstable unsupported openings, by one and the same characteristic line. Specifically, for a given cavity support pressure and strength drop f_c^r/f_c^p , stable conditions are characterised by a finite dimensionless convergence of the cavity. Otherwise, the convergence tends towards infinity. If the strength at the tunnel wall becomes equal to zero, the tunnel cannot be stable without support.

The derivation of closed-form characteristic lines was made possible by adopting the simplifying assumption of disregarding the elastic strains within the plastic zone. It was shown that the proposed solution consistently outperforms the simplified solution found in the existing literature. However, both analytical solutions underestimate the tunnel convergence compared to rigorous results obtained from the FD model suggested by Lee and Pietruszczak (2008).

ABSTRACT: During tunnel excavation, the accumulated wall displacement and the tunnel support load result from both the tunnel advance and the time-dependent behavior of the surrounding rock mass. One approach to analyze the interactions between tunnel wall displacement and support load is the Convergence-Confinement Method (CCM) using analytical closed-form solutions or empirical Longitudinal Displacement Profiles (LDP). This approach neglects the influence of time dependency on ground response, resulting in delayed deformation increasing significantly within time after the excavation stage. Failure to consider the added delayed displacements in the preliminary design can result in a false selection of the installation time and the support system type, causing safety issues, cost overruns, and project delays. Considering the time-dependent ground response, this paper discusses a revised CCM to estimate the tunnel's support system loads in squeezing ground conditions. The proposed approach combines laboratory-scale physical model test results and observations from the squeezing tunnels worldwide. The first part of this paper explains the CCM and the improvement offered to extend the methodology for squeezing tunnels. The second paper presents the validation of the proposed method.

Keywords: Convergence Confinement Method, Tunnel Support System, Squeezing ground

1 INTRODUCTION

Squeezing ground conditions during tunnel excavation leads to large ground deformations that may continue even after excavation (Barla 1995). In such situations, the load imposed by the ground on the tunnel support system also increases gradually. The ultimate support requirements can be two to three times more in squeezing ground than the same tunnel cross-section in non-squeezing conditions (Jethwa, J. L., Singh, B., & Singh 1984). Hence, estimating the deformations due to squeezing beforehand is vital to ensure safe, efficient, and economical tunnel construction (Barla 2000).

Squeezing ground conditions are associated with clay-rich minerals at a low ratio of rock-mass strength to the in-situ stress at the tunnel location (Terzaghi 1946; Wood 1972). Reported examples of such tunnels include but are not limited to, the John Street Pumping Station Tunnel in Canada (Lo et al. 1987), the Still Water Tunnel in the United States (Phien-wej and Cording 1991), the Uluabat Project Tunnel in Turkey (Bilgin and Algan 2012), and the Laodongshan Tunnel in China (Cao et al. 2018).

Numerous approaches have been proposed in the literature over the years to study tunnel squeezing, which included experimental techniques (Semple 1973; Mesri et al. 2015; Arora et al. 2019, 2021b, a; Arora 2020), numerical analyses (Dusseault and Fordham 1993a; Bonini et al. 2009; Barla et al. 2012; Kabwe et al. 2020), analytical methods (Kallhawy 1974; Ghaboussi and Gioda 1977; Gioda 1981, 1982; Sulem et al. 1987; Pan and Dong 1991; Gioda and Cividini 1996; Singh et al. 2018), and empirical equations (Terzaghi 1946; Deere et al. 1970; Barton et al. 1974; Singh et al. 1992; Goel et al. 1995; Aydan et al. 1996; Schubert 1996; Hoek and Marinos 2000; Manh et al. 2015; Vrakas et al. 2018; Arora et al. 2021c). According to the International Society of Rock Mechanics (ISRM), the most appropriate method for designing tunnels in squeezing ground conditions should incorporate field observations, numerical techniques, and conventional closed-form solutions (ISRM 1994). The methodology must consider ground deformation due to elastoplastic behavior, creep, consolidation, progressive damage and other physical phenomena.

Despite the commendable efforts of researchers over the years to study tunnels in squeezing ground

*Corresponding author: ketanarora@mining.iitkgp.ac.in

conditions, tunnels continue to encounter many engineering surprises (Wang et al. 2019). This lack of definite progress is primarily due to the existing approaches' critical assumptions and limited applicability. For example, the analytical methods proposed in the literature attribute squeezing with the creep and assume no volumetric deformations (Pan and Dong 1991; Gioda and Cividini 1996). However, several past researchers have observed that rocks experience significant volumetric changes during creep (Dusseault and Fordham 1993b; Fabre and Pellet 2006; Arora 2020). Similarly, numerical methods also require a reliable constitutive model for the time-dependent behavior of the rock derived with minimum assumptions (Bonini et al. 2009). On the other hand, the empirical methods are case-specific, hold discrepancies, and are derived from limited field and laboratory experimental observations (Arora et al. 2021c).

From the limitations of the different approaches, it is evident that squeezing phenomena have yet to be extensively studied. An applicable, reliable criterion for squeezing would improve the understanding and, more importantly, could guide the tunnel engineers in designing squeezing-resilient support systems. This paper discusses a convergence-confinement method (CCM) to estimate the loads on the tunnel's support system in squeezing ground conditions. CCM is prevalent in tunnel design, but its application remains limited in squeezing ground conditions. The first part of this paper explains CCM and the proposed extension of the methodology for squeezing tunnels. The second part presents the validation of the proposed method.

2 CONVERGENCE-CONFINEMENT METHODS (CCM)

Tunnel excavation is a three-dimensional (3-D) process involving geomaterial excavation at in situ stress and geostatic conditions. Tunneling mechanically leads to stress redistribution around the excavation boundary and further leads to ground deformation. It is well-studied that the closer the tunnel cross-section is to the tunnel face, the lesser the stress redistribution (Su et al. 2011; Zheng et al. 2016). The tunnel support system design must anticipate the ground deformations and keep the tunnel convergence within the safe limit. Researchers have proposed various analytical and numerical solutions for tunnel design considering the 3-D effects of the excavation (Zhang et al. 2008; Vlachopoulos and Diederichs 2009; Su et al. 2011; Lü and Low 2011; Vrakas and Anagnostou 2016; Hedayat and Weems 2019). Such analysis methods are a primary tool for quickly assessing the system's behavior. Most of the methods are based on the popular and widely used convergence-confinement method (CCM) (Paraskevopoulou and Diederichs 2018).

CCM is a way to incorporate 3-D rock-support interaction response in tunnels into a two-

dimensional (2-D) plane model (AFTES 1983). The method requires the study of the following three components:

- Ground reaction curve* (GRC) relating radial internal support pressure p_i and tunnel wall displacement (convergence) u .
- Support Characteristic Curve* (SCC) relating convergence provided by the support p_i to the support convergence.
- Longitudinal displacement profile* (LDP) relating convergence of the tunnel boundary u to the distance from the tunnel face x_f . The LDP approximates the 3-D deformation of the tunnel in a 2-D model.

GRC and SCC are derived analytically in a typical CCM, while the LDP is considered for the unsupported tunnel. Figure 1 illustrates the calculation of the stresses on the liner using CCM. Figure 1a shows an advancing tunnel in an isotropic stress-state p_o . For a given position of tunnel face, the liner is installed at some distance behind the tunnel face, creating a 'lag' in Figure 1a. The tunnel cross-section 1-1' at the lag distance from the face is shown in Figure 1b. Figure 1c shows GRC, LDP and SCC for the tunnel excavated in an anisotropic stress state. In the plot, internal pressure on the tunnel boundary p_i is normalized with p_o , and tunnel convergence u and distance from the face x_f are normalized with respect to the tunnel radius R . Support stress calculation using CCM by converting the 3-D tunnel problem into a simplified 2-D problem is elaborated in the following steps:

At the time of support installation

- Point 1 in Figure 1c represents the lag distance, i.e., the longitudinal distance between the tunnel face and the cross-section (AA' in Figure 1a) at which the tunnel support is installed.
- In Figure 1c, point 1 is projected on the LDP through a horizontal line to reach point 2. Point 2 represents section 1-1' on LDP.
- Point 2 is projected on the convergence axis to obtain point 3, representing the tunnel's convergence before support installation. If the tunnel does not advance further, this will be the ultimate convergence of the tunnel cross-section 1-1'. The SCC will govern any increment in tunnel convergence beyond this point.
- The convergence point of the previous step is marked on the GRC as point 4, and its projection of the internal pressure axis will provide support pressure p_f supplied by the tunnel face to section 1-1' (point 5).
- As the tunnel advances further, the longitudinal distance of section 1-1' from the tunnel face will increase. Once the tunnel excavation is complete, the position of this section is defined by point 6 in Figure 1c and represented by point 7 on the LDP. The critical point to be considered in the further analysis is that the LDPs are defined for unsupported

- tunnels, and in this case, section A-A' was supported as the tunnel advanced by distance x_f .
- f) Project point 7 on the LDP vertically to the SCC in Figure 1c to get point 8. This point represents the load carried by the support system and the total convergence of the tunnel. The support pressure is represented by the 9 in Figure 1c.

Using the steps mentioned above, tunnel designers have determined the support system's design load for a given allowable convergence. However, in squeezing ground conditions, the surrounding ground continues to converge even after the excavation.

The LDP of the tunnel also changes due to the time-dependent behavior of the material. This paper presents a new approach for estimating the loads on the tunnel support system in squeezing ground conditions. A time-dependent LDP is incorporated in

the CCM, which accounts for the increase in support load with time. The new methodology and the changes included in the existing CCM (defined above) are discussed in the following section.

3 METHODOLOGY

3.1 A time-dependent LDP

One major shortcoming of the CCM technique described above is that the time-dependent behavior of the ground material around the tunnel boundary is not explicitly considered. Time-dependent closure in squeezing ground can have a considerable impact on support loading. Failure to account for these additional loads can result in unforeseen failures, causing safety concerns, ultimately leading to tunnel collapse

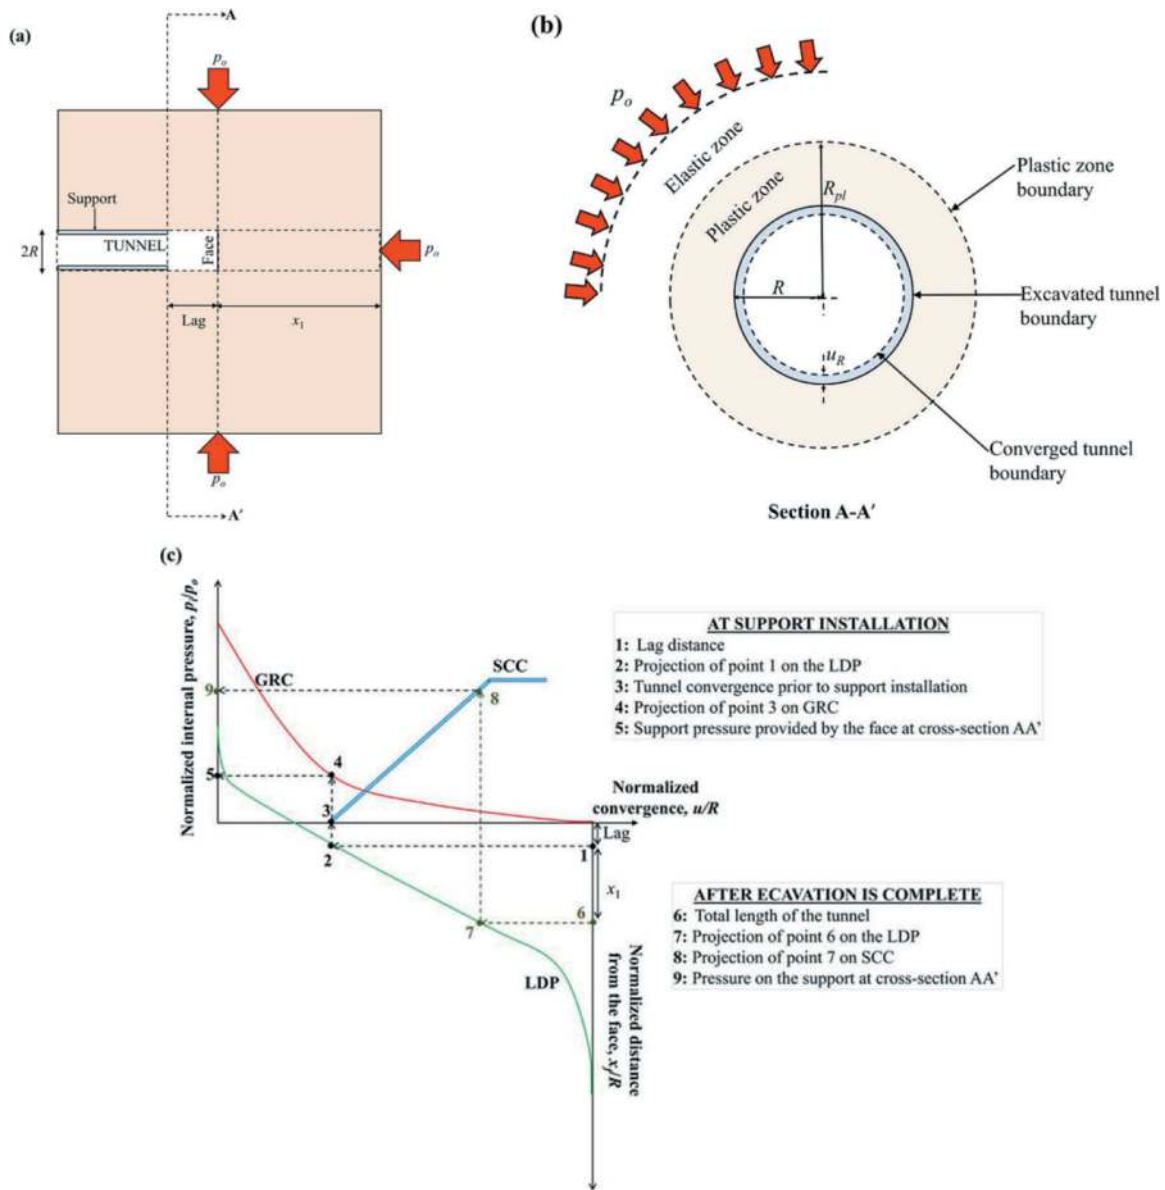

Figure 1. Schematic diagram of (a) an advancing tunnel of radius R in isotropic stress p_o , (b) tunnel cross-section A-A' and (c) plot showing GRC, SCC and LDP for section A-A'.

Figure 2. Application of the time-dependent LDP in CCM to estimate the post-excavation squeezing loading on the tunnel support system.

(Arora 2020). Gschwandtner & Galler (2012) suggested applying CCM in squeezing ground to investigate the behavior of different support systems (e.g., combinations of shotcrete and rock-bolts) with time.

One possible way of introducing the time-dependent behavior in the CCM is by introducing time-dependent LDP. Based on their experimental observations, Arora et al. (2021b) proposed the following time-dependent LDP for the tunnels in squeezing clay-rich rocks:

$$\frac{u}{R}(t) = a - b(d)^t \quad (1)$$

where, for any tunnel cross-section, u/R is the normalized tunnel convergence (in percentage) for

a tunnel with a radius R ; a and b are the model parameter; d is the time-factor for squeezing ground conditions equal to 0.98; and t is the time (in hours) after excavation is complete. The model parameter a is a function of in-situ stress at tunnel level p_o and distance of the tunnel cross-section from the face x_f . Parameter b was observed to be a function p_o and independent of x_f . Hence, a and b can be expressed as:

$$a = f\left(X, \frac{p_o}{\sigma_c}\right) \quad (2)$$

$$b = h\left(\frac{p_o}{\sigma_c}\right) = 1.22\left(\frac{p_o}{\sigma_c}\right)^{1.913} \quad (3)$$

where $X = x_f/R$ is the normalized distance of the tunnel cross-section from the face; p_o is the isotropic stress at the tunnel location before excavation and σ_c is the unconfined compressive strength of the geomaterial at the tunnel location. For a given ratio of p_o/σ_c , parameter a was observed to increase linearly with an increase in X . Also, for a given tunnel cross-section (constant X), parameter a increases with an increase in ratio p_o/σ_c . The correlations presented in Equation (2) and (3) are based on the experimental observations from physical model tests on cubical synthetic mudstone specimens by Arora et al. (2021b).

