Keywords: Tunnelling, Large diameter tunnel, TBM technology, variable density

1 INTRODUCTION

In recent years, the United Kingdom (UK) has witnessed remarkable transformations in tunnel construction, primarily driven by the advancements in tunnel boring machine (TBM) technology. One of the most noteworthy trends in this evolving landscape is the continuous increase in the diameter of tunnels being constructed. The most recent project examples include hs2 and Silvertown tunnel which are under live construction; projects of large diameter such as A303 Stonehenge tunnel and Lower Thames Crossing are also planned down the pipeline.

Figure 1 illustrates the evolution of tunnel sizes of major projects in London, where the vast majority of tunnelling works take place, using data from a number of well-known projects both in the past and planned down the pipeline. A strong trend of increase in tunnel diameters can be observed, from the vintage London Tube to modern infrastructural projects such as Crossrail, HS2, Silvertown, and the Lower Thames Crossing down the pipeline.

The significance of tunnel dimensions is evident as tunnel design and construction inherently entail specific size-related implications. Based on personal experience, the author would like to acknowledge that with increased tunnel diameter, comes a host of

unique and multifaceted challenges, encompassing both construction-related and design-related aspects.

This trend in tunnel diameter is not merely a numerical progression; it represents a profound shift in the capabilities and possibilities of underground infrastructure development in the UK. As we delve deeper into the intricacies of this phenomenon, it becomes evident that this evolution is reshaping the way we perceive and harness subterranean spaces, with far-reaching implications for transportation, utilities, and urban development. In this exploration, we will delve into the factors driving this trend, its impact on various sectors, and the exciting prospects it presents for the future of infrastructure in the United Kingdom.

In the context of this paper, we define a ‘large diameter tunnel’ as one that has an excavation diameter of close to or greater than 10m. This paper aims to provide an overview of the following challenges that are unique to large diameter TBM mined tunnels, using plain English, without the reference to any equations, making it accessible to a wider audience. The larger the tunnel diameter is, the more pronounced the following challenges tend to be.

- Construction and logistics:
 - High power requirement, especially for EPB
 - Large and heavy tunnel segments

- Long ring assembling time
- Large spoil and grout volume
- Face stability and intervention
 - Mixed face condition
 - Pressure control
 - High groundwater pressure
 - Face intervention
- TBM selection
- Design:
 - Spatial utilisation
 - Low overburden at launch
 - Deformation control
 - Surface settlement
 - Buoyancy uplift

2 CHALLENGES IN CONSTRUCTION AND LOGISTICS

Firstly, a substantial amount of torque is required to operate large diameter cutterheads. Bambridge et al. (2013) find that the TBM torque is cubically proportionate to the tunnel diameter, which means a 10m diameter TBM requires a torque output of

approximately 8 times that from a 5m diameter one under the same ground conditions, as an example. The required torque is even higher in the case of Earth Pressure Balance (EPB) tunnel boring machines, which inherently involve more abrasive cutting processes, handling the muck in a solid or semi-solid state. This necessitates a considerable amount of power, making the engineering of power systems a paramount concern. Availability of electric supply in large diameter TBM may be a show-stopper for certain rural locations or cities that are unable to facilitate a significant increase in local power demand, especially if two TBMs are driven simultaneously. The biggest diameter TBM in the UK on a live project is from the Silvertown project, at an excavated diameter of 11.87m, with a cutterhead power of 5,600 kW and a torque of 31,093 kNm (source: Herrenknecht).

Furthermore, the thickness of tunnel segments presents another noteworthy aspect. Segments of 500mm to 600mm or even beyond in thickness are not uncommon around the world for large diameter tunnels, as the segment thickness largely follows a linear relationship with tunnel diameter (Salas and Della Valle, 2012). This places significant demands

on the volume capabilities of the tunnel logistics. Width, height and weight restrictions of highways and bridges apply if the segments are transported via roads. Due to the limits logistics capacity, it is common practice to divide a full tunnel ring into more segments, making each segment smaller in size and lighter in weight, albeit at the expense of prolonging the ring assembly cycle. For a normal sized tunnel, typical ring assembly cycle time is approximately 20-30 minutes; whereas for a large diameter tunnel, the assembly cycle time can be 40 minutes or more. Therefore the decision-making process on the segment geometry usually involves a trade-off between ease of construction logistics and speed of assembly.

The problem of prolonged ring-building cycle makes measures that can achieve continuous mining more cost-effective. Whilst in hard-rock conditions, this can be achieved by a 'double-shield' TBM, where the TBM advancement thrusts off a pair of grippers as the ring building is taking place, it is relatively more challenging to achieve in soft ground conditions that prevails in the UK. As an UK example, Hs2 Chiltern tunnel adopted a 'semi-continuous mining' methodology for the TBM ring building, allowing the TBM to re-start advancement thrusting off a partially completed ring (Reilly and O'Keefe, 2022). This makes the excavation and ring building to become a more continuously cyclic activity.

Moreover, the considerable quantity of excavated materials conveyed out from and into tunnel face simultaneously presents a monumental challenge, necessitating meticulous logistics planning and execution of spoil handling. Spoils are usually required to be disposed of at a defined location due to environmental considerations, and this may require logistics via the road, or usually better, the railway or barge. Hs2 S1/S2 contractor SCS adopted a 'NEMO' concept (Hooton et al., 2020) to maximise re-use of spoil locally on site for landscaping, based on a multi-disciplinary collaboration. They have also adopted a spoil conveyor belt to reduce disruption to road traffic (Moore, 2022). At the Chiltern tunnel site, the C1 contractor ALIGN adopted an innovative method of treating chalk spoil, turning it into 'chalk cakes' to be re-used for slope landscaping (hs2, 2021).

Simultaneous parallel operation is another particular challenge as well as opportunity for large diameter tunnels, due to its inherent large available space on cross-section. When planned right, simultaneous operation can be permitted to all or a number of activities in the TBM including but not limited to: out-logistics (mainly excavated spoil removal), in-logistics (mainly segments, tunnel internal structures and consumables such as grout), ground treatment, installation of tunnel internal structure, cross passage construction, TBM maintenance such as change of cutter tools. The 'scale factor' of large diameter tunnels increases the volume of these elements in a non-linear manner.

For example, the volume of excavated spoil and the annulus grout are both in a squared relationship to the tunnel diameter. Nevertheless, on the flip side of the coin, the large available cross-sectional area may permit parallel installation of multiple TBM configurations, which will be discussed in later sections of this paper.

3 CHALLENGES IN FACE STABILITY AND INTERVENTION

Tunnelling in the UK, and especially in and around London, where the majority of tunnelling work takes place, is primarily situated within the 'soft ground' remit, i.e. soil, as opposed to rock (Jones, 2022). In the context of this paper, chalk is also classified as 'soft ground'.

In 'soft ground' tunnelling, the stability of the tunnel face assumes critical importance, particularly in the case of large diameter tunnels. In the case of large diameter TBMs, considerable mixed face conditions, encompassing diverse rock types, soil compositions, fault zones, dissolution features and water table variations, may be inevitable. Even if a homogenous route is planned, the excavation may uncover unexpected ground conditions. Different layers could bear different face pressure, which calls for a higher level of accuracy in the face pressure control of the TBM.

The pressure control of EPB TBM is relatively less accurate compared to slurry, since it mostly relies on the muck itself to balance the pressure, which tends to be variable. The balancing pressure of a slurry TBM better follows a hydraulic gradient thanks to the presence of bentonite fluid, as well as an air bubble mechanism serves to regulate face pressure. When facing particular challenges such as high ground permeability, low ground cover or karst features, adopting a thicker and heavier bentonite suspension (slurry) can be a suitable solution – this will be further discussed later in this paper.

Furthermore, large diameter tunnels typically require deeper ground cover, resulting in high groundwater pressure at the face. Consequently, the management of hydrostatic pressure gradients at the face presents a multifaceted challenge. The implementation of robust dewatering systems, including wellpoints, pumping mechanisms, and grouting techniques, can be complementary measures for the control and prevention of water infiltration into the tunnel.

Bambridge et al. (2013) find that the TBM ram thrust increases almost quadratically with the tunnel diameter in order to resist the face pressure and overcome the shield friction. This places high importance on the TBM specifications and the structural capacity of the tunnel segments to resist such ram thrusts.

In addition, mixed face conditions, as well as the presence of boulders are likely to result in more

wear of the cutter tools. This leads to higher frequency of face interventions for maintenance, and stoppage of construction progress. Consequently, it is obviously imperative to minimize the frequency and duration of such face interventions, such as the replacement of cutters. Notably, Slurry Tunnel Boring Machines (TBM) exhibit a relatively reduced need for face maintenance compared to other alternatives.

Certain face interventions entail substantial costs and pose significant health and safety hazards, particularly when conducted under hyperbaric conditions, which underscores the paramount importance of meticulous planning for face intervention, in conjunction with the judicious utilization of so-called ‘safe havens’ wherever possible, to mitigate negative impact to human health when conducting hyperbaric face intervention. ‘Safe havens’ are discrete locations along the tunnel drive where face intervention can be undertaken under the atmospheric pressure, either under natural ground conditions or with human interventions such as ground treatment. These have been used on Lee Tunnels in chalk even under almost 8 bars of water pressure (Newman et al., 2016). Tunnels with large diameters pose greater challenges in identifying suitable ‘safe havens’ for conducting free air face interventions, primarily owing to their large span and heightened internal pressure. To ensure the ground is self-standing, prior ground treatment may be required, and this can possibly be achieved from within the TBM through the cutterhead.

Given the increased complexity associated with facilitating human access for face intervention within such tunnels, it becomes increasingly appealing to establish means for performing essential face maintenance tasks, including the replacement of cutting tools, without necessitating human presence. Various advanced technologies are currently accessible for ensuring accessibility to the cutterhead under free air conditions or for employing robotic arms to execute cutter tool replacements.

‘Saturation diving’ may be required in certain circumstances for situations where high water pressure is present and hyperbaric intervention is unavoidable. Regulatory authorities in the United Kingdom places tight restrictions over the exposure of compressed air and the use of saturation diving to achieve hyperbaric intervention. In the UK, the health of individuals is regulated by “The Work in Compressed Air Regulations 1996”, and accompanied by guidance document L96 (The Stationary Office, 1996; HSE, 1996).

4 CHALLENGES IN TBM SELECTION

4.1 TBM selection in soft ground conditions

There is a wide variety of TBMs available in the market, with each specifically designed to tackle a given type of ground conditions at maximum

efficiency (high speed, low cost and risk). In ‘soft’ ground conditions, particularly in an urban area, a tunnelling shield is usually compulsory, in order to control ground movement.

In the context of ‘soft ground’ tunnelling predominant in the UK, face pressure support can be achieved by one or more of the following measures:

- **Excavated material** – this type is typically called “Earth Pressure Balance (EPB)” machine. It uses the excavated material itself, mixed with conditioner to make it more fluid, to balance the pressure. As an example from the UK, the hs2 Northolt tunnel TBM “Sushila” is EPB type.
- **Hydraulic pressure** – this type is typically called “slurry” machine, because the fluid typically takes the form of slurry (bentonite), which is water with suspension of fine clay particles. As an example from the UK, the Thames Tideway East TBM “Selina” is slurry type.
- **Compressed air or mechanical support** – typically during a face intervention activity when the shield is backed away from the tunnelling face. These are not systematically used in the UK for large diameter tunnelling.

For major tunnelling projects in soft ground, particularly in an urban environment, the choice of the TBM usually comes down to a decision between EPB and slurry. The decision-making comprises a number of factors including the expected ground particle size, presence of ground water, production rates, upfront cost, and so on.

Nevertheless, EPB and Slurry machines do not necessarily have to be mutually exclusive. A TBM can be configured to include function for both modes. Multi-mode TBMs offer the flexibility of adapting to changing ground conditions, to cope with all foreseeable ground condition changes during the drive. However, the conversion typically can take between days and weeks to complete, during which is the TBM’s downtime (no production). This is particularly true if an additional stone crusher is required in front of the slurry circuit intake screen (Billota et al., 2022), which is commonly used to de-risk bands of flint which often occur in chalk in the ground conditions of the UK. Therefore the conversion has to be limited to as few times as possible, and typically only 1 to 2 times during the drive. Also, the upfront cost for procuring such a mechanically complex TBM is naturally higher compared to its peers.

4.2 ‘Variable density’ TBM

The ‘variable density’ TBM, which has been used on the hs2 project as the first in the history of the United Kingdom (smith, 2020), is a type of multi-modal TBM that permits switching modes almost freely without any significant internal system alteration. Especially in the case of large diameter

tunnels, the available space is sufficient to accommodate parallel installation of screw conveyor and slurry circuit in the invert section of the TBM. The ‘variable density’ TBM is by far the most versatile and mechanically sophisticated type of soft ground TBM in use. The variable density TBM used on hs2 project has four modes, EPB, slurry, mixed EPB and slurry, and high density slurry (source: Herrenknecht). It is capable of adapting to a large variety of benign and hostile ground conditions with short response time, reducing the need for pre-engineering and mitigation. Therefore it shines when dealing with long drive, variable face conditions and large diameter, for which a large number of swift switch-overs in mode is beneficial.

Needless to say, the capital cost of type of TBM can be prohibitive for the majority of tunnelling projects. However, in large scale and large diameter tunnelling, the capital cost of TBM procurement usually becomes less significant compared to their conventional peers, and more importantly a high-spec TBM can prove to be more cost-effective in providing risk mitigations for long drives and complex ground conditions, maintaining high efficiency and low risk throughout the drive alignment.

4.3 High density slurry

‘High density slurry’ is one of the four available modes in the variable density TBM used on hs2, as stated above. As the name suggests, this mode utilises ‘high density’ slurry, for which the following

features are more pronounced, as illustrated in Figure 3:

- Firstly, it has higher viscosity. Due to its insignificant shear capacity, slurry suspension fluid to a large extent behave as a liquid, seeping into the pore space of the ground. It has certain penetration distance into the ground ahead of the tunnelling face (DAUB, 2016). The larger grain size the soil has, the greater the penetration distance is. Higher viscosity increases its shear capacity, making it behave less like a liquid and more towards a solid. This way the frictional resistance between the slurry and the soil particles is increased, reducing the distance of penetration before equilibrium is reached. Therefore high density slurry can be used in ground with higher permeability, such as coarse sands and gravels.
- For the same principle, high density slurry also has significant advantages of bridging across fault zones or karstic features, to help prevent or reduce loss of slurry at these significant but frequently encountered ground hazards in tunnelling. It can allow the TBM pass some of these features without disruption from the necessity of other mitigation measures such as grouting.
- Due to higher solid suspension rate, high density slurry has higher density. This results in steeper hydraulic pressure gradient. For any given tunnelling face pressure to be balanced, the pressure at the crown of the tunnel is lower (low hydraulic head, as shown in Figure 3), and this reduces the

Figure 3. How high density slurry help mitigate blow-out risk.

Figure 4. Space utilisation examples from Lower Thames Crossing (image credit: Tunneltalk) and Barcelona Line 9 (image credit: TYPISA).

risk of ground heave or blow-out at the ground surface level

- Following on from above, since the hydraulic head of the balancing pressure is lower, and this can mitigate the risk of slurry infiltration to the ground surface (through an unfilled borehole or other natural cavities), especially for large tunnel with low cover.

5 CHALLENGES IN LARGE DIAMETER TUNNEL DESIGN

5.1 Space utilisation

This chapter shifts our attention to the realm of design considerations, beginning with the challenge of space utilization. In the context of metro or highway tunnels, one prominent issue frequently encountered by tunnel engineers revolves around the endeavor to reconcile the circular cross-section of the tunnel bore with the rectangular traffic envelope from vehicles. As illustrated in Figure 4, the cross-sectional profile of the Lower Thames Crossing (LTC) project in its early stages, it is evident that there exists a substantial amount of unutilized space beneath the deck, although this mass concrete is useful for anti-buoyancy purpose, which will be discussed later on in this paper. In subsequent design development of LTC, the under-deck space has been utilised for maintenance and emergency access. In contrast, when we look to international examples such as Barcelona's Line 9, a double-decker approach has been employed, showcasing a significantly more efficient utilization of space. This arrangement also eliminates the need for cross passages in the case of twin bore tunnels. It is worth noting that these are two distinctively different projects, one designed for highway usage and the other tailored for railway operations, thus no direct comparisons can be made between them due to different project requirement.

5.2 Waterproofing

The deep alignment of large diameter tunnels leads to challenges in the waterproofing design of the tunnels. In segmental lined tunnels, the waterproofing of the tunnel is usually provided by the gaskets around the perimeter of each segment. For a given compressive stress, the gasket can only resist water pressure up to a given limit. In the case of hs2 Chiltern tunnel, due to the high section depth, double gaskets, one on the intrados and another on the extrados, were used to provide sufficient resistance against the high groundwater pressure encountered on the Chiltern tunnel (Reilly and O'Keefe, 2022).

5.3 Shallow launch

As a fundamental guideline in tunnelling, it is advisable to have at least 1 time the tunnel diameter as ground cover. This first-principle criterion ensures that the surrounding ground provides sufficient confinement, increasing bending moment capacity, and more uniform ground support to the tunnel ring. Furthermore, this can help distribute movement in the ground, leading to a more even settlement trough, and also prevents possible 'blow-out' of TBM face pressure. However, in the case of large-diameter tunnels, particularly within urban environments, achieving this required depth for launch can be notably challenging, since for a given alignment gradient, a significantly long section of tunnel would be required to lower the tunnel alignment sufficiently deep to achieve the 1 diameter ground cover. Launching the TBM with less than 1 tunnel diameter of ground cover can be defined as "shallow launch" in the context of this paper, and it introduces several critical hazards including reduced confinement and bending moment capacity of the tunnel segments, higher risk of tunnel face blow-out, more liable to encountering soft ground conditions, and less resistance to buoyancy and floatation. As a design oriented solution, Hs2 adopted a design of

piled slab confinement in combination with ground treatment and embankment (Torello et al., 2020).

5.4 *Large spatial requirement at launch*

The construction of large tunnels often necessitates sizable shafts for the launch and reception of TBMs. If a TBM is launched within a deep shaft, typically a front/back shunt mined tunnel (typically in the form of sprayed concrete lined tunnel) would be required for a full TBM assembly including all backup gantries. The construction of the front/back shunt tunnel in the case of large diameter tunnels can be particularly challenging since they are ‘hand’-mined. Occasionally when it is driven by programme, the ‘umbilical’ launch, or partial launch is chosen, such as Thames Tideway (Tideway, 2019). In the case of large diameter TBMs, the front/back shunt tunnel option may not be feasible given the large tunnel diameter required, whereas the umbilical launch may cause logistics bottleneck up and down the shaft due to the heavy weight of the elements and large volume of spoil. A third possible solution is to provide a long trench, which would result in excessive propping required due to the depth and width.

In response to this challenge, a novel solution known as the ‘caterpillar’ shaft has gained more use in recent years. Notably, caterpillar shafts have found application in large diameter tunnelling projects in the UK in the most recent years including HS2 (High Speed Rail Group, 2021) and the Silvertown tunnels (Smith, 2021), emerging as a cost-effective method for deploying these large TBMs. The circular structural arrangement of caterpillar shaft maximises the arching effect of both the concrete structure and the ground itself, achieving optimal structural arrangement, reducing element thickness and propping.

5.5 *Deformation control and structural capacity*

It is stated earlier in this paper that large diameter tunnels tend to have higher number of segments per ring due to logistic constraints. More longitudinal joints will result in higher ring deformation and joint rotation. This is particularly challenging in a soft ground condition such as the UK, especially where the tunnel face condition traverses multiple hard-and-soft layers or is subject to perched water table, leading to local peaks in bending moments or joint rotations, which may result in excessive cracks and loss of water tightness. Experiment results have also shown that fibre reinforced segments perform less well than conventional bar reinforced segments. Therefore, in certain challenging soft ground conditions, or where fire design is governing, fibre reinforcement alone may not provide sufficient robustness and conventional bar reinforcement, or a mixture of the two, may be necessary.

The TBM gantries run as trailers behind the shield supported by wheels, which exert concentrated loadings on the tunnel segments, creating localised bending, especially when the annulus grout is relatively

fresh. Large diameter TBM gantries usually carry a lot more service units, adding significant weight to them, exerting higher concentrated loads on the segments. Particular attention should be paid to the design of the TBM and the grout mix, for the grout to cure long and fast enough before bearing the wheel loads.