3.1 Revised CCM

The inclusion of the time-dependent LDP in the CCM to determine post-excavation increment in design support pressure due to squeezing ground is presented in Figure 2. Consider a tunnel cross-section 1-1' at a distance x_1 from the tunnel face. The LDPs for the tunnel at three different times t_1 , t_2 and t_3 in hours ($t_3 > t_2 > t_1$) are shown in the plot in Figure 2. The points on the three LDPs representing tunnel cross-section A-A' are projected on the GRC as shown in Figure 2.

For the tunnel cross-section A-A', the normalized reduction in ground pressures due to squeezing are marked as P_1 , P_2 and P_3 at time t_1 , t_2 and t_3 , respectively, in Figure 2. In Figure 2, it can be observed in Figure 2 that from time t_1 to t_2 , the decrease in ground pressure is $P_1 - P_2$. This research considers that this difference in ground pressure is directly transferred to the support, as shown in Figure 2.

The stability of the tunnel support system in the squeezing can be checked using the proposed CCM. The first step is to determine the tunnel's LDP infinite time and mark the convergence for this unsupported tunnel cross-section on the LDP. Then this LDP is projected vertically on the GRC to find the reduction in ground pressure. This pressure reduction is projected on the SCC as an increment. If the new point crosses the yield after increment, the support has failed.

4 EXTENSION OF THE TIME-DEPENDENT LDP

The approach proposed in this paper to estimate the squeezing loads on the tunnel support system utilizes a time-dependent LDP. The parameters a and b for this LDP are well defined by Arora et al. (2021b) for synthetic mudstone at different stress to strength ratio p_o/σ_c and normalized distance from the tunnel face X . The dependency of the parameter a and b on material properties should be calibrated for broader applicability.

The parameters a and b can be defined as follows: At time $t = 0$ and for $d = 0.98$ hours in Equation (1), the convergence can be determined by the following equation,

$$\left(\frac{u}{R}\right)_i = a - b \quad (4)$$

where $(u/R)_i$ is the convergence of the tunnel at time $t = 0$ hours, i.e., the ground has not squeezed yet. Similarly, as the time approaches infinity in Equation (1), the convergence reduces as,

$$\left(\frac{u}{R}\right)_u = a \quad (5)$$

where $(u/R)_u$ is the ultimate convergence of the tunnel due to squeezing and non-squeezing factors. The ultimate convergence as defined by Hoek & Marinos (2000) for the tunnels excavated in squeezing ground conditions can be defined by the following equation:

$$\left(\frac{u}{R}\right)_u = 0.2 \left(\frac{p_o}{\sigma_{cl}}\right)^2 \quad (6)$$

Equation (6) is defined for the tunnel cross-section at a considerable distance from the tunnel face. However, for tunnel cross-sections closer to the face, Equation (6) changes to,

$$\left(\frac{u}{R}\right)_u = 0.2 \left(\frac{p_o}{\sigma_{cl}}\right)^2 F_L \quad (7)$$

where σ_{cl} is the long-term compressive strength of the geomaterial at the tunnel location; F_L is the long-term tunnel face factor introduced to convert the 3-D problem into 2-D defined by Vlachopoulos & Diederichs (Vlachopoulos and Diederichs 2009) as,

$$F_L = 1 - \left[1 - \frac{1}{3} \exp(-0.15R^*)\right] \exp\left(-\frac{3X}{2R^*}\right) \quad (8)$$

In the above equation, R^* is the ratio of the extent of the long-term plastic zone radius R_{pl} to the excavated tunnel radius R . The plastic zone radius R_{pl} can be defined as (Hoek and Marinos 2000),

$$R_{pl} = 1.25R \left(\frac{p_o}{\sigma_{cl}}\right)^{0.57} \quad (9)$$

Combining Equation (5) and (7) yields,

$$a = 0.2 \left(\frac{p_o}{\sigma_{cl}}\right)^2 F_L \quad (10)$$

Similarly, the convergence of the tunnel immediately after the excavation can be defined by the following equation:

$$\left(\frac{u}{R}\right)_i = 0.2 \left(\frac{p_o}{\sigma_{cs}}\right)^2 F_S \quad (11)$$

where σ_{cs} is the short-term compressive strength of the geomaterial at the tunnel location. The major difference between short-term and long-term compressive strength is that the latter considers the effect of creep, progressive breakdown of individual rock pieces under high stress and groundwater percolation. The parameter F_S is defined as,

$$F_S = 1 - \left[1 - \frac{1}{3} \exp(-0.15R^*)\right] \exp\left(-\frac{3X}{2R^*}\right) \quad (12)$$

where R^* is the ratio of the extent of the plastic zone R_{pl} in the short-term to the radius of the excavated tunnel R . To determine short-term R_{pl} , σ_{cl} is replaced by σ_{cs} in Equation (9).

Using Equation (4), (10) and (11) results in,

$$b = 0.2 \left[\left(\frac{p_o}{\sigma_{cl}}\right)^2 F_L - \left(\frac{p_o}{\sigma_{cs}}\right)^2 F_S \right] \quad (13)$$

Substituting a and b in Equation (10) and (13), respectively into Equation (1), a generalized time-dependent LDP for the tunnel is obtained as follows

$$\frac{u}{R}(t) = 0.2 \left\{ \left(\frac{p_o}{\sigma_{cl}}\right)^2 F_L - \left[\left(\frac{p_o}{\sigma_{cl}}\right)^2 F_L - \left(\frac{p_o}{\sigma_{cs}}\right)^2 F_S \right] 0.98^t \right\} \quad (14)$$

The above LDP can be incorporated in CCM as described above to estimate the time-dependent squeezing load on the tunnel support system.

Considering the effect of time in the interactions of support load and tunnel pressure is essential to have a safe and economic support system. Using long-term response alone will be unsafe if shear strength increases with time because actual failure can occur at a lower strength and at an earlier time (i.e., using long-term shear strength is unconservative). For ground where shear strength decreases with time, long-term shear strength will be uneconomical because the actual shear strength at failure will be larger than the long-term shear strength.

5 APPLICATIONS OF THE PROPOSED CCM

The model presented in this paper is applied to the Yacambu'-Quibor tunnel in the State of Lara in Venezuela. This tunnel is recognized as one of the most challenging tunnels ever excavated. The primary reason for the difficulty was the squeezing. The project, geology and the significant issues are briefly discussed in the following section.

5.1 Yacambu'-Ouibor tunnel

The 5-m diameter and 24.3-km long tunnel was designed to carry water through the Andes from the Yacambu dam in the wet tropical Orinoco basin to the semi-arid yet fertile Quibor basin in western Venezuela. The tunnel was located in silicified and graphitic phyllites at depths of up to 1270 m below the surface. As per the descriptive method of classifying rock, Yacambu'-Quibor tunnel location had five classes of rock identified as A, B C, D1 and D2. The class A rock predominantly was silicified phyllite with small amounts of calcareous and/or graphitic phyllite. Class B rock had calcareous silicified phyllite with intervals of graphitic phyllite. In the class C rock, Graphitic phyllite with some intervals of silicified phyllite was found. The class D1 rock was tectonically deformed, folded and sheared form of classes A, B and C. The highly

squeezing class D2 had class D1 rock with clay gouge in contact. Several tunnel sections along class D2 rock experienced severe squeezing problems, creating technical, financial and political conflicts between the client and contractors (Hoek and Guevara 2009).

In 1976, ineffective attempts were made to counter the squeezing by using an open-face TBM and a heavy support system. For the next 28 years, several shapes of tunnels cross-section and support type were analyzed to overcome the difficulties encountered during construction. In 2004, the agreement on the use of yielding support with circular cross-section was cleared by the owner's and the contractor's conflicts. The emphasis was placed on developing a routine construction procedure, irrespective of the rock conditions encountered at the face. Figure 3 shows the longitudinal cross-section along the alignment of the Yacambu'-Quibor tunnel. Eight contractors constructed the tunnel in more than 32 years, and the breakthrough was finally achieved in July 2008.

5.2 Study of the most challenging tunnel cross-section

Hoek & Guevara (Hoek and Guevara 2009) identified the most challenging tunnel segments of the tunnel alignment based on the combination of overburden and rock mass properties. The analysis was carried out for a 5.2-m diameter section of the Yacambu'-Quibor tunnel mined at a depth of 1000 m below surface in class D2 rock. The short-term and long-term properties of the class D2 rock as considered in their analysis are summarized in Table 1.

Figure 4 Shows the short-term and long-term ground reaction curves (GRCs) for the Yacambu'-Quibor tunnel in D2 rock as monitored in the field (Hoek and Guevara 2009). Calculating the GRC for short-term and long-term rock mass properties has only been applied to the plastic zone. It is assumed that long-term changes due to displacement-induced damage, air and water circulation, and the like will be restricted to this zone. Upon comparing the

Figure 3. Cross-section along the alignment of the Yacambu'-Quibor water conveyance tunnel in Venezuela.

plotted GRCs, there is a significant amount of squeezing that the rock experiences with time, and designing the tunnel considering short-term properties as design parameters will be disastrous.

The model-generated short-term (at $t = 0$ hours) and long-term LDPs are plotted in Figure 5 for the studied tunnel alignment using the properties in Table 1 and Equation (1) through (14). It can be seen in Figure 5 that the difference between short-term and long-term convergence is between 2.5% to 15% for X , varying between 0 to 20. This longitudinal displacement profile is based on the combination of experimental study by Arora et al. (2021b) and field observations of Hoek & Marinos (2000). The extent of the plastic zone R_{pl} was 9.90 m and 12.98 m, respectively, considering the short-term and long-term properties listed in Table 1.

Table 1. Short-term and long-term properties of D2 rock along Yacambu'-Quibor tunnel's alignment.

Property for tunnel section in D2 rock	Short-term value	Long-term value
Depth below surface H	1000 m	
Unit weight of rock mass γ	0.026 MN/m ³	
In situ stress p_o	26 MPa	
Cohesive strength c	1.26 MPa	0.84 MPa
Friction angle ϕ	21.2°	17.4°
Rock mass compressive strength σ_c	3.68 MPa	2.29 MPa
Elastic modulus E	1.65 GPa	0.93 GPa

From several years of experience and field observations, tunnel designers determined that, for the deepest sections of the tunnel in the poor-quality rock, the tunnel would be circular and that it would be lined with a high-quality shotcrete lining (Hoek and Guevara 2009). The shotcrete was mixed at surface batching plants adjacent to the portals and transported by rail to the faces, where it was applied as a wet mix. The tests on in-situ drilled shotcrete cores provided a uniaxial

Figure 4. Ground reaction curves (GRCs) for the critical section of the Yacambu'-Quibor tunnel for the short-term and long-term properties, as Hoek & Guevara (2009) reported.

compressive strength of 30 MPa with a minimal standard deviation. The shotcrete had no fiber added as a reinforcing material, as the lining was under compressive loading only. The only parameters to be decided were the thickness of the lining and the timing.

Figure 5. Short-term ($t = 0$ hours) and long-term ($t = \infty$ hours) Longitudinal Displacement profiles (LDPs) for the critical zone of Yacambu'-Quibor tunnel.

In this study, the stability analysis of the tunnel liner thickness between 0.2 m to 1.0 m has been studied. The unconfined compressive strength of the shotcrete is taken as 30 MPa, and the shotcrete is installed 2 m behind the face. The shotcrete's Support Characteristic Curves (SCC) were determined by the methodology defined by Hoek & Brown (1980). The increment in load due to squeezing ground conditions was determined as per the procedure discussed in section 3.2. Figure 6 shows the CCM for the critical cross-section of the Yacambu'-Quibor tunnel. It can be observed from the CCM analysis that, due to squeezing, the change in p/p_o is 0.13. This change will be added to the tunnel support system per the proposed method. If the support does not yield due to this stress increment, it is stable against the squeezing.

Figure 6 Also shows the SCC for shotcrete liner thickness 0.2 m to 1 m. Considering that the tunnel did not advance after installing the shotcrete liner, it will be reasonable to assume that all stresses on the

Figure 6. CCM for the Yacambu'-Quibor tunnel along with SCC for the tested shotcrete liners for different shotcrete thickness.

liner will be due to squeezing. It can be seen from the SCC of shotcrete in Figure 6 that the 0.2 m shotcrete will yield when subjected to p_i/p_o increment of 0.13. The 0.4 m thick shotcrete liner will be on the verge of yielding and should be considered a primary tunnel support system. The shotcrete liner having a thickness of 0.6 m and more will take the additional squeezing load without yielding. This 0.6 m liner thickness is the same as the actual thickness of shotcrete used in constructing the Yacambu'-Quibor tunnel (Hoek and Guevara 2009). Based on these results, the application and validity of the proposed method for estimating the squeezing load on the tunnel support system are demonstrated for the Yacambu'-Quibor tunnel.

6 CONCLUSIONS

Convergence Confinement Method (CCM) is one of the popular techniques for the three-dimensional study of tunnel construction. However, most CCM studies do not consider the ground time-dependent behavior around the tunnel boundary. The revised CCM proposed in this paper can be used to estimate tunnel support loads in squeezing ground conditions. The methodology considers time-dependent behavior due to creep and progressive breakdown of individual rock pieces under high stress.

The method is relatively simple and requires only the ground's short-term and long-term strength parameters, which can be easily determined through laboratory tests.

The methodology has been derived from laboratory-scale physical model tests and observations from the hundreds of tunnels excavated in a highly overstressed squeezing zone. Hence, the method is reliable and will have broader applicability. The applicability and validity of the proposed procedure were verified using the Yacambu'-Quibor tunnel.

It is envisioned that the proposed time-dependent CCM will contribute to tunnel design and construction theory and practice in squeezing ground, mainly if used in conjunction with tunnel monitoring and laboratory data.

Tunnelling in weak sandstone: A case study of Subansiri Lower Hydroelectric Project (2000 MW)

Mohammed Shakeel Chouhan

Vice President – Projects, Patel Engineering Limited, Patel Estate, Jogeshwari (W), Mumbai, Maharashtra, India

Sandeep Potnis

Professor & Head, Tunnel Engineering Program, MIT World Peace University, Pune, Maharashtra, India

ABSTRACT: The Subansiri Lower, *the largest under construction Hydro Electric Project in India having installed capacity of 2000MW*, stands as a prominent run-of-river scheme strategically situated near the gorge mouth of the Subansiri River, which forms a natural boundary between the states of Arunachal Pradesh and Assam. Being a significant right bank tributary, the Subansiri River contributes around 11% of the total discharge of the mighty Brahmaputra River. At present, the project is in its final stage of construction, gearing up to harness its full potential. This ambitious venture encompasses a complex network of tunnels. The Hydraulic Headrace Tunnel (HRT) complex boasts an impressive arrangement of 08 parallel tunnels, while the Surge Tunnel comprises an additional 08 tunnels, each boasting a finished diameter of 9.5 m. The geological composition of the project region primarily comprises fragile sandstone from the Middle Siwalik group of rocks. Nestled within the delicate Outer Himalayas, the project site is demarcated by the imposing Main Boundary Fault to the north, and the formidable Main Frontal Fault to the south. The rocks in this area exhibit an Unconfined Compressive Strength (UCS) ranging from 10 to 25 Mpa under dry conditions and 2 - 7 Mpa under saturated conditions. Tunnelling operations in this geological setting have faced significant challenges due to the soft nature of the rock mass, lack of fissility, and the presence of a higher percentage of fine grain matrix, resulting in low cutting rates and substantial dust generation. Innovative engineering solutions, including the use of road headers and twin cutters, were adopted for excavation, and dust suppression techniques were implemented. However, the formation of slush due to water usage for dust suppression posed difficulties in muck handling. Rock mass classification using the Rock Mass Rating (RMR) system was limited in addressing the rock's massive and weak nature. Hence, a hindrance-based classification approach was introduced, considering factors like rock support and excavation difficulty. This approach offered a more comprehensive understanding of the challenges encountered during tunnelling. This paper presents a detailed case study of the tunnelling operations undertaken in the Subansiri Lower HEP, focusing on the unique geological complexities of weak sandstone and the innovative engineering solutions applied to ensure successful tunnel construction. The study sheds light on the specific challenges faced during tunnelling in weak sandstone and provides valuable insights for similar projects in comparable geological conditions.