5.6 *Ground movement and settlement control*

A feature pronounced for large diameter tunnels is the large annulus gap. The dimension of the annulus gap for conventional tunnels is in the order of 100mm, subject to project requirements. With regard to large diameter TBM, however, the annulus gap can usually reach 150mm or 200mm, or even beyond. This is one of the key reasons leading to large settlement for constructing large diameter tunnels. Bambridge et al. (2013) coined the phrase of “scale factors”, describing the phenomenon of non-linear numerical relationship between the tunnel diameter and some key metrics in tunnel design, including the annulus gap, grout volume and surface settlement.

In terms of prediction of surface settlement due to tunnelling works, the conventional assumption of 1% volume loss assumed by default in tunnel design would need to be challenged and mitigated, otherwise this may lead to overly conservative assumptions. For example, a 1% volume loss on a large diameter tunnel could result in a theoretical maximum surface settlement in the order of 100mm to 200mm. Bambridge et al. (2013) find that a single bore large diameter TBM at an excavated diameter of 17.48m needs to be able to control face loss to a figure of approx 0.04% if it is to yield a surface settlement value which is equivalent to that of a 4m diameter tunnel with the same depth to the tunnel crown.

Actual ground settlement data as reported by Cording (2018) and Yang, Z. et al. (2010), from Seattle SR-99 tunnel and Yangtze River tunnel respectively, both suggest actual volume loss to be lower than 0.5%.

Since large diameter tunnels are usually buried deeper to achieve sufficient cover, the settlement trough extends well beyond the normal range, causing settlement effects on a much wider range of surface and underground assets.

5.7 *Buoyancy stability control*

Buoyancy stability is a failure mode of underground structures where the minimum guaranteed self weight of the structure and any ground directly above it, must be sufficiently high compared to the buoyancy uplift force of the groundwater, after load factors are applied. However, it is not usual to for buoyancy stability to govern for a normal sized tunnel, as in the vast majority of cases, simply by inspection, the factor of safety is sufficiently high. However, large diameter tunnels in particular, face the buoyancy uplift issue in a much more pronounced way – the tunnel alignment is usually shallow relative to its ground cover, and the tunnel is usually without sufficient backfill to increase its

weight. From the author's experience, as a 'rule of thumb' a minimum ground cover of 0.5 times tunnel diameter should be maintained throughout the route, subject to more explicit buoyancy stability checks.

6 CONCLUSIONS

Based in the particular context of tunnelling in the United Kingdom, this paper has presented a number of technical challenges in large diameter tunnelling. It has categorised these challenges into four categories.

- In terms of construction and logistics, a vast amount of spoil and material to will be handled, and the weight of the tunnel segments will be quite significant.
- From a face stability and intervention requirement perspective, large diameter tunnelling is more susceptible to mixed face conditions, high groundwater pressure, more geological hazards such as karst or faults. Wear of the cutter tools can also be expected to be heavier than usual, with more frequent need for face intervention. Hyperbaric intervention must be best avoided through sound planning and the use of 'safe havens' where possible.
- In terms of TBM selection, this paper provided a high level comparison between EPB TBM and slurry TBM in the use of soft ground tunnelling. It went on to explain the use of multi-modal TBM and then the latest technology of the 'Variable Density' TBM, and the advantages of high-density slurry. In large scale tunnelling projects, these prominent technologies are more likely to be adopted, since the capital cost of the TBM itself plays a smaller part proportion compared to the gigantic overall project cost, and are therefore more cost effective in risk management.
- With regard to the design aspects, this paper explained the challenges in space utilisation by reconciling the rectangular profile and the circular tunnel bore, higher water pressure necessitating more robust waterproof design, the high demand of 'shallow launch', large spatial requirements at launch leading to the more frequent use of the 'caterpillar' type of shafts, large ground movement, difficult settlement control and also noted the importance of checking buoyancy stability of the tunnels.

ACKNOWLEDGMENTS

The author would like to thank TYP SA Group and particularly colleagues within the Tunnelling and Geotechnics department for their technical and mental support in the production of this paper. A particular thanks is owed to Helena Castellvi who provided extremely valuable comments on the draft of this paper.

Smarter, larger, leaner, greener – trends of the tunnelling industry towards a sustainable future in the United Kingdom

Si Shen* & Arabel Vilas Serin
TYPSA Limited, London, UK

ABSTRACT: The latest trend of the tunnelling industry in the United Kingdom can be summarised as ‘Smarter, Larger, Leaner, Greener’. This paper provides an overview of a number of leading-edge technologies and methodologies in practical application in the tunnelling industry, attributed to the aforementioned 4 categories, using case studies of projects in the UK. On the ‘Smarter’ front, this paper will discuss the importance of good practice in ground investigation data management and automation for its interpretation, as well as the application of BIM and design processing technologies. In terms of ‘Larger’, there is an observable trend of tunnels getting bigger over time, right from the classic London Tube to Crossrail, HS2 and Silvertown and Lower Thames crossing. Advancement of TBM technology has enabled bigger and bigger tunnels, which in turn makes certain types of projects feasible. As tunnels get bigger comes a raft of challenges, some construction related, some design related, and this paper will select several aspects of challenges specific to large diameter tunnels to discuss. With regard to being ‘Leaner’, it means to reduce material wastage by combining temporary works and permanent works, which often requires a collaboration between the permanent works designer and the contractor, and sometimes the temporary works designer. Certain advanced design and testing methods can also be used to improve the efficiency. In terms of becoming greener, the UK tunnelling industry has been world-leading in terms of reducing road congestion, noise, carbon and air pollution, for which numerous examples from the hs2 project provide good practice.

Keywords: TBM, design, sustainability, United Kingdom, large diameter, lean construction

1 INTRODUCTION

Through the experience and observation of the authors, the trend of technological advancement in the United Kingdom (UK) can be summarised as “Smarter, Larger, Leaner, Greener”. This means: the integration of digital technology in design; the trend of increase in tunnel diameter; less materials and temporary works and a more sustainable way of working. The authors believe that the UK has been standing at the forefront of all these aspects and will continue to do so in the foreseeable future, taking the lead in the tunnelling industry across the world. For each of these four aspects, this paper will provide a brief overview of selected case studies for leading-edge but tried-and-tested technologies and techniques used in the United Kingdom. It will not delve into great depth about any of the case studies but aims to provide a conceptual framework for the latest technological advancement and demonstrate the trend of future developments. The case studies are of course non-exhaustive, but selected based on the authors’ personal experience. This paper aims to use plain English, without reference to any equations, making it accessible by a wider audience.

2 SMARTER TUNNEL DESIGNS

2.1 *The importance of data*

In the recent years, the amount of information designers receive from ground investigation campaigns has increased immensely. Data analysis has become an indispensable skill for geotechnical and tunnel engineers and plays a crucial role in order to optimize processes, improve efficiency and support the decision-making process during tunnel design.

Understanding the geotechnical behaviour of the ground is the only path to make informed decisions during the design, considering site-specific factors, assess risks, and optimize design solutions.

For this, data analysis is a powerful tool to optimize the process for geotechnical interpretation, visualisation and extraction of meaning insights from data. However, any engineer in charge of efficiently and effectively manage data for the design face some challenges during the analysis for parameter derivation and generation of ground models from ground investigation data. In addition, the extracted data need to be understandable and

*Corresponding author: sshen@typsa.es; avilas@typsa.es

readable for other departments working on the project. Figure 1 shows a glimpse of an in-house data management and visualisation tool that TYPISA has developed, used on projects worldwide.

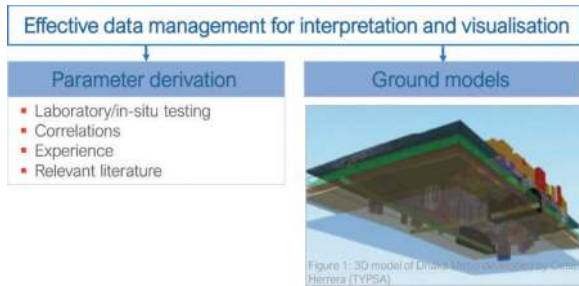

Figure 1. Data management and visualisation (image credit: TYPISA Group).

2.2 AGS data & data-related challenges

In the UK, AGS is a standardised format to transfer geotechnical and environmental data between parties from ground investigation, laboratory testing and monitoring. Although there is a common dictionary to transfer

geotechnical data, every company needs to figure out how to deal with this vast amount of data and how to face the issues related to data quality, data variability, uncertainties in the data base for data validation, interpretation and visualisation. In the end, how efficiently and effectively engineers manage ground investigation data will have a direct impact on productivity, risk mitigation for safe and cost-effective construction projects, and therefore in the success of the project.

As an example, an automated workflow was developed to convert AGS format data into 3D geological surfaces in a BIM environment, requiring minimal manual input. The output is a CAD file stored in Common Data Environment that allows digital traceability and internal baselining (Bottomley and Fernandez, 2020).

2.3 Turning data into information

Challenges during ground investigation data collection, management and analysis arise at the early stages of a tunnel project. Data pre-processing techniques along with a good understanding of the dictionary of the data base is key to make sure that data is turned into design information. Therefore, it is of utmost importance to ensure an appropriate workflow/framework is in place for data quality (inaccurate, inconsistent or contain error), data integration and data analysis for data visualisation before the results are distributed. These steps must be followed while engineers do not lose sight of the fundamental, which is dealing with a non-linear issue: geology. It is a 3D problem with 3D site conditions, so it is important to critically address any piece of data to

work towards more value-engineering designs, while understanding the geohazards, raise them to other disciplines and controlling the risk during the design. For example, with LiDAR scanning results, the risk of faulting was automatically mapped and visualised on hs2 contract C1 (Sercombe et al., 2023).

2.4 Geotechnical data integration

The field of data analysis is constantly evolving. Emerging trends and technologies that are shaping the future of data analysis – integrating BIM and GI data.

Analysing large volumes of data to ensure reliable insights and decision-making processes is one of the main challenges to be addressed. The integration of the data into other software, e.g. GIS that correlates ground parameters with topographical data, can lead to the visualisation of wrong or missing data in the wrong place. For this, it is important to understand geo-statistics and how interpolations are done by the software in order to understand lateral variability of non-linear properties to improve accuracy and risk management.

2.5 Present and future trends

By employing effective analysis techniques and considering site-specific factors, engineers can extract valuable insights, assess risks, and optimize design solutions. As advancements in data analysis continue to unfold, ground investigation data analysis will remain a cornerstone of tunnel engineering.