1 INTRODUCTION

The Subansiri Lower HE Project (2000MW) is a run-of-river scheme and is located near the gorge mouth of the river Subansiri bordering both the states of Arunachal Pradesh and Assam. Subansiri River, contributing about 11% of total discharge, is a major right bank tributary of great Brahmaputra River. It originates in the high Himalayan ranges in southern Tibet. As per the study on "Reassessment of Hydroelectric Potential" carried out by CEA during 1978-87, a total of 25 hydroelectric schemes with a potential of 6892MW, have been identified in the Subansiri Basin. Subansiri Lower H.E project is around 471 kilometers from Guwahati and 16 kilometers from Gogamukh, a small town on NH-52.

The dam is located on the river Subansiri, 2.3 kilometers upstream of Gerukamukh Village on the Assam-Arunachal Pradesh border. The dam's left abutment is in Assam, and its right abutment is in Arunachal Pradesh. The proposal proposes to use 91m of gross head by building a 166m high concrete gravity dam with a surface powerhouse with a capacity of 2000MW. The stored water is routed to the powerhouse via eight 9.5 Dia horse shoe shaped head race tunnels and an 8m diameter steel walled pressure shaft. After flowing through the turbine in the powerhouse, the water will be dumped back into the river via tail race channel (Figure 1 &2). Because this is a run-of-the-river scheme, there will be a constant flow of water even during the lean season in the river system.

2 LITERATURE REVIEW

1. Geotechnical Challenges of Tunneling in Weak Sandstone: A Case Study by A. Smith and B. Johnson: The geotechnical difficulties encountered during a tunneling project in brittle sandstone are covered in this case study. It emphasizes the value of ground improvement methods, site-specific description, and support systems.
2. Strength and Deformation Characteristics of Weak Sandstone for Tunneling by M. Patel and S. Gupta: This study paper provides a thorough examination of weak sandstone's strength and

deformation characteristics. It investigates laboratory testing techniques and how they apply to tunneling operations.

3. Numerical Modeling of Tunneling in Weak Sandstone by J. Wang and X. Li: In this paper, the main topic is the simulation of weak sandstone tunneling using numerical modeling. It talks about modeling techniques like the finite element method for predicting ground behavior and evaluating tunnel stability.
4. Numerical Modeling of Weak Rock Tunneling by H. Kang and H. Konietzky: The behavior of tunnels in weak rock is examined and predicted using numerical modeling in this research. It investigates several modeling strategies and their uses.
5. Tunnel Support Systems for Weak Sandstone: A Review by R. Sharma and N. Verma: In this review paper, numerous tunnel support systems are analyzed along with how well they work with weak sandstone conditions. It talks about the efficiency and effectiveness of ground reinforcement procedures.
6. Tunnel Support Design in Weak Rocks: A Case Study by M. Ghosh and S. Das: This case study investigates the difficulties encountered with constructing a tunnel through brittle rock and the engineering of tunnel support systems. The significance of site-specific assessments and monitoring is emphasized.
7. Influence of Geological Features on Tunnel Stability in Weak Rock” by L. Li and C. Tang: This study investigates the effects of fault zones and joint systems on the stability of tunnels in weak rock. It talks about the necessity of thorough geological studies and suitable countermeasures.
8. Ground Improvement Techniques for Weak Sandstone Tunnels by K. Tan and G. Lim: This study investigates soil reinforcement and grouting as ground enhancement techniques to increase tunnel stability in sandstone that is brittle. It explores real-world applications while presenting case studies.
9. Grouting Techniques for Weak Rock Tunneling by P. C. Chiu and K. Soga: This study discusses grouting methods for strengthening the stability of tunnels in brittle rock. It talks about the uses of different grouting techniques and how effective they are.
10. Tunneling in Sandstone with Varying Strength: Lessons from Field Projects by E. Chen and H. Liu: The tunneling efforts in sandstone rocks with varying strengths are discussed in this publication's insights learned section. It highlights the importance of flexibility and ongoing observation.
11. Instrumentation and Monitoring of Weak Sandstone Tunnels by S. Das and P. Kumar: In order to determine the behavior of weak sandstone during tunnel construction, this paper highlights the significance of equipment and monitoring. It

- addresses methods for gathering data, analyzing it, and reducing risks.
12. Instrumentation and Monitoring in Weak Rock Tunnels by M. Karakus and H. K. Kim: This study focuses on the significance of monitoring and instrumentation systems in identifying and controlling the hazards related to tunneling in weak rock. It offers perceptions into the gathering and interpreting of real-time data.
 13. Case Studies of Tunnels in Weak Sandstone by D. Zhao and L. Wu: These case studies highlight tunneling initiatives carried out in brittle sandstone deposits across the world. It offers understanding into the problems encountered and the solutions put into practice in varied circumstances.
 14. Case Studies of Weak Rock Tunneling Projects by D. Hoek and E. Marinos: A collection of case studies from weak rock tunneling projects from all around the world are presented in this paper. It highlights the difficulties encountered and the lessons discovered via these undertakings.
 15. Tunneling in Soft Rock – Subansiri Hydroelectric Project, Arunachal Pradesh, India. - by Arvind Garg, Alok Kumar Rahul, and Dr. Devojit Bezbaruah: The study highlights the importance of comprehensive geological and geotechnical investigations for tunneling projects. Mechanical excavation methods should be carefully chosen and accompanied by proper ventilation plans. the project faces significant challenges due to the weak sandstone rock type found in the region. The rock exhibits unique characteristics such as low uniaxial compressive strength (UCS) and the presence of fine-grained matrix and carbonaceous material, resulting in reduced tunneling efficiency. Furthermore, the limitations of existing rock mass classification systems must be acknowledged in challenging geological conditions. This literature review explores the geological setup of the area, construction methods, and the challenges encountered during tunnel excavation, including dust generation and water use. Additionally, it discusses the limitations of conventional rock mass classification systems like RMR and Q-system and presents an alternative classification approach based on hindrances during tunneling.
 16. Challenges in Weak Rock Tunneling and Their Mitigation Measures: A Review by V. R. Sastry and G. R. Reddy: This review study explores the numerous difficulties that can arise while tunneling through brittle rock formations. It talks about ground improvement techniques, grouting procedures, and support systems as examples of mitigating strategies.
 17. Tunneling in Weak Rock - A Review by R. Gertsch and F. F. B. Zettler: In-depth analysis of tunneling in weak rock is provided in this work, with a focus on geotechnical considerations, rock mechanics, and case studies. It goes through how weak rocks are categorized, what makes them weak, and how geological circumstances affect tunnel stability.
 18. Rock Mass Classification for Weak Sandstone Tunneling by A. Gupta and S. Rajan: The classification of rock masses for weak sandstone is covered in this article. It talks about the difficulties in describing diverse formations and how they affect tunnel design.
 19. Rock Mass Classification Systems for Weak Rock Tunnels by E. Hoek: This study covers strategies for classifying rock masses that are particularly pertinent for tunneling through weak rock. It examines the Hoek-Brown failure criterion and how to use it to evaluate tunnel stability in weak rock.
 20. Issues and Challenges in Construction of Hydro Tunnel in Extreme Geological conditions in India – An Empirical Study by Rakesh Kumar Khali and Dr. Sandeep Potmis: This review explores the numerous difficulties geological challenges encountered during the construction of the Vishnugad Pipalkoti Head Race Tunnel project, which navigates through a geologically intricate landscape characterized by dolomitic limestone and slate formations, thrust zones, shear zones, and fault zones. These geological challenges profoundly influence excavation procedures, safety measures, and project timelines. The HRT, located in an area dominated by dolomitic limestone and slate, requires a nuanced understanding of these geological units and their implications for tunnel construction. The adoption of Tunnel-Boring Machines (TBMs) stands as a vital solution to mitigate risks and ensure project success in the face of extreme geological conditions.

3 REGIONAL GEOLOGY OF THE PROJECT AREA

The entire project is made of sandstone from the middle Siwalik Formation. The sandstone is medium to fine grained, soft having typical salt and paper texture. It is massive to moderate joint and current bedded at places. Stringers and lenses of carbonaceous materials as well as concretionary nodules (of much harder sandstone) are also present occasionally. Due to the soft nature of the rock valley slopes are deeply dissected by streams (nallahs) controlled by the master joints.

The rock units are aligned in NE-SW trend with folded and local window structures. The project area is separated by two major tectonic plates namely main boundary fault (MBT) at about 9 km U/s of the dam site at north and Himalayan frontal thrust (HFT) at about 5 km D/s of the project layout. MBT, the northerly dipping fault demarcates the tectonic boundary between the Lesser Himalayas and Sub Himalayas while HFT, the north dipping low angle thrust has brought the Siwalik group of rocks in juxtaposition with recent alluvium of Brahmaputra plains.

4 OVERALL STRATIGRAPHIC SUCCESSION OF THE AREA ARE AS FOLLOWS:

Table 1. Stratigraphy of project area.

Age	Formation	Rock Type
Recent to Sub Recent (0.01 million Year till date)	Alluvial & Terrace Deposit	Boulders, Pebbles, Silt & Sands (Unconsolidated)
Pleistocene (0.01 - 1.80 million Year)	Younger Parts of Dihing beds & Upper most Siwalik	Weakly consolidated beds of Sandstone, Mudstone & Pebbles showing slight dips
Pliocene (1.8 - 5.3 million Year)	Siwalik (Upper) Dihing Namsangs	Sandstone, Conglomerate, Pebbles beds
*****Unconformity*****		
Miocene (5.3 - 23.8 million Year)	Middle Siwalik Lower Siwalik (Equivalent to Tipams, Surmas)	Sandstone, Siltstone, Claystone
Project Location		
*****Unconformity*****		

5 LITHOSTRATIGRAPHIC SUCCESSION OF THE PROJECT AREA

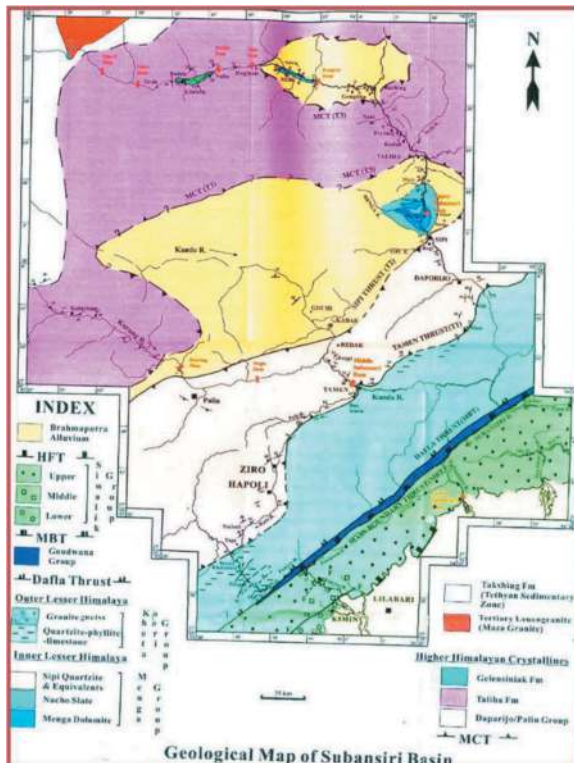

Figure 4. Geological map of subansiri basin.

6 SITE GEOLOGY

The Subansiri Lower HEP site is predominantly composed of sandstone from the middle Siwalik formation, also known as the Subansiri formation. These sandstones exhibit a medium to fine grain texture, characterized by a typical “salt and pepper” appearance, and possess a soft and friable nature. At various locations, the sandstone forms massive beds, while occasional occurrences of stringers and carbonaceous materials are also observed. Notably, the sandstone exhibits embedded rounded pebbles of quartzite and lenses of pebbles originating from concretionary nodules with diagenetic origins. Upon conducting a petrological analysis of the rock, it is revealed that the sandstone primarily consists of quartz (3-5%) and feldspar (5-8%), along with trace amounts of chlorite, biotite, and muscovite (approximately 3-5%). The fine-grained matrix is composed of quartz, calcareous, and carbonaceous material, constituting approximately 15-20% of the rock’s composition. Comparison of UCS values during investigation and construction stages is illustrated in Figure 5. Geotechnical characteristics of discontinuities observed in during underground excavation are given in Table 2.

Figure 5. Comparison of uniaxial compressive strength determined during investigation & construction stage.

7 HEAD RACE TUNNEL (HRT)

Two sets of tunnels, each comprising 4 no’s horse shoe shaped HRT of 9.5M dia. each are constructed on right bank of Subansiri River with their intakes located between 180m and 445m upstream of dam axis keeping invert at EL. 160M. The total length of HRT designed for excavation is 7124m. The longest tunnel, HRT-1 having 1164m length and HRT-8 having shortest length of 608m have been completed. HRT is aligned almost NNE - SSW cutting sub-parallel to obliquely to the bedding planes. The lateral cover between consecutive two tunnels is 21M, and rock cover over tunnels varies from 40m to 150m. Head race Tunnel are envisaged to convey water from Intake to pressure shaft then to power House

Table 2. Discontinuities characteristics of HRT.

Discontinuous	Orientation	Persistence (m)
S1	100°-150°/55°-75°	5-15
S2	200°-260°/35°-60°	4-6
S3	300°-350°/35°-70°	2-10
S4	010°-040°/45°-75°	3-8

Discontinuous	Spacing	Aperture	Condition
S1	Widely to very widely	Tight to partly open	Rough Planar
S2	20 cm to very widely	Tight to partly open	Rough to Slightly rough
S3	very Widely	Tight to partly open	Rough planar to slicken sided
S4	20 cm to very widely	Tight to partly open	Rough planar to Smooth

8 SURGE TUNNELS (ST)

Eight nos. of horse shoe shape inclined surge tunnels of finished 9.5 m Dia of length varying from 400m to 485m have been located above HRTs. The surge tunnels are on the slope of 1:10 thus the elevation varies from EL 212 to EL 171.5. Each Surge Tunnel relates to HRT by a 9.50m Dia circular Surge Shaft. The rock cover between crown of HRTs and invert of surge tunnels varies from 9 m to 44 m. Wherever the rock cover is minimal, steel ribs are provided in HRTs as adequate support measures as per design drawings. Surge tunnels have also been negotiated all through similar geological conditions as observed in HRTs. During the progressive excavation of surge tunnels (01 to 08), shear seam/zone having thickness from 10cm to 50cm associated with fractured/shattered rock mass were observed.

9 METHOD OF EXCAVATION, ROCK MASS CONDITION AND TUNNELABILITY

Due to the weak nature of Siwalik sandstone's low UCS value (25.85 MPa in dry condition & 7.11 MPa in wet condition), poor tensile strength (1.12 MPa in dry condition & 0.30 MPa in wet condition), low modulus of elasticity (3.29 MPa in dry condition & 1.15 MPa in wet condition), and proximity of tunnels, mechanical method was used instead of drilling and blasting. Road header and Drum cutters are the two prominent machines being used for the excavation of HRT and Surge Tunnel by adopting heading and benching method. Road header T3.20 of Wirth from Germany is being used for the excavation of the tunnels. The average cutting rate of Road Header observed at site is 6.69 cum/hr. and pick consumption is 0.15 pick/cum. Road Header takes approximately 8-10 hrs. in cutting 1m

stretch of heading area of 60 sqm. The monthly average progress of Road Header is 20m to 25m.

The most common underground partial face excavation machine for soft to medium strength rock is the road header. In addition to their higher and more versatile adaptability, road headers are often lower capital cost systems than most other mechanical excavators. Because of their increased cutting power density and smaller cutting drum, they can extract rock that is harder and more abrasive than continuous miners and borers.

Figure 6. Road header's performance parameters by manufacturer.

Road Header: WIRTH Road Header T3.20

- Total Weight: 131 Ton.
- Length: 16.59 M; Height: 3.94 M
- Maximum Cutting Height: 0.92 M to 7.60 M
- Maximum Cutting Width: 9.6 M
- Total Install Power: 1000 V (485 Kw)
- Number of Picks: 144 No's.

Figure 7. Road header's performance parameters by manufacturer.

Figure 8. Road header.

Drum Cutter ERC 1500xl (Attached to Kobelco 380XDLC):

- Gross Weight: 40 Ton.
- Drum Cutter Weight: 2.5 Ton.
- Rotation Speed: 75 rpm.
- Max. Operating Pressure: 350 bar.
- Number of Picks: 48

Figure 9. Drum cutter.

The observed cutting rates of the twin cutter machines and road headers were notably lower than the rates predicted by manufacturers. Table 3 provides a summary of the cutting rates of various rock cutting machines used in Siwalik sandstone, the primary tunnelling medium for both the HRT and Surge Tunnels.

Table 3. Cutting rate of equipment.

Machine Type	Cutting rate m ³ /hr.		
	Max	Min	Average Cutting rate m ³ /hr
WIRTH Road Header T3.20	9.96	4.04	6.69
Drum Cutter ERC 1500xl (attached to Kobelco SK380XDLC):	3.62	0.39	2.01

10 THE LOW CUTTING RATE ARE MAINLY ATTRIBUTED TO FOLLOWING REASONS

- a) The rock's characteristics, which range from marginally jointed to huge and lack fissility,

constitute a problem. The rock cutting process has distinct obstacles. Because the rock cutting machine grinds the rock rather than chipping it, more energy is required. Cut more efficiently. This increased energy requirement affects the overall cost and time required for tunnel excavation. In addition to the energy considerations, the rate of cutting is significantly influenced by the presence of various geological features, including discontinuities such as joints, faults, and bedding planes. Their spacing and orientation concerning the direction of tunnelling, play a crucial role in determining the machine's performance. Proper analysis and understanding of these geological characteristics are vital for optimizing the cutting process and ensuring smooth progress during tunnel excavation. Gehring (1997), Thuro and Spaun (1996a & 1996b), and Verhoef (1997) have extensively studied the impact of geological factors on the efficiency of rock cutting machines. Their research provides valuable insights into designing effective cutting strategies and improving tunneling operations in similar rock formations.

- b) A large amount of energy is lost due to the cushioning effect of the matrix due to the presence of 15-20% fine-grained matrix and carbonaceous materials. As a result, cracking the rock necessitates a tremendous amount of energy. Furthermore, this position impedes fracture propagation throughout the cutting process, resulting in unsatisfactory results.
- c) The cutting process generates large quantities of dust, causing a significant challenge in tunnel excavation. Measurements of fine dust near the tunnel face have shown levels as high as 85-90 mg/m³. The excessive dust generation results in poor visibility at the face, leading to intermittent excavation halts to remove the dust through the ventilation system installed in the tunnel. The need for frequent interruptions to clear the dust has a detrimental impact on the productivity of the rock cutting machine. The constant start-and-stop nature of the excavation process not only consumes valuable time but also increases wear and tear on the cutting equipment, further affecting overall efficiency. Efficient dust control measures, such as improved ventilation systems and dust suppression techniques, are essential to mitigate these issues and enhance the productivity of the rock cutting process. Proper dust management not only ensures a safer working environment for the crew but also contributes to maintaining a smooth and uninterrupted tunnel excavation process.
- d) The use of water for dust suppression had a detrimental effect, as it led to the formation of slush, making it challenging to handle the generated muck. The combination of water with the dust created a muddy and sticky mixture, significantly impacting the flow of excavated material and

causing handling difficulties. The presence of slush and muck not only slows down the excavation process but also poses a risk of clogging machinery and equipment. Furthermore, the handling issues increase the time and effort required for waste removal, further contributing to reduced productivity.

11 GEO-MECHANICAL CLASSIFICATION OF ROCK MASS

The geo-mechanical classification of the rock mass, known as Rock Mass Rating (Bieniawski, 1976), has been adopted for the Head Race Tunnels and Surge Tunnels. The distribution of rock classes at the negotiated tunnel grade is provided in the Figure no. 9. Notably, much of the tunnel rock falls under class-III. It is essential to apply the RMR system to assess the geomechanics characteristics of the rock mass and plan the tunnelling process accordingly. Classifying the rock mass into different categories helps in understanding its behavior, stability, and the potential challenges that may arise during excavation.

Figure 10. Comparison of rock class based on RMR classification at HRT & ST.

12 ROCK CLASSIFICATION BASED ON THE HINDRANCE

Given the limitations and challenges associated with traditional classification systems, an alternative approach to categorizing underground excavations is adopted based on the concept of hindrance. This method divides underground excavations into different classes to differentiate the difficulties and hindrances encountered during excavation work, which are often influenced by the properties of the materials encountered. The classification of excavation is established in relation to the hindrance it poses to the progress of excavation works, primarily caused by the type and amount of rock support installed within the tunnel heading zone. As the excavation progresses, the characteristics of the rock mass and the need for rock support can vary significantly, affecting the overall difficulty and complexity of the tunnelling process. By categorizing underground excavations based on the hindrance factor, engineers and tunnelling teams

can gain a better understanding of the challenges they are likely to face at different stages of the project. This approach allows for more targeted planning and selection of appropriate excavation methods, support systems, and safety measures.

Factors such as the rock mass quality, jointing patterns, presence of groundwater, and expected ground convergence play a vital role in determining the class of excavation. As the excavation class changes, adjustments to the support systems and excavation techniques may be necessary to ensure safe and efficient progress throughout the tunnelling process.

Overall, this hindrance-based classification system provides a practical and adaptable framework for evaluating and managing the complexities of underground excavations, promoting successful project execution while mitigating potential risks and challenges encountered in varying geological conditions.

13 THE UNDERGROUND EXCAVATION CLASSES, DESIGNED TO CATEGORIZE THE LEVEL OF HINDRANCE ENCOUNTERED DURING EXCAVATION WORK, ARE AS FOLLOWS:

Class IIIA: The implementation of support measures significantly impedes the advancement of heading excavation to the extent that support installation becomes an integral component of the work cycle. The support system entails the utilization of steel fiber-reinforced shotcrete (SFERS) applied in one or multiple layers, combined with a configuration of patterned rock anchoring or rock bolting in both heading and benching zones. This configuration may encompass the option of incorporating wire mesh as reinforcement for the shotcrete.

Class IIIB: The implementation of support measures introduces a certain level of interference and deceleration to the progress of excavation activities. The support system entails the utilization of steel fiber-reinforced shotcrete (SFERS) applied in one or multiple layers, combined with a configuration of rock anchoring or rock bolting in both heading and benching areas. This configuration may include the option of incorporating wire mesh as reinforcement for the shotcrete.

Class IV: When implementing support in this category, the excavation process encounters considerable delays in both heading and benching activities. The support strategy involves incorporating sturdy steel ribs within both these sections. Alongside these ribs, wall plates and a continuous lagging system are promptly positioned at the forefront of the excavation site. To reinforce stability, a meticulous rock anchoring approach is applied to the entire cross-sectional area. In certain scenarios, complete encasement of the steel ribs in shotcrete might be necessary, supplemented by the inclusion of wire mesh reinforcement if the lagging component is omitted. This comprehensive support method ensures the

structural integrity of the excavation despite the notable hindrance it introduces to the work process.

Class V: Excavation in this category necessitates a simultaneous installation of support for both heading and benching, ensuring the protection of the ongoing work. The support system is characterized by the incorporation of steel ribs within both these sections, accompanied by the utilization of invert bracing or struts. Additionally, wall plates and continuous lagging are promptly placed at the freshly exposed surface after any segment of the cross section is excavated. For enhanced stability, a systematic rock anchoring technique is implemented, providing reinforcement to the steel ribs and lagging. In specific circumstances, the steel ribs might require complete envelopment in shotcrete, with the potential inclusion of wire mesh reinforcement, particularly when lagging is not utilized. This comprehensive support approach guarantees the structural integrity of the excavation process, allowing it to proceed despite the need for simultaneous support installation. The allocation of different underground excavation classes based on hindrance to the head race tunnel (HRT) and surge tunnel (ST) is illustrated in the figure below.

Despite the various engineering classifications of the rock mass, there is no strong correlation observed between the percentage of the engineering classification and the percentage of hindrance class. The hindrance class is influenced by a combination of factors beyond the engineering classification, such as the specific tunnelling method used, geological variations within the tunnel alignment, and the effectiveness of support systems implemented. As a result, the hindrance class provides a more comprehensive understanding of the challenges encountered during excavation, considering a broader range of factors than the engineering classification alone. This reinforces the significance of adopting the hindrance-based classification approach to better address the complexities of underground excavation and ensure successful project execution.

Figure 11. Comparison of rock class based on hindrance classification at HRT & ST.

14 CONCLUSIONS

The Subansiri Lower Hydro Electric Project (HEP) presents a unique case study of tunnelling in weak sandstone, which has posed several geological and engineering challenges during its construction. The soft and friable nature of the sandstone, coupled with the lack of fissility and the presence of fine-grained matrix and carbonaceous matter, has significantly impacted the tunnelling operations. To tackle these challenges, innovative engineering solutions and support systems were employed to ensure the successful construction of the project.

The use of mechanical excavation methods, such as road headers and twin cutters, proved effective in handling the weak sandstone. However, the low cutting rates observed were primarily attributed to the massive nature of the rock mass and the grinding effect during excavation. The substantial generation of dust during the cutting process led to poor visibility at the tunnel face, resulting in intermittent excavation halts for dust removal. This hindered the productivity of the rock cutting machines and required additional time and effort for waste removal.

The engineering classification of the rock mass using the Rock Mass Rating (RMR) system provided valuable insights into the geomechanics characteristics of the rock, but it was limited in addressing the specific challenges posed by the weak sandstone. As a result, an alternative hindrance-based classification approach was adopted, considering various factors, including the type and amount of rock support installed within the tunnel heading zone. This classification proved to be more relevant in assessing the difficulty and complexity of the excavation process.

Excavation classes were established based on the hindrance approach, providing a practical framework for evaluating and managing the challenges encountered during tunnelling. The support systems used in these classes, including steel fiber-reinforced shotcrete and rock anchoring or rock bolting, played a crucial role in ensuring the stability and safety of the tunnel structures.

Despite efforts to correlate the engineering classification of the rock mass with the hindrance classes, no strong correlation was observed. This highlights the significance of considering a broader range of factors beyond the engineering classification to better understand the challenges of underground excavation.

Overall, the case study of tunnelling in weak sandstone at the Subansiri Lower Hydro Electric Project has provided valuable insights and lessons for similar projects in comparable geological conditions. The successful application of innovative engineering solutions and hindrance-based classification approaches has contributed to the safe and efficient construction of the tunnels. By addressing the specific challenges posed by weak sandstone, the project has made significant progress towards its completion and has added to the knowledge base for future tunnelling endeavors in similar geologies.

Correlation of empirical classification systems in squeezing anisotropic environment and optimisation of underground supports in a headrace tunnel; a case study from Tanahu Hydropower, Nepal

Eirinaios Christakis*

Tractebel Engin. GmbH, Bad Vilbel, Germany

Bibash Parajuli, Pengcheng Yao & Radha Krishna Adhikari

PowerChina Chengdu Engin. Corp. Ltd, Chengdu, China

ABSTRACT: The headrace tunnel of Tanahu Hydropower Project was excavated in the Benighat Slates of the Lesser Himalayan zone, located at West-Central Nepal. The tunnel runs underneath a high overburden massif that comprises thinly foliated Slates with distinct presence of multiple sheared zones, characterised by anisotropy. Geotechnical information retrieved for the construction of the adjacent underground powerhouse was utilised for the numerical analysis, whereas the design for the temporary support was initially based on Bieniawski's RMR system. For the design and the in-situ assignment of reliable support measures to ensure underground stability, a realistic evaluation that resembles the actual geological regime is significant. Should difficult ground conditions hinder excavation and geological uncertainty contributes to the unforeseeable, the necessity for the most adaptive classification system becomes apparent. Rock-mass classification systems are the basis for the real-time evaluation of underground stability, and a supplementary tool, wherever design parametrization is based on limited pre-excavation information or lacks of realistic numerical analysis. Moreover, the risk for overestimation or underestimation in case of erroneous rock-mass assessment might lead to over-supporting (uneconomical and time consuming) or under-supporting (entails instability risk). For the particular tunnel, the distribution of support classes based on RMR was found unsuitable to address anisotropy and squeezing phenomena. In order to deal with similar classification shortfalls, temporary supports were re-designed based on Q-system. Researchers have developed empirical correlations between classification systems, which cannot always reflect specific geological conditions. Hence, the authors attempt to develop relevant correlations between Q, GSI and RMR which derive from statistical analysis; and recommend the most optimal equations compared to equations from other researchers. The parallel use of two or more classification systems for the particular underground environment provides a more reliable assessment tool, and subsequently assures the assignment of optimal rock support measures.

Keywords: Squeezing ground, Rock mass classification, Correlation, Tunnel support, Slate, Anisotropy

1 INTRODUCTION

A fundamental tunnelling aspect that assures underground stability, is that the extent of applied rock support should reflect the behaviour of the excavated rock mass, whilst rock mass behaviour is reflected by the used classification approach. The comprehension of the actual physical and mechanical rock mass characteristics plays an important role in determining the actual rock support requirements and their limitations. However, considering the self-supporting capacity of rock mass, its geomechanical behaviour and the principal economic factors of tunnelling, i.e., time and cost; there is always space for the optimisation of support measures. The selection of tunnel rock support should

be based on the sound understanding of rock mass characteristics, the stress regime, and stability issues (i.e. the geotechnical risk) that may arise (Nilsen & Thidemann, 1993).

Several classification systems have been developed throughout the years focusing to the inclusion and the quantification of the most important factors/parameters which influence stability, aiming to provide a realistic evaluation of rock mass quality. Apart from selecting the optimal support, classification systems in tunnelling intend to assess rock mass behaviour under particular in situ stress conditions in order to adopt a safe excavation strategy. In other words, an attempt to quantify rock mass quality. From the beginning of 20th century, empirical

*Corresponding author: renos.christakis@tractebel.engie.com

approaches for rock mass classifications have set the basis for support design, for underground structures and open excavations. The most prevalent classification systems such as RMR, Q, and GSI are employed in the engineering practice since long time now. These classification systems constitute the quantitative estimation of rock mass quality, linked with empirical design rules in order to assess adequate rock support measures (Palmström, A., 2009).

2 EMPIRICAL CLASSIFICATION SYSTEMS

Bieniawski developed Rock Mass Rating (RMR) in 1973. RMR classification system is based on the algebraic summation of six geomechanical parameters, emphasising on the intact strength, the blockiness, the characteristics of discontinuity surfaces, the groundwater conditions, and the orientations of the structural planes with respect to the underground structure. Thus, RMR derives from the following equation.

$$RMR = A1 + A2 + A3 + A4 + A5 + B \quad (1)$$

A1 corresponds to rates related to the intact rock strength, A2 relates to RQD, A3 refers to the spacing of discontinuities, A4 comprises a series of joint surface condition parameters (i.e. persistence, aperture, roughness, infill material and weathering), A5 represents groundwater conditions, and B is the rating adjustment for joint orientations. The derivative value ranges from 0 to 100, and with reference to the excavation span, they define specific stand-up times, the optimal excavation guideline, and recommend estimated rock support measures.

In 1994, Hoek introduced the Geological Strength Index (GSI). GSI evaluation is based on the observation of the rock structure system -and in particular, to its interlocking degree, in conjunction with the quality of joint surface conditions. Since then, a number of system updates included the consideration of weak or jointed rock masses (1998 and 2000), and also special classifications for heterogeneous masses (e.g. flysch). For an ample variety of geological conditions, GSI system facilitates the determination of rock mass properties, aiming to provide estimates for the rock mass strength and its deformation modulus, whilst the system can be used as part of the empirical Hoek-Brown failure criterion. The validity of the index depends on a precondition; rock mass exhibits isotropic behaviour, without considering structural failures. The values derive from matrix charts by combining the primary factors of the index (i.e. the visual estimate of structure and surface conditions), represented in the form of diagonal contours (ranging between 0-100).