Automatising these processes is key to reduce human error in validating the data during the error detection/data correction process. Programming language such as MySQL, R, Python, etc. allow us to improve the timing in the process.

The field of ground investigation data analysis is continuously evolving. There are some emerging trends and advancements in geotechnical data analysis, such as the integration of artificial intelligence, machine learning algorithms, and geospatial data analysis techniques that will be soon incorporated if they are not yet.

3 ‘LARGER’ TUNNEL DIAMETERS

Figure 2 illustrates the evolution of tunnel sizes in London, using data from a number of well-known projects both in the past and planned down the pipeline. A discernible trend is evident in the expansion of tunnel diameter over time, extending from the venerable London Tube to modern infrastructural projects such as Crossrail, HS2, Silvertown, and the Lower Thames Crossing. This progression has been facilitated by advancements in Tunnel Boring Machine (TBM) technology, enabling the constructability of increasingly larger tunnels. Consequently,

the feasibility of specific types of projects has been significantly enhanced. Notably, the latest and largest diameter tunnel projects Silvertown and Lower Thames Crossing exemplify this trend as they represent highway tunnel infrastructure developments, whereas other projects are from the rail infrastructure sector.

Figure 2. Evolution of tunnel sizes in London over time.

The significance of tunnel diameter is evident as tunnel design and construction inherently entail specific size-related implications. Based on our personal experience, the authors would like to acknowledge that with increased tunnel diameter, comes a host of unique and multifaceted challenges, encompassing both construction-related and design-related aspects.

Due to the page limit of the paper, the authors will provide only a cursory overview of these considerations. These will be further detailed in another paper the authors have submitted – “Distinctive considerations in the design and construction of large diameter TBM-built tunnels in urban environment – a UK perspective”.

3.1 Challenges in construction and logistics

The first challenge pertains to the substantial torque requirements necessary for the operation of large cutterheads, particularly in the case of Earth Pressure Balance (EPB) tunnel boring machines, which inherently involve more abrasive cutting processes. This necessitates a considerable amount of power, highlighting the importance of sufficient power supply.

Furthermore, the thickness of tunnel segments presents another noteworthy aspect. Segments of 500mm to 600mm in thickness or even beyond are not uncommon around the world (Salas and Della Valle, 2012). Coupled with significant width and ring perimeter, the large concrete volume which leads to significant weight places significant demands on the weight-bearing capabilities of the tunnel infrastructure. To mitigate this, it is common practice to divide tunnel rings into smaller, lighter segments, albeit at the expense of prolonging the ring assembly cycle.

Furthermore, the management of materials transported into and out of the tunnel bore represents a significant logistical challenge. For example, how

excavated materials (spoil) are transported and disposed of; how materials transportation is shared with other simultaneous works in the tunnel.

In addition to spoil handling, ensuring face stability remains a critical concern, particularly due to the larger tunnel diameter. Variability in ground conditions across the tunnel face is more likely in such cases, necessitating rigorous evaluation. Moreover, the deeper burial often required for larger tunnels results in increased groundwater pressures, making the management of hydrostatic pressure gradients at the tunnel face a complex endeavor. These challenges underscore the importance of meticulous planning for face intervention and the judicious use of safe havens for free air intervention, where feasible. Adherence to safe pressure limits for hyperbaric intervention is essential, given the high groundwater pressures involved.

3.2 Shallow launch

One notable challenge associated with large tunnels is the concept of shallow launch. As a guideline, it is advisable to have at least 1 time the tunnel diameter as ground cover above the tunnel crown. This first-principle criterion ensures that the surrounding ground can effectively mobilize its shear capacity to achieve arching effect, ensuring minimum required confinement of the tunnel, and leading to a more uniformly loaded tunnel ring. Furthermore, this can help distribute movement in the ground, leading to a more even settlement trough, and also prevents possible ‘blow-out’ of TBM face pressure. However, when dealing with large-diameter tunnels, particularly within urban environments, achieving this required depth for launch can be notably challenging, since a significantly long section of tunnel would be required to lower the tunnel alignment sufficiently deep to achieve the 1 diameter ground cover. Launching the TBM with less than 1 tunnel diameter of ground cover can be defined as “shallow launch” in the context of this paper, as it introduces several critical hazards:

1. **Reduced Confinement:** The lack of ground cover reduces confinement of the tunnel, thereby reducing the bending moment capacity of the tunnel segments. From a serviceability perspective, the lack of confinement also leads to higher joint rotation under the same bending moment, resulting in higher risk of water leakage through the gaskets.
2. **Face Stability and Slurry Infiltration:** The shallow depth aggravates the vulnerability of the tunnel face against blow-out or ground heave. Where there are unfilled boreholes or cracks in the surrounding ground, it could potentially lead to slurry infiltration at the surface causing loss of slurry and contamination.
3. **Soft Ground:** At shallow levels, encountering ground with low deformation modulus such as

alluvium or peat is highly likely. This introduces challenges related to controlling ground settlement and segment joint rotation.

4. Buoyancy and Floatation: Large tunnels, in particular, face a somewhat uncommon issue—buoyancy floatation. This problem is more pronounced for large tunnels due to the sheer size of void in the ground the tunnel creates.

To address these challenges, a holistic solution was implemented in the case of HS2. This solution involved the adoption of a permanent slab with piles, and a permanent embankment immediately following the slab. As shown in Figure 3, for Part A (immediately adjoining the portal), a concrete slab is cast at the surface level, supported by piles situated below. The piles are designed to resist both compression and tension, with the compression capacity for the scenario of heavy crane operating on the platform, and the tension capacity for resisting uplift force from either the face pressure from the TBM, or long term buoyancy floatation. Within the enclosure created by this setup, ground treatment measures are implemented. For Part B that is immediately downstream from Part A, a permanent embankment is placed, preventing buoyancy and floatation issues, thus ensuring the long-term stability and safety of the tunnel. This innovative approach effectively addresses the unique challenges posed by shallow launch in the context of large-diameter tunnels, particularly within urban environments like HS2.

3.3 ‘Soft’ ground

‘Soft’ ground – ground with low deformation modulus, exemplified by Peat, is a typical ground hazard for tunnelling in the UK. Peat has certain presence in the Greater London region and has been encountered during the construction of HS1 (Gallagher et al., 2003). The presence of Peat can pose notable challenges, particularly in the context of large-diameter tunnelling, owing to its inherently low stiffness and high creep, low bulk density, low shear strength and potential flammable gas content. Measures commonly employed to mitigate the presence of Peat include pre-loading with surcharge, installing vertical drainage system and ground improvement, including dig-and-replace, jet grouting, deep soil mixing and soil reinforcement.

3.4 The ‘caterpillar’ shaft

The construction of large diameter tunnels often necessitates the use of large diameter and long Tunnel Boring Machines (TBMs), which, in turn, require sizable shafts for their installation. In response to this demand, a novel solution known as ‘caterpillar’ shafts has gained prominence in recent years. Notably, caterpillar shafts have found application in prestigious projects such as HS2 S1/S2 (High Speed Rail Group, 2021) and the Silvertown tunnel (Smith, 2021), emerging as a cost-effective method for deploying these large TBMs. Figure 4 illustrates their outline configurations from the two projects. The shaft consists of multiple circular shaped

Figure 3. HS2's solution to ‘shallow launch’ (image source: Torello et al., 2020; hs2).

Figure 4. Examples of ‘caterpillar’ shafts (source of images: Rail-leaders.com and NCE, respectively).

vertical bores in a continuous manner with intersections, forming a long, wide and deep trench.

Characteristics of caterpillar shafts include:

1. **Space Optimization:** Caterpillar shafts provide a generous allocation of space, accommodating the size and requirements of large and long TBMs.
2. **Structural Efficiency:** These shafts are designed with a focus on structural integrity and efficiency, ensuring the safe launching of the TBMs.
3. **Reduced Propping:** Caterpillar shafts are engineered to minimize the need for additional structural support, streamlining the construction process and reducing associated costs.
4. **Minimal Ground Displacement:** The caterpillar shafts contribute to minimisation of ground movement, reducing the potential impact on the surrounding environment and infrastructure.

However, it’s important to emphasise that the design and construction of intersection panels (so called ‘Y’ panels) remain a technical challenge within this innovative approach. Careful consideration and engineering expertise are required to address this aspect effectively, ensuring the temporary stability of these intersection panels. In difficult ground conditions, ground treatment or other temporary works may be required.

4 ‘LEANER’ TEMPORARY WORKS

4.1 *Umbilical launch*

The concept of “lean” in this context pertains to minimizing spatial demands due to launch for a given

situation. Typically, a TBM’s full length falls within the range of 100 to 200 meters. However, in urban environments, spatial constraints often prevail, placing doubts over the feasibility of a full sized launch.

For launching a TBM at significant depths, a method known as “umbilical launch” has been employed in the UK tunnelling industry as a lean design for spatial demand, as illustrated in Figure 5. The term ‘Umbilical Launch’ refers to the methodology where the TBM is launched with a minimal operational setup, ensuring that its operations are sustained through the utilisation of ‘umbilical’ cables and pipelines. As the TBM progresses, auxiliary gantries are incrementally deployed, resulting in an extended launch duration but a reduced spatial requirement. This method derives its name from the analogy of a baby’s umbilical cord, as the TBM initially relies on pipelines and cables extending to the surface worksite for its operations.

Umbilical launch was used on Thames Tideway in London (Tideway, 2019). In this scenario, the TBM was launched with the bare essentials, primarily consisting of the shield and the minimum required backup gantries, while relying heavily on the umbilical cord infrastructure. As the TBM excavated the earth, it generated space for itself, and the supplementary gantries were progressively dropped down as additional space became available. It should be noted that this approach necessitates a protracted launch duration, but it becomes particularly advantageous in situations where spatial constraints are a predominant concern. Moreover, programme saving is possible as it can achieve a launch milestone sooner since less work is required to create space.

Figure 5. Schematic illustration of ‘umbilical launch’.