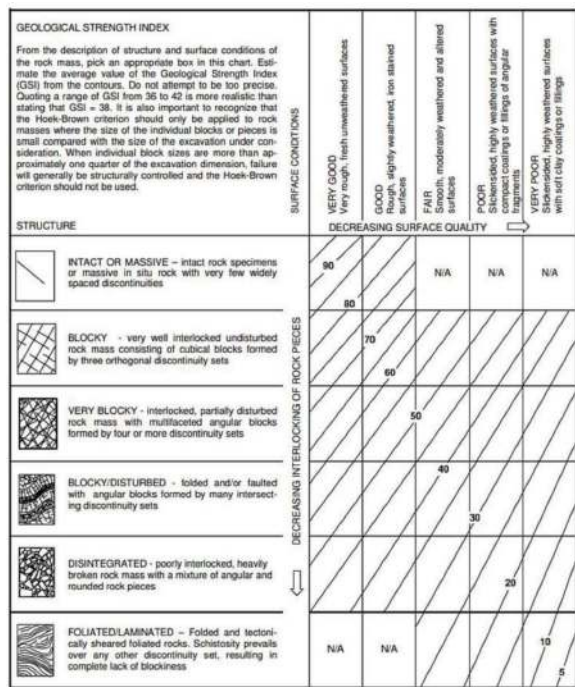

Figure 1. General GSI matrix chart (Marinos et al., 2005).

In 1974, Barton et al. developed the first version of Q-system at the Norwegian Geotechnical Institute, based on a large number of tunnelling reference data, taking into consideration the stability of the underground openings. The system has been updated several times by integrating more reference cases until lately (latest update 2022); aiming to provide a realistic description of rock mass quality, and at the same time, recommend design guidelines, and the estimation of rock support (with respect to the size of the opening, and the purpose of the structure). Q-value comprises the product of three fundamental geomechanical characteristics: i) the degree of jointing, i.e. the quotient of RQD and the number of joint sets (J_n); ii) joint friction, i.e. the quotient of joint roughness (J_r) and the joint alteration (J_a); and iii) the stress regime, i.e. the quotient of groundwater regime (J_w) and the effect of stress (SRF or stress reduction factor).

$$Q = RQD/J_n \times J_r/J_a \times J_w/SRF \quad (2)$$

The derivative ranges on the logarithmic scale, and support measures are assigned considering the excavation's span and purpose, based on a schematic chart.

2.1 Correlation between classification systems

Considering the variable degree of geological uncertainty and the complexity of an underground excavation, neither a particular system, nor can any index explicitly "describe" rock mass or simulate the behaviour of rock mass under particular circumstances. None of them can be viewed as panacea on its own. In several cases, rock mass, the stress

regime and the salient features of an excavation would set the path and point out the factors to be considered, in order to address geotechnical risk and assure stability. The use of a single system entails the risk of disregarding or undervaluing an important stability factor that might lead to an imprecise assessment of the geomechanical conditions.

Provided that classification parameters from each system overlap to some extent, numerous researchers attempt to correlate different systems by developing corresponding equations, opting to better understanding the ground reaction on applied supports for specific rock classes. The majority of the equations are resultants of statistical analysis based on data collected from case studies of various projects, various lithologies and geomechanical regimes. The following tables summarise the most common correlation equations between the three main empirical classification systems, i.e. Q, RMR and GSI. It shall be noted that every equation relates to particular geographical, geological and stress conditions.

Table 1. Correlation equations between Q, GSI and RMR.

2.2 Methodology and metrics

Three classification systems -as described in the preceding chapter have been utilised for the evaluation of rock mass quality, and for correlation purposes. For each advanced face, during the geological mapping task, geologists calculated three separate values with reference to the respective classification systems (i.e. RMR, Q and GSI). Recorded values were tabulated for statistical processing in line with the linear regression approach; aiming to produce optimal correlation equations between two systems (should this be feasible), and evaluate the degree of accuracy for those equations. In addition, to select the most suitable and realistic mathematical expression (i.e. equations from Table-1 with the highest correlation and the lowest error coefficients, including the produced optimal correlation from project data), regression analyses were also performed between the theoretical rock mass quality derivatives and the actual values which were assigned during the tunnel mapping process. The following metrics were utilised for data analyses.

The Mean Absolute Percentage Error (MAPE) is calculated in order to define the degree of accuracy of the produced equations; hence, it provides a comparison index between the forecasted value (*calc.*) and the actual values as those measured in the tunnel (*act.*). The MAPE value for a particular data population (*n*), expresses the average of the absolute percentage errors based on the following equation.

$$MAPE = \frac{1}{n} \times \sum_1^n \left| \frac{act. - calc.}{act.} \right| \quad (29)$$

The Mean Absolute Error (MAE) corresponds to the absolute difference's average between the in-situ recorded (*act.*) and calculated values (*calc.*). Therefore, MAE measures the average of the residuals in a dataset population (*n*) of rock quality predictions, where all individual differences have equal weight. MAE value is given by the following equation.

$$MAPE = \frac{1}{n} \times \sum_1^n |act. - calc.| \quad (30)$$

The Root Mean Squared Error (RMSE) is a quadratic index which measures the average magnitude of the error for a data set (n), and defines data concentration (their proximity) around the optimal regression line, based on the equation.

$$RMSE = \sqrt{\frac{\sum_1^n (act. - calc.)^2}{n}} \quad (31)$$

The coefficient of determination (R^2) or R-squared in linear regression analysis, indicates the level of variation by measuring the square of the correlation between the actual site values (x) and the values produced by the theoretical equation (y). The validity and trend of a linear relationship of the analysed data sets is quantified with values ranging between 0 and 1.0. The closest to 1.0 the R^2 is measured, the more reliable the theoretical correlation is. R^2 derives from the correlation coefficient formula (Pearson's R index).

$$r = \frac{n(\sum^x y) - (\sum^x)(\sum^y)}{\sqrt{[n \sum^x x^2 - (\sum^x)^2][n \sum^y y^2 - (\sum^y)^2]}} \quad (32)$$

3 GEOLOGICAL BACKGROUND OF TANAHUN PROJECT

Tanahun Hydropower Project is a storage type project located at Tanahun District of Gandaki Province in the West-central Nepal. The main salient features of this project comprise a 140-metres high RCC gravity dam, the underground powerhouse (89x22x51m), a 25.5m wide underground surge system, and its 1418m long headrace tunnel (HRT). The excavation shape of headrace tunnel is horse-shoe, excavated in two phases (i.e. top heading and benching) along a 2% gradient, with an average span of 10.2m.

The tunnel runs along medium to high overburden (minimum 70m and maximum 695m). Almost 60 to 70% of the headrace tunnel passes through rock cover of greater than 300m, which means high vertical stresses and a risk of high deformation magnitudes. The excavation was carried out with conventional drill and blast method (D&B), and in exceptional cases of weak rock mass, with mechanical means (i.e. use of hydraulic breaker and excavator). The average advance length per drill & blast round is less than 1.8m, and the excavation commenced from the powerhouse towards the power intake (Dam area).

Based on the preliminary investigation conducted during the design stage of the project, the anticipated lithology of the HRT consists of Benighat Slate series of the Upper Nawakot group (Lesser Himalayan sequence). Benighat Slates overlay a series of very thick bedded, massive, blue-grey Dolomite (Dhading formation). The encountered lithology during the excavation phase substantiated the

literature references as well as the results of the design stage. Dhital (2015) describes Benighat Slate as light grey to black and green-grey formation, containing very thinly (<1mm) cleaved varieties. Carbonaceous Slate is regarded as special continuous formation, where weak zones parallel to foliation are playing an important role to its anisotropic behaviour. Moreover, its deformability and strength directly depends on the cleavage plane orientation with respect to the principal stresses. It is important for numerical modelling, to conceive rock mass characteristics and its anticipated behaviour, in order to facilitate the adoption of realistic design parameters. Such parameters would allow the precise analysis of probable failure mechanisms and deformation thresholds. Thus, the lack of proper understanding of those characteristics and the inaccurate determination of failure mechanisms entails the risk of an uncertain numerical model (Marinos, 2014).

Considering the purpose of the underground structure in conjunction with the anticipated geomechanical conditions, the tunnel will be permanently supported with concrete lining segments (lining thickness 0.50-0.90m, depending on the encountered rock mass conditions). The temporary supports include the application of reinforced shotcrete (with steel fibres or embedded wire mesh), ranging from 50 to 200mm depending upon the support classes; 4 to 6m long fully grouted passive rock bolts; and steel supports in stretches of very poor or extremely poor rock mass (lattice girders or H-beams). A typical tunnel profile and its characteristic lithology are shown in Figure 2.

Figure 2. Typical carbonate Slate; overburden 380m (approx.).

It is notable that in almost 55% of the tunnel stretches, the encountered rock mass quality necessitated the installation of steel ribs or lattice girders.

Numerous shear zones of ranging thickness (from few centimetres up to 300cm) were encountered during the top-heading stage, influencing the tunnel's stability. A number of prevailing geomechanical parameters such as the distinct anisotropy, the localised low intact strength, the joint spacing (very thin to laminated), the

intense shearing and folding in conjunction with the high overburden; resulted in the increment of anisotropic strain and consequently to several low-squeezing incidents that led to localised defects of the temporary support shell. Defects had localised characteristics and consisted of swayed lattice girders, shattering or bulging of bearing plates, and shotcrete cracks or detachments. It is worth to note, there was no significant groundwater activity apart of scattered damp/wet areas of dripping (i.e. flow < 1.0 lit/min.).

Considering the encountered deformations, in order to optimise the temporary support strategy (prevent support inadequacies or even avoid over-support), the numerical model was re-assessed based on the real-time excavation data, the design of the temporary support was reviewed, and the NGI's Q classification system replaced RMR for the remainder of the excavation. Few examples of defects are illustrated in the Figure 3, below.

Figure 3. Rock support defects due to low squeezing.

Panahi (2006) states that the strength of intact rock for Slates reaches the lowest possible margin when schistosity dips with 45° degrees. In particular, for the entire HRT, Slate's schistosity strikes parallel to tunnel drive, dipping with 40° to 50° to the SW wall, an additional critical squeezing factor. When the underground opening exhibits anisotropy as governing stress mode, it can lead to a situation where the applied supports may experience variable magnitudes of support pressures around their periphery. (Shrestha & Panahi, 2014). Very poor rock masses with distinct persistent schistosity, tend to react in an elastic - perfectly plastic mode. However, under high overburden conditions, a poor quality anisotropic formation might behave in a quasi-isotropic mode whilst the anisotropic factor is gradually outweighed, resulting in squeezing failure. In that case, the Slate's low strength plays a major role for the

occurring deformation. In stretches of medium strength, minor chimney and shear failures occurred close to the advancing face. The magnitude and attitude of profile deformation was closely monitored with a dense network of convergence stations alongside with daily routine observations. The maximum deformation in some sections reached nearly 200mm having a maximum strain of 2.5% which indicates minor squeezing, whereas the average strain values range between 0.5 and 0.7%, a figure which reflects to the defects of the temporary support elements.

4 CORRELATION OF FACTUAL CLASSIFICATION DATA

The classification data relate to specific geological-geomechanical conditions. In brief, data were collected from a 1070 m tunnel stretch that comprises medium strong, light grey to black micro-folded Slate. Table 2 presents the summary of the geomechanical properties of the excavated rock mass. A typical cleaved, micro-folded Slate encountered in many excavated faces is shown in Figure 4.

Table 2. Particular geomechanical properties of research.

Overburden	120-695m
Groundwater	Dry to damp, with localised scattered drippings (<1.0 lit/min)
Structure	Intense foliation (crenulation cleavage); spacing <60mm (average 10-40mm); foliation dips 45°, striking parallel to tunnel alignment
Discontinuities	Persistence: 1-3m Separation: tight to 2mm (localised 3-6mm) Roughness: smooth, planar to undulating Infilling: graphite, patches of clay, quartzite Weathering: slightly weathered to unweathered
Tectonic features	Shear bands parallel to foliation (10-200cm)

For reference, the data range of rock mass quality based on the geological mapping records are summarized below.

For the statistical analysis of the factual values and for the three classification systems, geologists mapped 548 tunnel faces and assigned values for each system separately. Regression analysis was conducted for the data couples resulted from classification systems, for all three combinations (Q-RMR, RMR-GSI, and Q-GSI). These data were interpolated in order to generate the best fit curve. Each combination was evaluated based on five regression modes: i) exponential, ii) linear, iii) logarithmic, iv) power, and v) 2nd order polynomial.

Figure 4. Typical cleaved Slate; close up photograph.

Table 3. Actual rock mass quality values (548 data).

	Highest value	Lowest value	Mean value	Most frequent value
Q-value	1.44	0.016	0.184	0.07
RMR	53	31	40	39
GSI	49	20	34	31

Such curve may provide a reliable correlation between two classification systems.

4.1 Factual Q-RMR evaluation

Five different possible regression curves were evaluated, in order to conclude to the most reliable (the highest possible R^2 derivative). With reference to the mapped Q and RMR factual values, the highest coefficient of determination results from the power equation, and equals to $R^2=0.5965$, therefore $R=0.772$, a relatively acceptable value.

$$RMR = 49.411 \times Q^{0.1084} \quad (33)$$

Figure 5. Correlation between Q and RMR actual values.

4.2 Factual RMR-GSI evaluation

The same evaluation approach was adopted to define the relationship between the RMR and GSI mapped values (factual data). Similar to the preceding correlation analysis, the highest coefficient of determination results from the logarithmic equation, and equals to $R^2=0.4047$, therefore $R=0.636$, a relatively low value, not highly recommended for a reliable correlation between RMR and GSI.

$$GSI = 38.466 \ln RMR - 108.96 \quad (34)$$

Figure 6. Correlation between RMR and GSI actual values.

4.3 Factual Q-GSI evaluation

With respect to the relationship between Q and GSI (minimum index) mapped factual data, there is no coefficient of determination that exceeds 0.30 ($R<0.5477$), an indication of very low reliability between these classification systems. The coefficient of the power equation equals to $R^2=0.30$, therefore $R=0.5477$.

$$GSI = 42.902Q^{0.147} \quad (35)$$

Figure 7. Correlation between Q and GSI actual values.

5 EVALUATION OF LITERATURE CORRELATIONS

Aiming to evaluate the accuracy of the literature equations included in Chapter 2.1 (Table 1) with

respect to the real rock mass data, and compare with the most reliable equations which derived from the factual evaluation process (Chapter 4), analyses were conducted, and the metrics of the most reliable equations are summarised below.

Table 4. Evaluation of accuracy.

Equation	MAPE (%)	MAE	RMSE
Q to RMR			
$RMR = 49.411 \times Q^{0.1084}$ (33)	6.31%	6.51	7.78
$RMR = 2.8 \ln Q + 45.19$ (14)	6.86%	2.72	3.19
$RMR = 6.4 \ln Q + 49.6$ (13)	10.5%	4.17	4.84
(5)	11.6%	4.38	5.28
RMR to GSI			
$GSI = RMR - 5$ (17)	14.1%	4.53	5.18
No reliable equation from actual data correlation			
Q to GSI			
$GSI = 5.96 \ln Q + 47.85$ (25)	16.6%	5.26	6.21
No reliable equation from actual data correlation			

With respect to the correlation equations between RMR and GSI, and between Q and GSI, the metrics derivatives produced relatively high mean absolute percentage errors (MAPE>14.1%). In addition, the most optimal correlation equations for these combinations, which resulted from the actual recorded values (equations 34 and 35) show relatively low coefficients of correlation (Pearson's index). Thus, they are both considered unreliable.

With respect to the Q-RMR correlation, the comparison of the three most-reliable literature equations (i.e. Cosar, 2004; Moreno, 1980; and Kumar et al., 2004) and the power regression model of the actual values (eq. 33) are illustrated in Figure 8, below.

Figure 8. Best optimum Q-RMR correlation equations.

For very poor to extremely poor rock masses ($Q < 0.4$), Cosar's equation (14) is marginally matching to the logarithmic regression line equation (33). Both equations have similar MAPE, whereas Cosar's equation shows lower absolute error values.

Equation (14) utilised reference data from a Schist formation under medium stress regime, and its correlation coefficient is 0.818. On the other hand, for better rock mass qualities ($Q > 0.2$), Kumar et al. equation (13) is converging to the linear regression line of equation (33). Equation (13) has utilised reference data mainly from Schists and Gneiss formations under squeezing conditions, and its correlation coefficient is 0.55.

6 CONCLUSIONS AND RECOMMENDATIONS

The scope of rock mass classification systems constitute an attempt to quantify rock mass quality, to shed light in the anticipated ground behaviour, and to provide support quantitative estimates for the design of an underground structure. Given the fact that the rationale and foundation of each system differs; it is essential for the end user to be well-aware of those, and in addition to consider their limitations (Palmström & Broch, 2006). Another critical factor that is directly influencing the classification derivatives and subsequently may result in inaccurate or unrealistic design, relates to the degree of subjectiveness (i.e. how biased estimates can lead to misinterpretation), and how conservative or not a field practitioner could be. Therefore, the question: "which is the best or reliable classification system?" is invalid, and the authors suggest an alternative: "which is the most suitable system for site specific use?". As Young et al. (2021) recently underline, the characterisation and classification of rock mass should incorporate geology, and at the same time, should be tailored to specific rock mass types. Hence, no system can equally and accurately reflect each site's particular geological conditions.

6.1 Shortfalls and limitations

The reference data from which Q-system was established were obtained from metamorphic and igneous hard, jointed rocks, including weakness zones, aiming to provide an average estimate for the necessary rock support. The system considers the stress regime and in particular accounts for squeezing ground, and the dimensions of the underground opening. However, considering the scarcity of data from weaker formations and the small number of references under squeezing ground conditions; for the design and the evaluation of support measures Barton (2022) himself recommends the contribution of numerical methods, supplemented with monitoring. A basic shortfall of the system lies in the RQD dependency, where in weak rock masses the parameter turns practically meaningless.

The majority of reference cases which RMR derives from, relate to sedimentary formations. The system also aims to provide a crude estimate for the necessary rock support. In the RMR the stresses and

tectonic regime are not considered, whereas the influence of fault zones/weak zones is ambiguous. However, some parameters included in the system may represent fault conditions, although the complicated structure and composition of these features are generally difficult to characterize and classify (Palmstrøm, 2009). In addition, similar to Q-system, RMR is also dependent upon RQD, and subsequently tends to fail when addressing poor quality rock mass (and heterogeneity, as well).

GSI system excludes RQD in terms of a quantitative metric, whilst the system focuses on the structural composition and surface discontinuity conditions. It should be highlighted that its main objective is the estimate of rock mass properties, and specifically its strength; and not the direct recommendation of support measures. Provided that GSI does not rely on quantified parameters, its derivative results through a visual examination process. However, the system is not applicable to anisotropic rock masses or massive rock masses with few very wide spaced discontinuities with respect to the dimension of the opening (Marinos, 2005), but works quite well with poor quality rock masses. Moreover, GSI does not consider the stress and groundwater regime.

6.2 Applicability of classification systems to the HRT

With reference to the site specific conditions (i.e. Tanahu HPP Headrace Tunnel), the field geologist was expected to map excavated workfronts and assign classification indices in a low to moderately strong Slate (i.e. a metamorphic rock), characterised with foliation and cleavage, intersected by numerous shear or weakness zones, under a high stress environment with prominent long-term and slow response deformation due to mild-squeezing. In general, a very poor to extremely poor rock mass. Moreover, the margins that stresses exceed rock mass strength were considered inexplicit, rendering the threshold between anisotropy and pseudo-isotropy also fluid.

In order to produce a realistic quantifiable index, that adapts to the encountered geology and also assure safe and economical excavation, many key-authors of rock engineering (Bieniawski, 1989, and Palmstrøm, 2009) recommend the simultaneous use of two systems. Considering the particular geological conditions and the aforementioned shortfalls and limitations of each classification system, the authors recommend the “collaboration” of Q-system with the parallel application of GSI as the most suitable systems that could result in realistic rock mass evaluation. The selection of a suitable system is the key-tool for the conceptual geological model, the foundation for precise parametrization, and an important factor for the uncertainty risk mitigation when conducting analytical numerical methods. Instead of relying on a crude figure (i.e. an index value), a more analytical description of each system’s input parameters provide additional clarity to the actual or anticipated rock mass behaviour.

Further to this, with respect to the excavation of the 2nd phase (bench), the authors highly recommend a diligent and coherent monitoring strategy. Such strategy should include:

- i. the geodetic survey of optical target stations (convergence stations as those installed during the excavation of the top-heading phase and new stations where necessary), and
- ii. the installation of multi-point borehole extensometers (MPBX) in stretches under the highest overburden, and stretches of considerable deformation.

Geodetic survey of the convergence targets will provide information about supplementary deformation that may occur during benching phase. MPBX instruments will also monitor profile displacements, as well as they will determine deformation behaviour within the rock mass and provide an estimate of the extent of plasticity zone. Consistent monitoring plays an important role for the early detection of displacements beyond the assigned stability thresholds, and predispose the modification of supports or the installation of supplementary measures.

6.3 Optimal correlation equations

It is evident from the regression analyses, as well as from the comparison with the available literature correlations, that the applicability of an existing equation relates to the range of the encountered rock mass type and quality, and the stress regime. Therefore, for very poor to extremely poor Slate in a squeezing environment, Cosar’s (2004) equation (14) provides a satisfactory correlation output. However, for better quality Slates (poor or fair), Kumar’s (2004) equation (13) is mostly recommended. The most optimal Q-RMR correlation equation recommended for generic purpose in poor or worse quality Slates is equation (33).

Table 5. Recommended Q-RMR correlation equations.

Equation	Application
$RMR = 49.411 \times Q^{0.1084}$ (33)	Generic quality Slate; squeezing
$RMR = 2.8 \ln Q + 45.19$ (14)	Slates Q<0.4
$RMR = 6.4 \ln Q + 49.6$ (13)	Slates, schists; squeezing

However, no matter how perfect the regression metrics will be, no mathematical expression can simply “translate” and quantify geology from one system to another. In addition, the applicability of any correlation is linked to site-specific and geological conditions, and is subject to the discretion of the field practitioner. Hence, correlations should be used with caution, always with reference to their

database source, and only for validation purposes. As such, they cannot replace the direct use of any classification system.

Hydro-geo-mechanical properties for water flow prediction in tunnelling

Massimo Coli* & Roberto Emanuele Rizzo

Department of Earth Sciences, University of Florence, Firenze, Italy

ABSTRACT: Tunnelling projects often face challenges related to water inflow leading to operational safety issues, destabilisation, and increased costs. Accurate prediction of water flow is therefore critical. This study aims to provide guidance on how to achieve this goal by examining hydro-geo-mechanics principles for predicting water flow in tunnelling and highlighting the role of geology in rock mass discontinuities data collection. This study discusses the role of geology in rock mass discontinuities data collection. Understanding the geological setting is crucial for collecting appropriate discontinuities data. We present an overview of different data collection techniques, including information gathered from discrete and confined outcrops, and those collected from more continuous outcrops. It discusses data collection from borehole, hydraulic tests (e.g., Drill Stem Tests), and tracer tests, for 1D and 2D data to derive the rock mass zone. Furthermore, discontinuities statistical distributions for different rock types, such as stratified and non-stratified rocks, are discussed. The next aspect discussed in this study is fracture network attributes such as connectivity, transmissivity, and permeability. Connectivity and transmissivity of discontinuities can be used to derive the permeability tensor from discontinuities data in rock masses. The study provides details on how to use the fracture network data to derive estimation of the permeability tensor from, including a comparison of different methods. In conclusion, this study provides insights into hydro-geo-mechanics principles for predicting water flow in tunnelling. The discussion on discontinuities data collection, statistical distribution, and permeability tensor derivation provides valuable information for tunnel engineers to accurately predict and control water flow during tunnel excavation. The study emphasises the importance of considering the hydro-geo-mechanical behaviour of the rock mass in predicting water flow and provides a comprehensive understanding of the various techniques used in the process.

Keywords: Tunnelling, water, faults and fractures, permeability, inflow prediction

1 INTRODUCTION

Recent advances in tunnel engineering have facilitated the construction of long base-tunnels that face high water heads, presenting unique safety and environmental concerns. Water inflows, and more critically, inrush during tunnel construction, not only pose significant risks to both human life and machinery but also lead to project delays and increased costs. This is particularly true for tunnels executed with tunnel-boring machines (TBMs), which require comprehensive pre-construction knowledge of rock mass properties to optimise performance.

From an environmental standpoint, safeguarding natural water bodies has gained prominence, guided by regulatory frameworks such as the European Union's Water Framework Directive and more recently the principle of 'Do No Significant Harm' (DNSH). These frameworks mandate stringent environmental considerations for infrastructural projects. In Europe, the Hydrogeological Excavation Code (HEC) is

increasingly recognized as the authoritative technical guide for balancing water body protection with the technical and economic sustainability of tunnel projects (Coli & Tanzini, 2016; Coli et al., 2019a; Coli & Martelli, 2021).

Given these complexities, preliminary investigations must rigorously define the characteristics of natural water bodies and rock mass permeability (Figure 1). Such data enables the prediction of potential water linkages, inflows, or inrushes, thereby informing the design of effective countermeasures to ensure both construction safety and environmental protection (Coli & Martelli, 2021). Additionally, accurate predictions can facilitate the recovery of fresh water from the rock mass for beneficial uses, such as potable water supply or agricultural irrigation.

Many geological formations contain extensive networks of discontinuities (bedding, joints and fractures) that developed in lithification or in response to tectonic stress. Tectonic strain can be generated by various mechanisms: regional tectonic deformation,

*Corresponding author: coli@unifi.it

flexure over large folds or diapirs, local deformation around larger faults, or high-pressure fluids injected into the formation. Fractures and joints develop in response to the strain may be vertical Mode 1 dilatant, or inclined Mode 2 and Mode 3 shear, depending on the in situ stress state and fluid pressure at the time of deformation (Anderson, 1951). Such features can also interact with pre-existing lithological boundaries, thus forming a dense network of discontinuities.

Within the scope of preliminary investigations, the characterisation of such discontinuities in rock masses takes on paramount importance for multiple reasons (Figure 1). Firstly, the orientation, length, and aperture of these discontinuities must be accurately mapped. Traditional methods such as field surveys and mapping of exposed outcrops, together with advanced techniques like remote sensing, laser scanning and seismic imaging, can be utilised for this purpose (Welch, 2023). Secondly, detailed characterisation of the discontinuity network such as density and connectivity can also shed light on the hydraulic properties of the discontinuities, such as their transmissivity and permeability (Rizzo et al., 2017).

Networks of discontinuities have a major impact on fluid flow, especially when the host rock has low primary permeability (Figure 1). They will provide important long-distance conduits for water flow, influencing both the volume and velocity of inflows and potentially leading to water inrush — a critical safety hazard during tunnelling. They will also have a significant impact on the strength and elastic

Figure 1. Schematic of an underground excavation. The coloured areas contour the scales of interest for the discontinuity intersect the excavation. The REV incorporates the representative property for the rock-mass. Black lines indicate fractures at the large- (continuous) and small-scale (dashed), while blue lines show connected and percolating fractures. Light-blue arrows indicate the water flow (elaboration by the Authors).

properties of the fractured rock mass as a whole (the “bulk rock” properties), potentially introducing planes of weakness in the rock mass. It is, therefore, important to incorporate the discontinuity networks into any 3D models of the geology that may be used for hydromechanical models, essential for predicting the directional flow of water through the rock mass.

2 GEOLOGICAL FEATURES

2.1 Overview

Fluid flow through rocks with low matrix permeability (0.1–several mD’s) rely for a large part on networks of connected discontinuities such as fractures formed around structurally deformed zones (Bons et al., 2012; Smit et al., 2023; Gomez-Rivas et al., 2014; Sachau et al., 2015). Therefore, the importance of accurate characterisation of the discontinuities has been consistently emphasised both in the literature (e.g., Hoek & Brown, 1980; Bieniawski, 1989; Hoek, 1994; Pelizza & Soldo, 1995; Hoek, 2018) and at international meetings (most recently at the ISRM Conference in Iguazu, Brazil, in 2019).

Discontinuities in hard rock masses vary in nature depending on the rock type. These can be categorised as follows:

- *Massive*: Includes metamorphic, plutonic, and carbonate platform rocks, as well as sedimentary formations.
- *Regularly Bedded*: Features sedimentary and volcanoclastic rocks.
- *Regularly Alternating*: Characteristic of flysch and turbidites, but also of volcanic lava flows.
- *Irregularly Alternating*: Also typical of flysch and turbidites but with less predictable patterning.
- *Complex*: Includes debris, tectonically disrupted formations, scaly-fabric, schistosity planes, and fault-rocks.

2.2 Discontinuity systems

Discontinuities are not randomly distributed in rock masses; rather, they tend to occur in organised systems, sets, and families depending on the type of rock mass (Figure 2). It is also important to recognise that these networks evolve through geological time, and an observed network represents a snapshot in that evolution. Typically, the smaller features (joints and fractures) develop earliest, and then grow to form faults, so the ratio of larger to smaller fractures will generally increase through time. It is therefore necessary to consider the physical processes by which fracture networks develop, and the effect that this will have on their relationship on different scales, when characterising discontinuities size distributions. Therefore, outcrop characterisation of the discontinuity assemblage is essential to recognise and categorise these features.

- *Sedimentary Rocks*. In sedimentary formations, bedding planes act as primary discontinuity, often supplemented by joint systems and additional fracture. These features play a significant role in connected porosity, permeability, and fluid flow in the rock mass (Berre et al., 2019; Garland et al., 2012; Narr et al., 2006). Mechanical stratigraphy and lithology are particularly critical in carbonate sequences, affecting fracture systems and patterns (see Figure 2 as example) (Fay-Gomord et al., 2018; Laubach et al., 2009; Nelson, 2001; Sun & Pollitt, 2021; Suo et al., 2012).
- *Granitic Rocks*. Granitic rock masses typically exhibit a homogeneous distribution of fractures due to their intrinsic physical and chemical properties (Velde et al., 1991). Primary discontinuities, mainly fractures, are attributed to cooling and solidification processes (Cloos, 1922). These features often necessitate meticulous mapping and multidisciplinary risk assessment, particularly in tunnelling projects, with a specific attention to weathered bands (Thuro & Scholz, 2003).
- *Metamorphic Rocks*. Metamorphic rocks manifest discontinuities in various forms, including anisotropic foliation planes, unloading structures, and tectonic fractures (Özbek et al., 2018; Ramsey & Huber, 1983; Liu et al., 2020). These features can be complex, particularly in basement reservoirs that have undergone multiple episodes of tectonism and diagenesis (Liu et al., 2020).
- *Volcanic Rocks*. Volcanic rocks display a complex range of discontinuities, influenced by deformation around the volcanic edifice and cooling processes (Vitale & Isaia, 2014; Fuller & Sharp, 1992; Lodge & Lescinsky, 2009). In massive lava flows, fractures often appear as sub-vertical, columnar structures and are guided by thermal contraction and isotropic stresses (Lodge & Lescinsky, 2009).

Understanding the intricacies of discontinuity systems across various rock types is paramount for geological exploration, accurate modelling of fluid flow, and risk assessment in tunnelling and reservoir characterization. The distinctiveness of each rock type necessitates a multidisciplinary approach, integrating geological, hydrogeological, and geomechanical investigations.