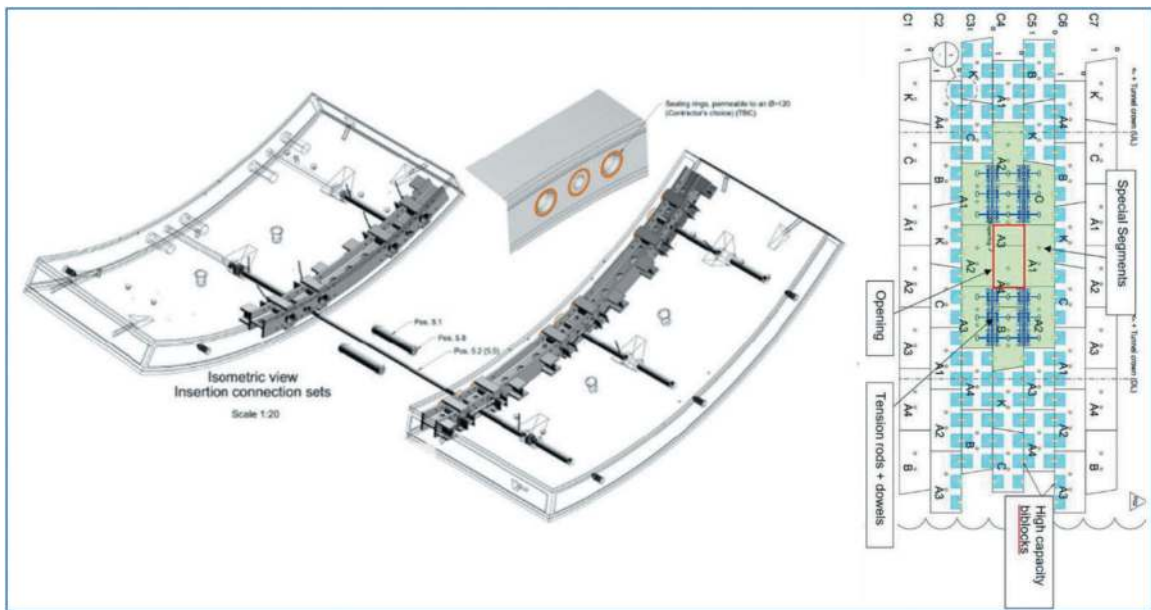

Figure 6. Layout of the ‘special segments’ (Source: Torello et al., 2021).

4.2 Saving of temporary propping

Lean construction principles encompass not only cost and time efficiency but also a reduction in temporary works. Conventionally, when creating openings within segmental tunnels for cross passages, the industry has relied on steel half-moon propping, or cast iron tunnel segments, as means to control deformation within the tunnel structure. However, on the HS2 project (Castellvi et al., 2023; Torelló et al., 2021; Gutierrez and Serna, 2020), an innovative and forward-thinking approach has been adopted in the form of “special segments.”

The overarching concept behind these special segments involves a departure from propping reliance, instead focusing on imbuing the segments with a high structural capacity around the opening area. This structural fortification allows for effective shear

transfer into the adjoining rings and serves as a pivotal element in deformation control. The special segments encompass four key structural components:

1. **Heavily Reinforced Segments:** These segments are engineered with robust reinforcement to bolster their bending moment capacity.
2. **Embedded Steel Beam:** Integration of a steel beam within the segments forms a composite section, enhancing their load-bearing capacity.
3. **High-Capacity Shear Dowels:** Utilization of high-capacity shear dowels facilitates effective deformation control of the segments once the opening is created, to limit stepping and lipping.
4. **Tension Rods:** Tension rods play a critical role in managing deformation and enhancing the stability of the tunnel structure above and below the opening.

Furthermore, a noteworthy aspect of this approach is the meticulous design of the segments to precisely match the width of the cross passage opening, thereby minimizing the amount of cutting required. This not only contributes to improved health and safety conditions but also enhances the overall quality of the construction process. By integrating these innovative techniques, the HS2 project exemplifies a commitment to lean construction practices that optimize efficiency, safety, and structural integrity in tunnel construction.

4.3 Composite sprayed tunnel lining

This paper now switches focus to the realm of lean construction towards the realm of Sprayed Concrete Lined Tunnels (SCL), which are also recognized as New Austrian Tunnelling Method (NATM) or sequential excavation method (SEM) in other parts of the world. The conventional construction employs a double-shell configuration, comprising a primary outer lining and a secondary inner lining, with a sheet of waterproof membrane sandwiched in between. Historically, the primary lining was viewed as temporary infrastructure and, consequently, was not factored into the assessment of permanent works. However, it is now becoming widely recognised practice in the United Kingdom to consider load sharing between the primary and secondary linings, specifically concerning effective earth pressure.

A more novel development has seen increase in use, wherein the waterproof layer is also sprayed onto the structure, subsequently hardening to attain a stiffness akin to concrete. This innovative approach fosters composite action between the primary and secondary linings (Su, 2022). In practical terms, this implies that no materials are considered redundant in load sharing. Moreover, this advancement holds the potential to significantly diminish the requisite thickness for the secondary lining, thus optimising efficiency and sustainability in tunnel construction.

5 'GREENER' TUNNEL CONSTRUCTION

5.1 Conveyor belt instead of lorries

Figure 7. HS2 spoil conveyor belt (source: NCE).

Undoubtedly projects at the scale of hs2 will produce a gigantic amount of spoil. At the Logistics Hub alone, over 430,000 tonnes of spoil will be produced and transported to its end destination (Moore, 2022). In order to eliminate the presence of muck-away lorries on the roadways, HS2 contractors SCS JV and BBVS JV have adopted a solution in the form of a conveyor belt system (Moore, 2022) that to the author's minds is reminiscent of baggage handling systems at airports – refer to Figure 7. The conveyor network is considered to have achieved a reduction of a million lorry journeys on the road. This innovative concept represents a remarkable advancement, characterized by its continuous operation, resistance to adverse weather conditions, minimal noise emissions, and a reduced requirement for human oversight and management.

5.2 Low carbon solutions

HS2 is at the forefront of implementing strategies to achieve low carbon emissions, with several notable examples showcasing their commitment to sustainability:

1. **Fibre Reinforced Tunnel Segments:** In the realm of tunnel construction, fibre reinforced tunnel segments have emerged as the predominant choice. They have essentially become the industry default solution in the UK, and widely adopted on Crossrail (King, Thomas and Stenning, 2017), Thames Tideway (Jewell et al., 2014; Rossi, 2020) numerous sections of hs2 (Rossi and Monks, 2022) due to their sustainability, efficiency and durability. Rebar reinforced tunnel segments remain to be important for scenarios where additional structural capacity is essential, such as soft ground sections, low ground cover zones and adjacent to cross passage openings.
2. **Low Carbon Concrete:** HS2 places a significant emphasis on the use of low carbon concrete, adopting it in general in its constructions (hs2, 2020) to reduce carbon emissions. This involves the incorporation of a high dosage of cement replacement binders such as slag or fly ash, which are commonly employed in the construction of tunnel segments. Low carbon concrete has also been used in the largest ever concrete pour to date in the UK at the Euston site (hs2, 2022a). These materials not only enhance the sustainability of the project but also contribute to the reduction of carbon emissions associated with concrete production.
3. **Hydrogen Power Generators:** On-site, HS2 (hs2, 2022b) has adopted the use of hydrogen power generators, marking a substantial step toward minimizing their carbon footprint. Improving air quality for workers and the local community. Hydrogen is renowned for its clean-burning properties and its potential to serve as

a green energy source, thereby aligning with HS2's dedication to eco-friendly practices.

By implementing these measures and continuously evaluating their environmental impact, HS2 underscores its commitment to achieving low carbon emissions and promoting sustainability in the field of infrastructure development. These initiatives represent a progressive approach to construction that seeks to balance infrastructure demands with ecological responsibility.

6 CONCLUSIONS

This paper has presented a number of case studies representing the 'tried and tested' technological advancements in the UK tunnelling industry. This demonstrates that the UK tunnelling industry is heading towards a future of 'Smarter, Larger, Leaner and Greener' future. 'Smarter' is exemplified by the vital role data analysis play in understanding the ground and make informed decision; 'larger' diameter tunnels lead to associated challenges such as logistics, 'shallow launch', 'soft' ground issues and the necessity of large launching shafts such as a 'caterpillar' shaft; 'leaner' mainly themes a reduction in temporary works such as propping around tunnel opening with 'special segments', an improvement in the utilisation of what traditionally was considered to be 'temporary' works only by using composite lining behaviour, substantial reduction in the spatial requirement for tunnel launch by using the 'umbilical launch' approach; as for the 'greener' front, hs2 has pushed the frontier significantly further ahead by adopting numerous green designs including conveyor belt system for removing spoil replacing road transport, fibre reinforced tunnel segments, low carbon concrete and hydrogen power generators.

ACKNOWLEDGMENTS

The authors would like to thank TYP SA Group and particularly colleagues within the Tunnelling and Geotechnics department over the world for their technical and mental support in the production of this paper. A particular thanks is owed to Helena Castellvi and Alberto Gomez-Elvira (both TYP SA) who provided extremely valuable comments on the draft of this paper.

Tunneling successes in West Los Angeles - Purple Line Project Section 3

Eleanor Sillerico*

Mott McDonald, Los Angeles, USA

Martin Ellwood & Codie Davis

WSP, Los Angeles, USA

Angel del Amo

Aldea Services, Orange, USA

Edouard Whitman

Frontier Kemper Constructors, Los Angeles, USA

ABSTRACT: Construction of bored tunnels for the Los Angeles Metro's Purple Line Extension Section 3 started in October 2020 and was completed in April 2023. Twin earth pressure balance (EPB) tunnel boring machines (TBM), each 23.5 feet in diameter, mined 27,077 feet (5.12 miles both tunnels) with crown elevations ranging between 50 to 120 feet below ground. The tunnels contract included a launch shaft 90 feet in diameter and 89 feet deep, twin bore tunnels, 14 cross passages mined with SEM (sequential excavation method), stations end-walls and ground treatment under critical utilities. The underground work was constructed in the soils of the Los Angeles Basin, a gassy environment. This paper presents the performance of the TBMs while tunneling in a challenging environment that included major sensitive structures such as the I-405 freeway, a 96-inch cast iron water main, and deep shoring piles at a commercial property.

Keywords: Tunneling, TBM, sensitive structures, gassy ground, gassy tunnel, permeation grouting

1 INTRODUCTION

The Westside Purple Line Subway Extension (WPLE) project is heavy rail transit subway that will operate as an extension of the Metro Purple Line in Los Angeles.

This mega-project brings seven underground stations and nine miles of twin-bore tunnels westward to the UCLA and VA Campuses in West LA, and through the Beverly Hills, Century City and Mid-Wilshire areas.

*Corresponding author: Eleanor.sillericomayta@mottmac.com

DOI: 10.1201/9781003495505-285

The project is separated into three Sections; this paper focuses specifically on the tunneling in the final (most westward) Section 3 (WPLE3), a 2.56-mile section of the project comprising twin 23.5-foot diameter tunnels excavated EPB TBMs and varying in crown depth from 50 feet to 120 feet below ground. Refer to Figure 1.

The tunnel design was developed to mitigate risks through several challenges along the alignment:

- Tunneling beneath the I-405 Freeway,
- Minimizing settlements for major utilities at Sepulveda Boulevard,
- Tunneling within five feet of building support of excavation piles,
- Tunneling in gassy ground,
- General TBM performance requirements.

The design/build project definition documents (bridging documents/contract documents) specified a series of measures to mitigate potential issues. The Final Designer generally incorporated these measures, and in some areas was able to amend them through design, analysis and TBM performance. This paper describes how each process unfolded and the means by which the mitigation measures were implemented or amended. The bored tunnels were successfully constructed between 2021 and 2023.

2 TUNNELING BENEATH THE I-405 FREEWAY

The Westside Purple Line Extension alignment terminates at the Veterans Affairs campus in West Los Angeles. To reach this terminus, the tunnels had to cross beneath the Interstate 405 (I-405) Freeway. This is a major north-south transportation corridor constructed in 1957, widened in 2007-2010, and reconfigured (on/off ramps) in 2013-2014. The tunnels pass under the Wilshire overpass bridge abutment structure, between two bridge bent structures and mechanically stabilized earth (MSE) walls constructed in 2013-2014 (see Figures 2 and 3).

Figure 2. I-405/Wilshire Boulevard intersection looking south.

Figure 3. Tunnel influence zone with respect to bridge bents.

Metro, WSP, Mott MacDonald (Metro's Construction Management Consultant), Frontier Kemper-Tutor Perini JV (FKTP), and Aldea worked closely with Caltrans District 7 representatives throughout the design and construction process to ensure all criteria were achieved.

2.1 Preliminary engineering

The project requirements included a Project Study Report – Project Report (PSR/PR) which was undertaken by WSP, Metro's design consultant, and approved by Caltrans in 2012. A further revision was approved in 2016 for work impacting the I-405 freeway and its ramps. WSP also prepared a Joint Permitted Use and Maintenance Agreement (JPUMA) in 2018, with amendments in 2020 and 2021. This was needed to grant approval for rights to build, operate and maintain Metro's facilities within the Caltrans right-of-way.

These documents were provided to the final designer for compliance, as well as additional performance requirements identified in the contract documents, such as a robust instrumentation program. This program included horizontal inclinometers positioned about three feet above each tunnel crown, arrays of Multipoint Borehole Extensometers (MPBXs) in the public roadway and VA property either side of the I-405 and surface settlement markers on the I-405 Freeway embankment. A Building Protection report was produced which assessed the impact of the tunneling from a preliminary design perspective. This was reviewed by Caltrans. The initial results showed that the maximum movements of the existing I-405 bents would be less than 0.02 inches for a tunneling volume loss of 0.35%. This is far less than the allowable settlement of 0.5 inches of total differential settlement across the bent structures or 1/600 (i.e., 0.002 radians) of slope across a structure/bay in accordance with Metro Rail Design Criteria (MRDC) Chapter 5. AASHTO LRFD Strength Limit States allow for 0.7 inches of settlement, but the MRDC governs as the more stringent project requirement.

Discussions with Caltrans and others resulted in several additional measures added to the contract documents:

- Hold Points – The contractor may not proceed with work until each Hold Point has been released by Metro, contingent upon the approval of a report demonstrating performance requirements have been met.
- Tunnel Construction Review Points (TCRP) – The contractor may not proceed beyond the TCRPs until it demonstrates that preconstruction surveys are complete, that instrumentation is installed and functioning, that Caltrans approval is received, and that previous instrumentation data is received and compliant.
- Continuous tunneling beneath the I-405 – Tunnel construction is to be continuous, without stopping work and with no planned interventions to reduce ground relaxation/settlement.
- Tunneling with greater control – The allowable settlement three feet above each tunnel, measured by Multi Point Borehole Extensometer (MPBX) and Horizontal Inclinator (SAAX Array), is 0.35 inches for Action Level and 0.5 inches for Alert Level (reduced from 1 inch for Action Level and 1.5 inches for Alert Level in areas with general control).

2.2 Final design

The final designer (Aldea Services) performed the detailed analyses and presented them to Caltrans. Metro's tunneling contractor FKTP (Frontier-Kemper Tutor Perini JV) prepared a pre-construction survey of Caltrans structures with an analysis of the current Caltrans bridge load rating assessment and inspection reports, including a LiDAR survey. FKTP developed a geotechnical investigation program to define geotechnical parameters for the design and construction of the tunnels. Aldea then used the geotechnical parameters to develop a Midas model and perform a numerical analysis to assess the effects of vertical, horizontal and transverse ground movements/deformations and induced strain on each Caltrans structure, the results and analysis of which were presented in a Structure Impact Assessment Report (refer to Figure 4).

Aldea concluded that the increase in loads in the bent piles, the increase in the stresses in the abutments, and movements of the abutments and bent piles due to TBM tunnel excavation were negligible for a predicted volume loss of 0.35%, and that no special mitigation measures were required.

FKTP simultaneously prepared and submitted the Plans, Specifications and Estimate (PS&E) Documents for the project elements within Caltrans right-of-way in order to obtain encroachment permits. Metro engaged a third party (STE LLC) to perform

Figure 4. Portion of I-405 Midas FLAC model with tunnels.

an independent check of the final design documents in compliance with Caltrans requirements.

2.3 Performance during construction

Both TBMs completed mining beneath the I-405 and Sepulveda Boulevard in nine days each, including the installation of 100 precast concrete rings while working in continuous mining mode 24/7 (2 x 12-hour shifts). The horizontal inclinometers comprised 147 anchors and measured 0.4 inches of maximum settlement above both the westbound (BR) and eastbound (BL) tunnel crowns, and no movement was observed at surface level, demonstrating the success of the permeation grouting operation. Measured settlement fell within allowable limits and Aldea's prediction to the satisfaction of Caltrans.

3 MINIMIZING SETTLEMENTS AT SEPULVEDA BLVD

3.1 Reason for enhanced ground control

Sepulveda Boulevard (at Wilshire Boulevard) is located towards the west end of the PLE3 tunnel alignment, adjacent to the I-405 Freeway. Sepulveda is a dense utility corridor and contained two critical utilities of significant interest to the tunneling: a 96-inch diameter water mainline, and a reinforced concrete box (RCB) storm drain measuring 12 feet x 12.5 feet.

The water line, with an inside-diameter of 96 inches, is a mainline feeder constructed in 1969 as a prestressed concrete pipe inside a steel jacket, at an invert depth of EL 280 feet, only 12 feet above the tunnel crowns. This pipe carries a significant amount of fresh water to the Los Angeles region under high pressure. Since the 96-inch water main would govern the design, this was the focus of the team in relation to minimizing settlements at Sepulveda Boulevard.

The preliminary design utilized an initial two-dimensional FLAC analysis of the tunnels and the

Figure 5. Geologic profile at Sepulveda Boulevard.

96-inch water main. The ground conditions consist of Young/Old Alluvium and San Pedro formations (see Figure 5), predominantly silty sandy material with lenses of gravel/cobbles, and reasonable stiffness. The water table is approximately EL 250 feet, which is 65 feet below grade, at the location of the top of rail in the tunnels.

The analysis was run initially for one tunnel passing under Sepulveda Boulevard, followed by the second tunnel, adopting various parameters including both non-grouted and grouted ground. The results were compared to the standard curves calculated from a basic Gaussian Distribution Approach representing a ground loss of 0.35%, to ensure ground stiffnesses were being reasonably represented in the non-grouted model. The analysis concluded that without grouting the soil matrix, the maximum settlement of the pipe invert would be 0.6 inches and with grouting it could be reduced to less than 0.2 inches.

3.2 Criteria and coordination with water utility owner

The project engaged with the water utility owner prior to, during, and after tunneling to ensure that communication was clear and criteria were being met. The owner mandated a maximum settlement criterion of 1/5 inch maximum for its waterline pipe. This requirement was added to the contract documents, along with a mandate to provide ground improvement above and around the entire tunnel cross section for a length of about 125 feet and a width of approximately 80 feet. This was anticipated to require permeation grouting techniques, a technique in which the space between soil grains is filled with grout injected at a steady pressure and which does not disturb the soil structure. Since this is performed at low pressures, it is ideal for use in close proximity to existing sensitive utilities.

An instrumentation and testing program was specified. This consisted of utility monitoring points (UMPs) along the length of the 96-inch water main

within the zone of influence of the tunnels, arrays of MBPXs, a horizontal inclinometer placed above each tunnel crown, and core testing of the grouted area to ensure the soil shear strength was achieved throughout.

Metro also required continuous TBM mining under a zone that started west of the I-405 and continued east under Sepulveda Boulevard until the zone of influence of the 96-inch water main was passed. This required the contractor to continuously operate the TBM machine within this zone, regardless of time of day or week.

Metro also included strategic Hold Points along the alignment. This included demonstration that key performance indicators were met at the machine measuring tail skin grout, face pressure, spoil removal and bentonite slurry injection behind the cutter head. Having documentation of indicators all performing correctly was considered a key element to controlling settlement under the 96-inch water main.

3.3 Final design

During final design, Aldea Services designed a permeation grouting plan which did not require the full cross section of the tunnel to be grouted. Instead, FKTP proposed a block of grout from the tunnel spring line to approximately eight feet above the tunnel crown. Finite Element Analysis using 2D and 3D models was produced in the MIDAS program to validate the approach and demonstrate that the design would meet the strict settlement criteria. An emergency response plan was prepared in the event that an incident occurred, identifying appropriate mitigation measures.

Figure 6. Proposal for compensation grouting beneath 96-inch water main.