2.3 Statistical analysis of discontinuities

When characterising the network of discontinuities in rock masses, most data collection techniques are limited to collecting data over a narrowly defined range of scales. Data smaller than this scale range are often unobservable due to resolution limitations (known as censoring), while discontinuities exceeding the scale range are omitted due to truncation — essentially, they are too large/long and thus are only partially included into a dataset.

The selection of an appropriate statistical distribution to model the dataset is crucial for making reliable predictions about the attributes at both small and large scales (Figure 2). The prevalent method for inferring statistical attributes of discontinuities involves calculating the slope of a regression line, often using data plotted on a bi-logarithmic scale (Rizzo et al., 2017). This method assumes that, for a given value of x (e.g., the length or aperture of a discontinuity), the corresponding y -values (the dependent variable) are normally distributed with a constant variance σ^2 (Kreyszig 1970). Various statistical distributions can model discontinuity attributes, including Log-normal, Exponential, Gamma, or inverse Power Law distributions (Hoek et al., 1995; Barton & Zoback, 1992). To find the correct statistics underlying our data, it is also fundamental to adjust the observed distribution of discontinuity attributes (e.g., length, aperture, and orientation) for sampling biases. The first type of bias arises from the probability of intersecting a fracture within the sampling area, which could be a tunnel or an outcrop. This bias is influenced by the fracture dip. The second type of bias is associated with the limitations of observational resolution, encompassing truncation — omitting small attributes — and censoring — failing to capture large attributes due to sampling area limitations. The ultimate aim of statistical analysis is to determine which statistical distribution — be it Log-normal, Exponential, Gamma, or Power Law — most accurately represents the macro- and meso-scale discontinuity attributes; this, in turn, allow us to build accurate upscale models of the discontinuity's networks (Rizzo et al., 2017).

Many authors (see Barton & Zoback, 1992 and references therein) have proposed that discontinuities at all scales in the Earth's crust exhibit self-similar behaviours. The self-similarity of a random variable conforms to an inverse Power Law distribution (Mandelbrot, 1977). Fractal geometry offers a framework for describing these features, which are irregular across all scales. The transformation from one scale to another depends on a specific parameter known as the fractal dimension (often denoted a D). This non-integer slope of the Power Law curve serves as a measure of the distribution's irregularity. Notably, self-similar distributions are scale-invariant, meaning that their features maintain a consistent appearance across different scales. If discontinuities like faults and fractures conform to Power Law distributions, this has significant implications for understanding the network structure of these discontinuities and their impact on the hydro-mechanical properties of the rock mass. More notably, if a Power Law distribution is confirmed that implies a scale-invariance of observed attributes, thus allowing us to directly upscale the observed network of discontinuities.

If a distribution does not follow a Power Law or Exponential distribution, key statistical parameters like the mode, median, mean, and variance can represent the discontinuities, specific to different

systems or sets of discontinuities. The choice of statistical distribution may also be influenced by the type of rock mass in question (Coli et al., 2007). The mode is usually the preferred statistical parameter for characterising rock masses (Bieniawski 1989). The variance also serves as a useful parameter for sensitivity analyses, especially when incorporating the Excavation Support Ratio (ERS) concept, as proposed by Grimstad & Barton in 1993. These parameters can help in selecting the appropriate statistical percentile values, in relation to the target of the project, thus enhancing the reliability of rock mass characterization.

Data should be systematically collected, focusing on systems, sets, and families of discontinuities. Depending on the scale of work, one may observe 1 to 3 discontinuity systems; within each system, 1 to 5 sets; and within each set, 1 or 2 families. The orientation or ‘attitude’ within these categories often exhibits a spectral distribution around a modal or median value.

Persistence varies widely based on the rock formation. For example, in bedding planes, persistence is practically infinite. In ubiquitous joints, persistence is constrained in one direction by bed thickness but can extend up to a few tens of metres in the opposite direction. In massive rocks, first-generation discontinuities are generally straighter, wider, and more persistent than subsequent generations, with scales ranging from tens to hundreds of metres. Notably, in neotectonics fracture bands, persistence can extend to hundreds or even thousands of metres. Such variations in persistence are crucial for an accurate *water flow* assessment and should be meticulously documented.

3 MODELLING THE ROCK-MASS PERMEABILITY

The nature of a hard rock-mass is inherently heterogeneous and discontinuous, which has important implications for what is known as the ‘scale effect.’ Specifically, as the size of the excavation expands, the area factor increases according to the square of the size, while the volume factor increases cubically. This non-linear scaling can lead to complex behaviours that must be accounted for in both study approaches and engineering solutions. Often, the size of the excavation exceeds that of individual rock blocks defined by their natural discontinuity patterns. These variations in size relationships can lead to diverse responses from the rock-mass, prompting the need for specialised study methods to address the unique challenges they present (Hoek & Brown, 1980).

The hydro-mechanical behaviour we observe in the rock mass varies based on the spacing of these discontinuities and the relative size of the excavation: it may focus on the properties of intact rock, extend to the broader rock mass, or even centre on a specific discontinuity.

To carry out a precise investigation — whether focused on hydro-mechanical behaviour or geomechanical stability — it is crucial to understand the 3D geo-structural configuration of the rock mass. This understanding is especially important in relation to the scale at which engineering projects and geological structures are observed. Such comprehension allows us to categorise the rock mass into four primary zones of interest, as reported in Coli & Pinzani (2014). These zones influence the methods we choose for modelling rock behaviour:

- *Very Near Field*: Defined by a single, well-understood discontinuity.
- *Near Field*: Defined by several known discontinuities.
- *Far Field*: Defined by a pervasive network of discontinuities, resembling a continuum.
- *Very Far Field*: Defined by omnipresent discontinuities coupled with distinctive regional tectonic structures, such as faults, thrusts, and fracture corridors.

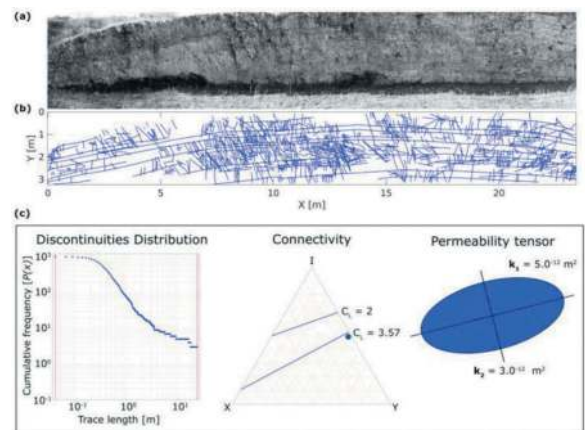

Figure 2. Example of discontinuity analysis performed on an outcrop analogue. (a) A vertical section of the Meso-Cenozoic carbonate unites of the Apulian foreland (Canale di Pirro, Apulia, Italy). (b) Trace of the discontinuities – fractures and bedding plane. (c) Example of data derived from outcrop analysis using the software FracPaQ (Healy et al., 2017): from left to right, statistical distribution of discontinuities; connectivity (blue dot) of the discontinuity network; and permeability tensor estimated using Oda (1986) (elaboration by the Authors).

A conventional approach to modelling these complex, spatially variable discontinuity networks involves statistical description. Statistical models allow us to account for key properties like density, orientation, and connectivity. Specifically, the intensity and density distribution can be characterised using cumulative density distribution functions P21 or P20 (Dershowitz & Herda, 1992). These functions describe the areal or mean linear intensity and density of discontinuities of a given size or larger. We then use these statistical properties to inform key

attributes of the bulk rock mass, such as its porosity and permeability (important for flow modelling), or its failure strength and elastic moduli (relevant for geomechanical modelling).

In particular, determining the permeability in hard rock masses requires a comprehensive analysis of discontinuity data, emphasising connectivity and transmissivity. Crucial discontinuity attributes, such as spacing/frequency, roughness, and notably, aperture (critical due to its cubic impact as per Lomize, 1951), need to be statistically assessed (Coli & Modugno, 1996). Based on this data, a tensor representing the bulk permeability of the rock mass can be derived using methodologies like those of Snow (1969), Oda (1986), and Kiraly (1969; 1978; 2002). These tensors then aid in estimating the potential impact and anticipated water influx for tunnel sections (Figure 2). For instance, when modelling the rock-mass permeability using these bulk methods, the following assumptions are generally made:

- The analysed rock mass is considered to have low primary (matrix) porosity; thus, the fluid flow occurs entirely within the discontinuities.
- Despite natural discontinuities having complex surfaces and irregular apertures, they are modelled by a parallel plate model—i.e., individual fractures lie in a single plane and have a constant hydraulic aperture (Rizzo et al., 2017).

One of the most common methods to estimate bulk permeability of rock masses is based on the combination of the cubic law and the crack-tensor formulation as expressed in Figure 2c according to Oda (1986) and Brown & Bruhn (1998). The permeability tensor incorporates information about discontinuity size (length and aperture), orientation and spatial densities. In recent developments, a novel analytical method for estimating the bulk permeability of rock masses has emerged, based on the work of Saevik & Nixon (2017). This innovative approach employs a straightforward formulation centred on the connectivity within the discontinuity network (Figure 2b). Factors like density and size distribution of observed features do influence connectivity, but it also encapsulates other geometric attributes such as spacing distribution and anisotropy of the discontinuity network. Importantly, connectivity exerts a significant, nonlinear impact on overall rock permeability; fluid flows far more easily through a network of interconnected discontinuities than through isolated fractures (Balberg et al. 1991; Berkowitz 1995; Odling et al. 1999).

While the two aforementioned analytical methods offer quick estimations of bulk permeability, they have the limitation of not explicitly accounting for stress conditions. However, their speed makes them widely preferred over more time-consuming numerical simulations. In addition to these methods, equations from Barton et al. (1985) and Wei et al. (1992) highlight the role of surface roughness in

constraining water flow within a discontinuity, leading to a laminar flow pattern. These laminar flow patterns are best described by Darcy’s Law (Coli et al., 2019b). Moreover, Barton et al. (1985) included the impact of in-situ stresses, and Wei & Hudson (1988) integrated the influence of depth-induced stress into their permeability equations. Building on these foundational methods and equations, the permeability values obtained can then serve multiple practical purposes. They can be incorporated into empirical charts for quick reference (Heuer, 1995; Marinos, 2001), used in analytical studies to fine-tune models (Goodman et al., 1965; Perrochet, 2005), or applied in numerical simulations like Finite Element Method (FEM) and Distinct Element Method (DEM) for detailed analyses of water flow in tunnel sections (as compared in Rutqvist et al., 2009a; 2009b; Coli et al., 2018).

Instead of using the bulk properties of the rock mass, a more sophisticated approach is to build an “explicit” stochastic model, comprising a series of geometric objects representing individual discontinuities, also known as a Discrete Fracture Network model or DFN (Dershowitz et al. 2000). The discontinuities in the DFN do not correspond directly with those actually observed on outcrop; instead, a DFN model has the same overall statistical and geometrical properties as the real discontinuity network. Key properties that a DFN encloses are the density and the size distribution, as well as the connectivity of the different elements — fractures, faults, and bedding planes — composing the network of discontinuities.

DFN models are invaluable tools for simulating flow and exploring both hydraulic behaviour and interactions between hydraulic and mechanical elements (Thomas et al., 2020). A range of methods exists for calculating mechanical and hydraulic properties in these models, including approaches like boundary element methods (Tuckwell et al., 2003), discrete element methods (Lisjak & Grasselli, 2014), finite difference methods (Karimi-Fard et al., 2004; Erhel et al., 2009a), and others such as finite elements (Vohraliket et al., 2007), finite volume (Koudina et al., 1998), and virtual element methods (Benedetto et al., 2017). Some approaches combine both *continuum* and *discontinuum* theories to tackle various challenges, such as arrest, force, and displacement solutions, as well as the dynamics and contact between elements (e.g., Berrone et al., 2015; Mailhot et al., 2016). DFN studies are crucial for determining permeability tensors in fractured rock masses. These tensors, which represent the rate at which fluid can move through a material, are calculated based on the geometry of the network and interconnectivity of discontinuities. For large-scale models where representing each discontinuity is impractical, effective, or ‘equivalent’ permeability tensors are employed. The process of upscaling

these properties to a larger model necessitates the use of a Representative Elementary Volume (REV) — a sufficiently large and intricately fractured and faulted volume that can encapsulate the rock mass essential characteristics. In rocks with sparse discontinuities, finding an appropriate REV is challenging because properties become highly dependent on scale. The size of an REV varies with the geological context and the scale of the engineering project (Franciss, 2010; Gustafson, 2012). Conceptually, an REV can be thought of as a cube, where each side is ten times longer than the modal block (B_v) as defined by the discontinuity network (Coli & Pinzani, 2014).

4 DISCUSSION

4.1 *Significance of the observations*

The advancements in rock-mass hydro-mechanical modelling, as discussed in this paper, have significant implications for real-world scenarios and elucidate several critical facets of hard rock excavations and their inherent heterogeneity. Firstly, the unveiled complexities surrounding the scale effect accentuate the necessity of adaptive approaches in geological and engineering analyses. Scale effects, characterised by the intricate relationship between excavation sizes and the behaviour of rock masses, serve as a fundamental parameter influencing engineering decisions, especially in tunnelling projects.

4.2 *Future work*

The journey to understand and model rock-mass behaviour, though extensive in our current research, opens avenues for future innovative explorations. A promising direction lies in the realm of technological advancements, specifically, the development of automated or semi-automated tools. By leveraging the prowess of deep learning segmentation techniques, it is conceivable to rapidly extrapolate a discontinuity network from images of outcropping rocks. This automated extraction could, in turn, facilitate more accurate and efficient calculations of an appropriate REV, grounded in geo-structural data, streamlining processes that currently demand significant manual intervention.

5 CONCLUSIONS

The presented work has examined the intricacies of rock-mass behaviour, focusing specifically on scale effects and the permeability of discontinuities in hard rock masses. By discussing the use of both analytical and numerical methods, we have highlighted the complexities involved in understanding and modelling the hydro-mechanical behaviour of rock formations for tunnelling projects.

While analytical methods offer quick insights into the hydro-mechanical properties of discontinuity networks, more sophisticated tools like numerical Discrete Fracture Networks (DFNs) provide practical advantages. These are particularly beneficial for large-scale projects and in areas with variable properties. Here, DFNs can more effectively incorporate the hydraulic behaviour and mechanical interactions within rock masses. The importance of correctly acquiring and statistically treating data from available outcrops cannot be overstated, as this information directly feeds into both analytical and numerical models.

The potential applications of the observations presented in this work are noteworthy. For engineers, these insights could serve as valuable reference points in tunnelling projects, emphasising considerations of both safety and cost. Looking ahead, numerous avenues for further research exist, from the development of automated analysis tools to the exploration of these methods in various geo-engineering and geo-energy contexts.

ABSTRACT: The most authentic geological information is exposed on the tunnel face, and the identification of rock integrity is an important basis for classifying the surrounding rock of the tunnel face. To solve the many shortcomings of traditional manual sketching, it is proposed to use image processing technology and point cloud processing technology to extract the structural characteristics of the surrounding rocks on the tunnel face. A 3D data acquisition instrument combining a camera and a laser radar has been developed for collecting tunnel face data. To adapt the collected data from the instrument, an algorithm was developed to establish a 3D model of the tunnel's invert and identify the structural planes of the surrounding rocks based on differences in their normal vectors. Simultaneously, a convolutional neural network was trained to automatically extract structural plane features from the 2D tunnel face images. Finally, the results of the 3D model identification and image feature extraction were synthetically evaluated to achieve automatic recognition of the joint structures of the tunnel face's surrounding rocks.

Keywords: Tunnel face, 3D reconstruction, Convolution, Convolutional Neural Network Tunnelling

1 INTRODUCTION

The geological information of the tunnel affects the safety and efficiency of the project. There is a significant discrepancy between the surrounding rock exposed during tunnel excavation and the geological survey results. When the surrounding rock exposed during excavation is found to be worse than the results of geological investigation, it may lead to unreasonable support parameters, resulting in increased project cost and prolongation of construction time. The geological structure of the surrounding rock during the excavation stage of the tunnel is closely related to the safety of the tunnel excavation. The traditional method of obtaining the surrounding rock structural information by manual sketching is incomplete and unable to form a 3D model. This kind of product has great limitations in evaluating the safety of the tunnel. At the same time, measurement results are affected by personnel experience and subjective judgment, and different personnel may obtain different results, making it difficult to evaluate the grade evaluation of the surrounding rock of the working face (Yang et al., 2009).