3.4 Performance during construction

The ground improvement was undertaken by Keller and consisted of 53 grout holes approximately seven feet apart to create the grouted envelope. The Shape Accel Arrays (SAA), aka horizontal inclinometers, and the permeation grout holes were constructed by horizontal directional drilling (HDD) from the surface, from a starter pit approximately 200 feet from Sepulveda Boulevard. The top row of grout pipes was approximately five feet below the 96-inch water main

invert. Sleeve ports every 48 inches along the grout pipes allowed the sodium silicate chemical grout to be pumped in with momentary high-pressure injection of water through the packer rod. Post-grouting, Keller performed three vertical cores with logging and sampling to ensure the target grout strength of 100psi at 28 days was achieved (refer to Figure 6).

During installation of the permeation grout pipes, a magnetic survey system installed in the roadway continuously collected survey information for each HDD borehole. The as-built survey information was provided to WSP which was then modeled in 3D and viewed in Navisworks to verify the design grout coverage was achieved. It was discovered that the HDD boreholes were installed higher than anticipated, and an additional row of boreholes was added by Keller. This coordination among the project team proved to be extremely valuable in meeting the performance requirements set by the owner and the design grout coverage area set by Aldea (refer to Figure 7).

Figure 7. Navisworks as-built model of compensation grouting beneath 96-inch water main.

Tunneling was undertaken on a continuous basis as required by the contract, including over weekends. The owner was engaged in daily briefing meetings with FKTP and Metro to ensure communication was clear. These meetings included a summary of the instrumentation readings such as the UMPs, horizontal inclinometers and MPBX readings, which were available from the prior shift.

Construction was successfully completed for both tunnels with minimal settlement, less than 0.1-inches above the BR tunnel and even less for the BL tunnel, which was well within the 0.2-inch limit set by the owner. No surface settlement was measured for either tunnel. Communication was well coordinated through all stages of the tunneling, particularly with the owner.

4 TUNNELING WITHIN FIVE FEET OF SOE PILES

The low point of the tunnel alignment between Constellation Station and Westwood/UCLA Station is near a commercial building located within a mixed commercial and residential corridor with

mid-rise buildings. The brick-clad building was constructed in 1984 and comprises a four-story commercial building on top of four parking basements, with a particularly deep row of support of excavation (SOE) friction piles along the north property line, approximately 80 feet deep at the toe. It is likely the deep piles were required because the adjacent road is a narrow alley and insufficient space was available for traditional tie-backs, which were used in other parts of the basement excavation. These piles are no longer in use structurally, as the building adopted a shallow foundation solution for the permanent structure consisting of pad foundations on competent ground. However, the steel H-piles are embedded into the permanent concrete basement walls. The Metro tunnel alignment was designed to provide five feet of clearance from the bottom of the steel SOE piles to the top of the tunnels. However, with limited record drawings available from the building owner, Metro elected to perform field investigations to verify the clearance in advance of tunneling and mitigate any risk of the TBM striking the steel piles. No load was expected to be present in the toe of the piles (refer to Figure 8).

Figure 8. Section showing Metro tunnels beneath deep SOE piles (design).

4.1 Pile investigation

Metro's design consultant, WSP USA, engaged specialty geotechnical consultants (Wood PLC and Olson Engineering, Inc.) to undertake a non-destructive investigation utilizing parallel seismic testing. The parallel seismic test consisted of dropping a hydrophone down ten water-filled PVC-cased borings and taking measurements along 20 steel soldier piles encased in concrete and located 65 feet to 85 feet below ground surface.

Each borehole was used to test the two adjacent soldier piles. The testing was performed by impacting the exposed piles to generate seismic compressional/primary wave (P-wave) energy down the pile to the hydrophone receiver at one-foot vertical test depth intervals. An inflection point in P-wave velocities experienced between saturated soils and steel W-beams indicates the pile tip. The results indicated that several piles were within five feet of the Metro tunnels.

Metro then elected to perform a second investigation using a magnetometer testing to obtain better accuracy on the closest piles. New borings were installed within two feet of the targeted soldier piles to improve the accuracy of the results.

The magnetometer test was performed by lowering a borehole magnetometer (gradiometer) into the PVC-cased boreholes to detect magnetic field strength between two sensors on the instrument which detects the greatest differential magnetic field at the tip of the steel pile when it transitions to concrete encasement at the toe.

Figure 9. Section at north SOE deep pile line based on investigation results.

The results of the magnetometer test provided the depth of the steel piles with an accuracy of +/- one foot. The combination of the two tests showed that the tunnels had 3.6 feet (BL tunnel) to 5 feet (BR tunnel) of clearance to the steel piles and 1.2 feet (BL tunnel) to 3.9 feet (BR tunnel) of clearance to the concrete encasement around the tip of the piles (refer to Figure 9).

4.2 Performance during construction

The successful non-destructive testing gave Metro and FKTP the confidence to proceed with tunneling beneath the deep SOE piles, which was successfully completed without incident. Metro and the building owner worked hand in hand to conduct the field investigation, prepare an emergency response plan and utilize continuous mining to minimize potential building settlement.

5 TUNNELING IN GASSY GROUND

During the initial geological investigation that Metro and WSP undertook between 2011 and 2017, methane (CH₄) and hydrogen sulfide (H₂S) were encountered along the alignment. Methane is less dense than air and is highly explosive; hydrogen sulfide is denser than air and is highly toxic. These results confirmed the findings of Los Angeles Department of Building and Safety, City Ordinance 175790, which includes a map of Methane and Methane Buffer Zones for the City of Los Angeles. The map indicated that the Purple Line Project, including WPLE3, would be inside the gassy zones.

Figure 10. Tunnel precast ring assembly showing double gasket.

Extensive studies were undertaken to determine suitable measures to deal with the elevated levels of gases on the project. The highest density of gas was found on Section 1 near the La Brea Tar Pits. However, the entire nine-mile alignment falls into the category of “gassy ground”.

For the tunnels, it was determined that double gaskets should be incorporated as a mitigation measure between the concrete segments along the circumferential and radial joints. This was included in all three sections of the project, including WPLE3 (refer to Figure 10).

Furthermore, the provision for a possible future “Secondary Liner” was incorporated in the tunnel internal diameter, which was increased by 12 inches to allow for a 6-inch liner all round should gases be found to be entering the tunnel during operation. This would not be installed in the current project but would be available for Metro in the future in the event of a gas/water leak which could not be remedied by grouting or other primary means of mitigation.

During construction, it was also required that CH₄ and H₂S gas sensors be placed along the TBMs as well as backup, self-rescuing equipment at strategic

locations and a certified gas tester present at all times when employees were in the tunnels. Employees entering the tunnel were required to undertake special training and carry self-rescue equipment including gas testing devices.

5.1 Probe Drilling from the TBM – CalOSHA variance

Due to the gassy ground, the contractor was required to probe ahead of the TBM in accordance with CalOSHA, Title 8, Subchapter 20, Tunnel Safety Order (TSO), Article 9. This requires “Tunnel-based horizontal probe hole drilling” where the likelihood of a dangerous accumulation exists.

EPB TBMs were used for excavation and support for both tunnels. With this method, the gas is controlled and measured to ensure that there is no dangerous accumulation of hazardous gases and that automated shut-down safety measures are incorporated into the TBMs.

During tunneling, the TBMs were always operated in the closed face EPB modes. This meant that the plenum and screw conveyor were full of conditioned material. A guillotine-type valve is at the end of the screw where the conditioned ground depressurizes. This would constitute the “true” face of the excavation in the context of the exposure to any hazardous gasses or contaminated soil.

In addition, a negative-pressure TBM and tunnel ventilation system was designed to dilute and capture any potentially harmful gases. The ventilation system was specified to supply an airflow rate of 100,000 cfm, which was sufficient to dilute the maximum off-gassing volumes to an allowable exposure limit. Large fans were installed in TBM gantry 12. The fans were capable of handling 100,000 cubic feet per minute (cfm) airflow but operated at reduced speeds using variable frequency drives (VFDs). These fans removed gases coming out of the auger directly into a ventilation hood, located approximately 12 feet behind the screw discharge, and into a steel duct which contained the exhaust air, discharging it directly to the surface.

In the event that CH₄ and H₂S gas levels were detected in excess of that anticipated by the TBM safety plan, the TBM would automatically shut down and cut operational power. This would be followed by closure of the screw discharge gate in under 60 seconds which would seal the entire tunnel immediately against any gas inflows. CalOSHA granted a variance for probe drilling, in lieu of the numerous measures described above, in 2022. At the end of mining of both tunnels, there were no incidents where gas levels were measured in excess of the allowable limits.

6 GENERAL TBM PERFORMANCE ALONG THE TUNNEL REACHES

The PLE3 tunneling commenced from the western-most end of the alignment (Tail Track Exit Shaft) and proceeded east 2.56 miles towards the PLE Section 2

Figure 11. BL TBM “Aura” cutterhead being lowered into the launch shaft.

Century City Constellation Station, which would receive the TBMs. Reach 6 refers to the tunnels between Century City Constellation Station and Westwood/UCLA Station. Reach 7 refers to the tunnels between Westwood/UCLA Station to the Tail Track Exit Shaft at the alignment terminus (refer to Figure 11).

The BR TBM began mining in October 2020 and the BL TBM in April 2021. Due to spatial constraints in the 90-foot diameter launch shaft, mining started with umbilicals (temporary cables and connections to the support equipment) until the four TBM starter gantries were constructed, at ring 100, approximately 500 feet into the tunnel.

An assembly period then commenced for commissioning the full mining mode, with a TBM support structure composed of 13 gantries that enable the installation ring 101 to 2703 (505 feet to 13,530 feet). Tunneling in full mining mode started in August 2021 for the BR TBM, and in November 2021 for the BL TBM. TBM and segmental lining specifications are listed in Table 1.

Table 1. TBM and segmental lining specifications.

Machine type	EPB
Bore diameter	7160 mm
Installed power	4000 kW
Nominal thrust force	56068 kN
Length TBM + back-up approx.	140 m
Theoretical thrust speed	30 mm/min
Working pressure (at axis)	6 bar
Tunnel curve radius (min.)	274 m
Segmental liner type	Universal 4+2
Outer ring diameter	6858 mm
Segment thickness	330 mm
Length	1524 mm
Backfill grout type	A (grout) + B (accelerator)

6.1 TBM performance

Regular tunneling operation by FKTP occurred in two 10-hour shifts for five days per week (Monday to Friday). The overall daily production average was 37 feet/day for the BR TBM and 42.7 feet/day for the BL TBM, with a maximum for both TBMs of 87 feet/day. This daily production was calculated for full mining mode and accounts for a learning curve, holidays, interventions, and maintenance stoppages excluding the breakthrough into the adjacent PLE2 structure. Figures 12 and 13 show the monthly production for both TBMs in Reach 6. Special operating modes occurred at strategic locations near or under sensitive structures. In these locations, additional tunneling shifts were implemented until the TBM's were clear of the sensitive facility. Higher rates of production were achieved in these locations, up to 55.6 feet/day. However, this required a highly focused effort from Metro, the contractor, stakeholders, and consultants.