With the development of photography and laser scanning technology, non-contact measurement methods have gradually been applied in the field of tunnel engineering. Digital photography technology has received widespread attention due to its convenience, speed, and easy data storage. Leng (2009) used monocular vision method to study the extraction of geological information from tunnel face images and visualized the geological structure of the excavated part of the tunnel. Chen et al. (2017) established a high-precision 3D model of the tunnel face by single-camera binocular technology, which realized the automated extraction of rock mass spacing and roughness. Li et al. (2022) used Unet neural network algorithm for automatic identification of traces in tunnel face image. Combined with the strength information to realized the classification of surrounding rock in palm face. However, digital camera image acquisition is greatly affected by the environment, and in the complex and harsh working environment of the tunnel. There are problems such as image quality is difficult to guarantee and it is difficult to match the same name points on the image (Li et al., 2018).

*Corresponding author: 1196761682@qq.com

Laser scanning can directly obtain the 3D coordinate information of the object surface to be measured. According to the three-dimensional coordinates, a high-precision 3D model can be directly established. Therefore, it is widely used in the acquisition of surrounding rock structural plane. Song et al. (2013) investigated the advantages and disadvantages of 3D laser scanning technology and digital photography technology in geological cataloging work. Although it lacks in real images compared with digital camera technology, 3D laser scanning technology can better obtain holographic data of geological structural surfaces. Fekete et al. (2010, 2013) detailed a method to establish a tunnel perimeter rock based on the 3D point cloud data of the tunnel face and surrounding wall. And use the model to evaluate the stability of the surrounding rock. However, laser scanning has the defect of not being able to obtain the surface texture information of the rock mass due to its own characteristics.

In this paper, a portable tunnel face rock information acquisition device that combines a small laser scanning device with a camera is used. Laser scanning has strong anti-interference ability and can obtain 3D coordinate information of the detected object surface. The camera can obtain the shape and color information of the detected object surface. This equipment can be used to realize the fast and high-quality acquisition of the surrounding rock information and the establishment of high-precision 3D model of the tunnel face. This article proposes an automated identification method for the joint information of the surrounding rock of the tunnel face, which provides support for the compilation of tunnel geological information.

2 METHOD OF CONSTRUCTING 3D MODEL OF TUNNEL FACE

2.1 Collecting tunnel face data

Before establishing a high-precision 3D model of the tunnel face, it is necessary to collect the geological information data of the surrounding rocks of the tunnel face. TK-SEG (smart eye geology) and external lighting are used to collect raw data. TK-SEG is a self-developed equipment that combines laser lidar and camera, as shown in Figure 1. The data collection process is carried out after the completion of excavation muck transport. Adopting image processing technology based on multi-view geometric projection, the overlap rate of neighboring images needs to be more than 30%. In order to avoid the effect of insufficient image overlapping area caused by manually rotating the camera, the equipment is combined with the gimbal to realize automatic data acquisition. To obtain the best data, the equipment needs to be leveled before acquisition, and the surface of the object should be as vertical as possible when collecting data. The equipment is placed near the center axis of the tunnel, and the whole tunnel surface image is automatically captured through the rotation of the gimbal at the erection

position. The placement position when collecting data is shown in Figure 2.

Figure 1. Equipment for collecting data.

Figure 2. Area for placing instruments.

2.2 Create 3D model of the tunnel face

SFM (Structure from Motion) technology is used to realize 3D reconstruction of tunnel surrounding rock based on tunnel face image data. A camera is used to take a sequence of highly overlapping photos of the same object from multiple angles to obtain the feature points of the neighboring photos. The spatial structure equation of the feature points of the photographed object is constructed by using the geometric projection relationship, and the spatial position relationship between the feature points of the photographed object and the camera is obtained by solving the equation. In this paper, SMART EYE software is applied to reconstruct the 3D model of the tunnel face. The scene information such as the camera position is obtained by matching the feature points in the neighboring pictures of the tunnel surface and calculating with the projective theorem. Then the scene information is combined with the original pictures to get the 3D

point cloud of the object. Finally, the Poisson Surface Reconstruction algorithm is used to connect the point cloud to form a triangular mesh to construct a 3D surface to complete the reconstruction of the image.

To determine the scale of the reconstructed tunnel face model, it is necessary to combine the separate 3D models of the tunnel face created by the camera and laser lidar. The distance and angle relationship between the instrument and the surrounding rock acquired by laser lidar is utilized to determine the scale of the image 3D model. Matching the excavation mileage with the model enables the model to be positioned in the design line. The image and laser 3D model are shown in Figure 3.

Figure 3. Reconstruction model of tunnel face.

2.3 Classification of reconstructed models

The reconstructed 3D model includes tunnel face and surrounding wall. Both of these are valuable for identifying joints on the tunnel face. However, it is necessary to classify both in the model for accurate analysis. After determining the dimensional relationship between the model and the design contour, the reconstruction model is positioned with the mileage information to determine the correspondence between the model and the mileage of the designed line. The normal vectors of the triangular mesh of the tunnel face have obvious parallel relationship with the design line, and the normal vectors of the triangular mesh of the surrounding wall have obvious perpendicular relationship with the design line. The tunnel face and surrounding wall in the model are segmented by utilizing the corresponding

relationship. The result of tunnel face and surrounding wall segmentation is shown in Figure 4.

Figure 4. Result of reconstruction model classification.

3 METHOD OF CONSTRUCTING 3D MODEL

3.1 Structural surface recognition based on 3D model

In the reconstructed model of the tunnel face that has been localized, the occurrence of the structural surfaces in the tunnel face can be obtained directly. Based on the feature that the normal vector orientations of different structural surfaces have large differences, the structural surfaces are recognized from the point cloud of tunnel face. It is realized as follows: (1) The structural surface of the tunnel face model is divided into small closed regions. (2) The closed regions with the same normal vectors are aggregated using a clustering algorithm. (3) The

boundaries between the different aggregated regions are the 3D traces of the structural surface. After the structural surface 3D traces are aggregated and eliminated, the projection algorithm is used to project the 3D traces onto the 2D image of the tunnel face. The two-dimensional structural surface traces of the tunnel face can be obtained. The structural surface identification and projection are shown in Figure 5.

Figure 5. Structural surface recognition and projection.

3.2 Extraction of palisade nodules based on CNN

Traditional image processing techniques and machine learning algorithms utilize contour extraction and feature point matching to identify the structural surface of the tunnel face. However, the scenes targeted are single, the scope of application is narrow, and the correct rate is low. The different lighting and different acquisition angles will have a great impact on the results of image processing, and the extracted contour contains a lot of noise. Convolutional Neural Networks (CNN) is one of the most effective means to carry out image recognition research, which can accomplish the extraction of complex image features. Therefore, this paper chooses the CNN training software to recognize and extract the perimeter rock joint traces in the tunnel face image. The training process is as follows:

(1) Training dataset: Geological engineers annotate the generated tunnel face images with structural surface traces, and the annotated structural surface trace image data are recorded in the form of text. The annotated text and images are

Figure 6. Structural surface recognition training.

summarized to form a dataset together with the original images, as shown in Figure 6.

- (2) Expansion of the dataset: The tunnel face images are large in size, which are directly used for training and have higher requirements for hardware equipment. It is necessary to crop the images into small-sized images and exclude the tunnel face images that do not contain structural surface trace annotations. To increase the diversity of the dataset, the training image will be randomly rotated, flipped, mirrored, and adjusted for brightness and saturation. Annotated image data needs to be processed simultaneously to maintain consistency.
- (3) CNN training: CNN is used to obtain the output by forward computing the inner product of the inputs and the weights. The weights are updated iteratively by back propagation algorithm. Finally combined with gradient descent method to get the weights that make the whole network optimal. Therefore, the dataset image is cropped to 800×800 pixel size. Supervised learning using CNN. The training is stopped after the software recognition effect reaches the design accuracy requirement or the design number of times. The training results are shown in Figure 7.
- (4) joint feature extraction: the feature image obtained through the CNN is a probability distribution map, which needs to be processed in order to obtain the pending structural surface area. This paper adopts the Conditional Random Field algorithm (CRF) to mark the structural surface image. The steps of the algorithm are as follows:
Set the random variable $X_i \in L = \{l_1, l_2, \dots, l_L\}$ to denote the label of pixel i and form a random vector X according to X_1, X_2, \dots, X_N, N denotes the number of pixels in the image.

Assuming the image $G = (V, E)$, where $V = \{X_1, X_2, \dots, X_N\}$, the global observation is I . The Gibbs is used to transform $G = (V, E)$ to $P(X = x|I) = \frac{1}{z(I)} \exp(-E(x|I))$. In the fully-connected CRF model, the labeling x_i energy is denoted as $E(x) = \sum_i \varphi_u(x_i) + \sum_{i < j} \varphi_p(x_i, x_j)$. $\varphi_u(x_i)$ is a unitary energy term representing the partitioning of pixel i into labels x_i energy. $\varphi_p(x_i, x_j)$ is the energy of simultaneous segmentation of pixel points i, j into x_i, x_j . Thresholding judgment is performed for the obtained $E(x)$. The pixel points with probability greater than 0.5 are retained. The final images are obtained as shown in Figure 8.

Figure 7. CNN training result.

Figure 8. Probabilistic threshold maps for structural surface.

- (5) Burr rejection and joint grouping: The connected regions are extracted in the thresholded labeled image and line refinement is applied to the extracted connected regions to obtain irregular lines with single pixel widths. The training-acquired joint traces are used to determine the degree of overlap with the traces of structural surfaces projected onto a 2D plane by 3D model identification. Calculate the minimum closure rectangle overlap rate of the both using the absolute difference of their angles, and eliminate areas with closure areas less than the preset threshold.

When grouping joint traces, the overlap of 0° and 360° results in the inability to cluster using Euclidean distance. Equation (1) is used to compute the angle based on the uniform reference axis. And Equation (2) is used to map the angle to the circumference to obtain the coordinate points of the position.

$$\theta = \arctan \frac{y_2 - y_0}{x_2 - x_0} - \arctan \frac{y_1 - y_0}{x_1 - x_0} \quad (1)$$

Where: x_0, y_0 are the coordinates of the origin.

$$P(x, y) = (\sin \theta, \cos \theta) \quad (2)$$

Coordinate points are used as data input for clustering using Meanshift algorithm. The first three groups with the highest number are taken as retained nodes. The remaining groups are taken as cluttered structural surfaces. The recognition effect obtained after clustering is shown in Figure 9.

Figure 9. Result of geological sketching on tunnel face.

4 APPLICATION OF GEOLOGICAL RECONSTRUCTION

4.1 Calculate the rock integrity

The BQ method is used to evaluate the surrounding rock, which is based on two indicators: rock mass hardness and integrity. The hardness of the rock mass is determined by the uniaxial saturated compressive strength R_c of the surrounding rock. The integrity of

the rock mass is determined by the rock integrity index K_v . Calculate BQ through Equation (3). The R_c can be obtained directly through the strength test of surrounding rock. The K_v is the research objective of this paper. There is a corresponding relationship between K_v and J_v . The J_v is the number of structural surfaces per cubic meter of rock volume. The formula for calculating K_v from J_v is shown in Equation (4) (Hu et al., 2010).

The spacing method is a commonly used method to measure the J_v . After the convolutional neural network algorithm extracts and groups the joint traces of the tunnel face, the distance between each group of joint traces can be obtained and the average value can be obtained by making virtual measuring lines. Then the J_v is calculated by Equation (5). As can be seen from Equation (5), the default assumption is that the length of the normal calculation line of each group of joints is 1m. But the distribution of joints in the actual rock mass is uneven. There is obvious dispersion between the spacing of the joints. When the group of joints is diagonally intersected with the surface of the unit body, the length of its calculation line is greater than 1m. So the actual calculation of the value of J_v is multiplied by the correction coefficient of 1.05~1.1.

$$BQ = 90 + 3R_c + 250K_v \quad (3)$$

$$\begin{cases} K_v \approx 0.75 (J_v < 3) \\ K_v = 0.75 - \frac{J_v - 3}{35} (3 < J_v < 10) \\ K_v = 0.55 - \frac{J_v - 10}{50} (10 < J_v < 20) \\ K_v = 0.35 - \frac{J_v - 20}{75} (20 < J_v < 35) \\ K_v = e^{-0.054J_v} (35 < J_v) \end{cases} \quad (4)$$

$$J_v = S_1 + S_1 + \dots + S_n + S_k \quad (5)$$

Where: S_n is the number of joints per meter of measuring line in the n th group of joints, S_k is the number of joints per meter of measuring line in the non-grouped joints.

4.2 Joints analysis of tunnel face

Eighteen sets of tunnel face data were collected in the test tunnel to analyze the integrity of the surrounding rock. The information of the surrounding rock at the tunnel face was collected by using the TK-SEG equipment. The 23 images were automatically collected at one tunnel face. Some of the tunnel face images are shown in Figure 10. After importing the raw data into TK-SEG software, the 3D model of the tunnel face was obtained as shown in Figure 11.

Based on the aforementioned method, the joints of the tunnel face are obtained as shown in Figure 12(a). The tunnel face contains two groups of joints. The main direction of Group 1 joint inclination is 49° , the joint spacing is 0.51 m, the average length is 2.85 m. The main direction of Group 2 joint inclination is -8° , the

Figure 10. Original image of tunnel face.

joint spacing is 0.79 m, the average length is 3.26 m. The J_v of surrounding rock mass is 3.55, and the K_v is 0.73. Compared with the sketch results of geological engineers (Figure 12 (b)), the software recognition results can identify the corresponding joint traces. It has been proven that this method is feasible and accurate for use in tunnels.

Figure 11. 3D reconstruction result of tunnel face.

4.3 Analysis of rock integrity of tunnel face

In the test tunnel of 18 groups of tunnel face surrounding rock joint information as shown in Table 1. The data results show that the excavation exposed tunnel face surrounding rock K_v is in the range of 0.66~0.75. The integrity of the rock mass is complete and more complete. Overall, the integrity of surrounding rock mass in the test section is relatively

(a) Software identification result

(b) Engineer sketch result

Figure 12. Result of identifying joints.

good. This situation is conducive to tunnel excavation. The 150m test section was constructed for a total of 46 days. The construction progress proves the accuracy of the method used in this article in identifying the integrity of surrounding rock.

Compared with the manual measurement method, the method of this paper can flexibly and quickly obtain the information of surrounding rock joints. Combined with the information of surrounding rock strength, it can carry out the work of enclosing rock classification.

5 CONCLUSIONS

On the basis of image recognition technology, this article proposes to use convolutional neural network algorithm to automatically extract the structural features of surrounding rock in the surrounding rock image of the tunnel face. A method for identifying the integrity of surrounding rock is established. And this method is applied to the integrity analysis of surrounding rock in test tunnel. The conclusion is as follows:

- (1) Using a combination of photography and laser to obtain images of the tunnel face and 3D coordinates of the surrounding rock surface. 3D reconstruction of tunnel face images using SFM technology. The combination of images and spatial information obtained by laser enables the determination of model scale. Simultaneously achieve positioning on the design line. This method solves the shortcomings of two technical methods in data collection and model building, and has good application value.
- (2) The method based on convolutional neural network training can quickly and automatically extract the features of surrounding rock structural surface under the condition of guaranteeing the recognition accuracy. Combined with the J_v , the method of recognizing the integrity of surrounding rock at the tunnel face is established. The accuracy and feasibility of the method are verified in the field application of test tunnel.
- (3) The surrounding rock classification in the tunnel face is a research hotspot, which is an important parameter for determining the rationality of tunnel design. The research content of this paper is mainly the recognition of perimeter rock integrity, which is only a part of the parameters of surrounding rock classification. The following work will study methods for automatically obtaining other parameters required for automatic analysis of surrounding rocks.