Figure 12. BR TBM Reach 6 (Rings 797 to 2703) monthly production and total advance.

Figure 13. BL TBM Reach 6 (Rings 811 to 2703) monthly production and total advance.

6.2 Earth pressure balance pressures

In general, the face pressure was maintained within the range established during the design phase for Reach 7 for BR TBM (rings 1 to 796) and for BL TBM (rings 1 to 810). However, as the TBMs were gaining depth in Reach 6, the face pressures were adjusted based on actual geology and existing water table, maintaining the face pressure at a minimum of 1.20 bar above the ambient combined hydrostatic and ground pressures at the TBM crown. The piezometers installed in the

Figure 14. BR TBM Reach 6 face pressures.

Figure 15. BL TBM Reach 6 face pressures.

MPBXs every 200 to 300 feet along the alignment provided actual water table levels. Figures 14 and 15 show the measured EPB pressures for both TBMs in Reach 6.

6.3 Mucking system and annular grouting

Figure 16. BR conveyor belt scales average weights.

The mucking system was composed of horizontal conveyor belts being fed in the tunnels from vertical supply structures (cassettes). Along the 2.56 miles of tunnel length, no booster stations were installed. Once the muck was delivered from the excavation face to a muck pit (max capacity of 4.5 advances) in the launch shaft, the muck was extracted using a crawler crane and two circular buckets 18 cy capacity each.

The muck weight was monitored with two scales installed at TBM gantry 12. While the theoretical weight per advance was calculated to be 120 tons, this figure was derived from the interpretation of limited exploratory boring samples gathered during the design phase. Figure 16 shows the average weights of the two BR TBM scales, and reflects actual geological conditions encountered by both TBMs. Note that while the actual weight of material extracted by advance was at times substantially less than what the theoretical average had anticipated; the geotechnical instrumentation installed along the alignment did not indicate under-excavation or uplift. If over-excavation was suspected at any time, the contractor proceeded to perform secondary (check) grouting through the tunnel liner.

Grout was injected in the annular gap behind the tunnel lining simultaneously with each TBM advance. The injection pressures were maintained between 0.5 and 1.2 bar above the EPB face pressure. The theoretical volume was 5.07 m³ for a five-foot ring. The grout was a two-component A+B where A is a mix of bentonite, cement and stabilizer and B is an accelerator: a sodium silicate base activating the A component at the rear of the tail skin. The grout gel time was between five and ten seconds. The tail skin was equipped with four grout ports facilitating the homogeneous distribution of grout behind the tunnel lining. Figure 17 shows the grout volume injected along the BL and BR tunnels (average volume across the four grout ports). The data collected offered no indication of a correlation between the

Figure 17. BR and BL annular grouting volumes.

grout takes per advance displayed in Figure 17 and the geologies encountered as reported by the belt scales in Figure 16.

7 CONCLUSIONS

The Purple Line Extension Section 3 tunneling project included some significant challenges in both design and construction. These were overcome by the following strategies:

- Mitigations were included in the contract documents to safeguard the construction at sensitive structures such as the Sepulveda Boulevard 96-inch diameter water main, I-405 Freeway, and for encountering known gassy ground conditions.
- The contractor followed the mitigations in the contract and was able to add value by modifying some of the mitigations during final design.
- The contractor was able to control settlement below allowable limits during the project, which provided confidence to Metro to allow some of the design mitigations to be adjusted based on calculations using the standard TBM ground loss.

ABSTRACT: Based on the geological conditions of Shenzhen region, the experience of traditional single mode shield tunneling was summarized. Studied the adaptability and technical characteristics of shield tunneling, proposed the concept of EPB-TBM dual mode shield tunneling machine, and fully applied it to the fourth phase of Shenzhen Metro project. This paper analyzes and studies the practical applications of multiple engineering projects, summarizes and analyzes the efficiency, consumption of cutter tool, mode switching, economy, and existing problems of dual mode shield tunneling, and puts forward relevant suggestions to provide reference for similar projects in the future.

Keywords: Shenzhen Metro, EPB, TBM, dual-mode shield

1 APPLICATION BACKGROUND OF EPB-TBM DUAL-MODE SHIELD

After 25 years of construction, nearly 98% of underground excavation in the Shenzhen Metro utilizes the shield tunneling method. Taking the fourth phase of the Shenzhen Metro construction project as a case study, a total of 150 shield tunneling machines were deployed, with a peak of nearly 120 machines simultaneously in operation in 2020. In that year, the total tunneling length reached 140 km, marking the highest in its history, a rarity compared to other cities in China and abroad.

With the ongoing expansion of the Shenzhen Metro construction, the geological conditions and surrounding environments along metro lines have become increasingly complex and variable. Traditional single-mode Tunnel Boring Machines (TBM) are no longer adequate for meeting the demands of construction projects, leading to the gradual development and implementation of multi-mode TBMs. Since 2019, Shenzhen Metro has invested in 16 EPB-TBM double-mode shields across eight sections of Metro Line 12, Line 13, and Line 14 in the fourth phase of metro construction, as well as Metro Line 8 Phase II in the third phase of metro construction project. In subsequent projects, such as Line 8 Phase III, Line 13 Phase II, Line 16 Phase II, and the construction of the pipe gallery, a total of 13 EPB-TBM dual-

mode shields have consistently been deployed to ensure the smooth progress of these projects. As of now, approximately 45 km of tunneling has been completed across multiple sections, with 14 successful in-tunnel mode transitions, as seen in Figure 1.

2 APPLICATION OVERVIEW OF EPB-TBM DUAL-MODE SHIELDS

2.1 *The key characteristics of the equipment*

The EPB-TBM dual-mode shield machine combines the design principles and functionalities of both Earth Pressure Balance (EPB) shield machines and Single Shield Tunnel Boring Machine (TBM), as seen in Figure 2. It can function in two different modes for spoil removal. In soil and broken rock conditions, the EPB mode is utilized to ensure construction safety. In hard rock conditions, it switches to the open-mode Single Shield TBM to prevent secondary abrasion of the cutterhead and cutters, thereby prolonging their lifespan and reducing the frequency of tool replacement. Additionally, the cutterhead is engineered to operate at higher rotational speeds (up to 6.6 RPM), leading to increased tunnelling efficiency compared to traditional single-mode EPB shields.

The EPB-TBM dual-mode shield is classified into two types depending on the spoil removal system:

central screw conveyor type and central belt conveyor type, as seen in Figure 3. Out of the 29 dual-mode shields used in the Shenzhen Metro, 22 belong to the central screw conveyor type, while 7 are of the central belt conveyor type, as seen in Table 1.

2.2 Key parameters of the equipment

The initial set of dual-mode shields (TBM) is equipped with a cutterhead excavation diameter ranging from 6470 to 7000 mm, an overall opening ratio of 28 ~ 32%, and a maximum rotation speed of 6.6 RPM. The cutterhead is exclusively electrically driven, boasting a total drive power of 1400 ~ 2100 kW, a rated torque of 5920 ~ 7200 kNm, and an extricating torque of 7100 ~ 11000 kNm. The

the Shenzhen Metro Phase IV Project, focusing on Line 12 and Line 14, as seen in Figures 4 ~ 6. The details of the statistical analysis are outlined below.

In the Huaide Station to Fuyong Station section of Shenzhen Metro Line 12, the left line's dual-mode shield began operations in April 2020. The dual-

Figure 5. Monthly advance rate bar chart of dual-mode shield in selected segments of Shenzhen Metro Line 14, from Qingshuihe Station to Buji Station section.

Figure 6. Monthly advance rate bar chart of dual-mode shield in selected segments of Shenzhen Metro Line 14, from Buji Station to Bushifeng Well section.

Table 3. Comparison of the cutter consumption between the dual-mode shield in the Huai-Fu section and the EPB shield in the adjacent Cui-Huai section.

Section	Shield type	Ring No.	Tunnelling length (m)	Normal abrasion	Abnormal abrasion	Replaced cutters number	Cutter consumption index (cutter/m)
Huai-Fu section (left)	EPB-TBM	223-328	157.5	19	3	22	0.14
Huai-Fu section (right)	Dual-Mode shield	208-310	153.0	11	4	15	0.10
Cui-Huai section (left)	EPB	195-290	142.5	67	38	105	0.74
Cui-Huai section (left)		204-360	234.0	163	19	182	0.78

mode shield utilized EPB mode with an average advance rate of 2.8 rings/day and TBM mode with an average advance rate of 4.4 rings/day. Similarly, the

right line's dual-mode shield started operations in March 2020, employing EPB mode with an average daily advance rate of 2.7 rings/day and TBM mode

Table 4. Comparison of cutter consumption between TBM mode and EPB mode of dual-mode shield in the left Bu-Shi section of Line 14.

Tunnelling Mode	Stratigraphic Type	Ring No.	Tunnelling length (m)	Cutter abrasion type			Cutter consumption index(cutter/m)
				Normal abrasion	Abnormal abrasion	Replaced cutters number	
TBM	Slightly weathered hornstone	0-347	520.5	98	39	137	0.26
EPB	Slightly weathered hornstone	491-600	165.0	35	26	61	0.37
		951-1165	322.5	75	73	148	0.46

with an average advance rate of 3.8 rings/day. During this period, the TBM mode encountered light weathered granite ground with a compressive strength of 130-150MPa, achieving a maximum daily advance of 16.5m and a maximum monthly advance of 271.5m.

In the Shenzhen Metro Line 14 section from Qingshuihe Station to Buji Station, the left-line dual-mode shield commenced excavation in July 2020 using the EPB mode, achieving an average advance rate of 3.7 rings/day. Simultaneously, the right-line dual-mode shield initiated excavation in August 2020 also using the EPB mode, achieving an average advance rate of 4.2 rings/day. During this period, the EPB mode encountered geological formations of light weathered schist with a compressive strength exceeding 120MPa, achieving a maximum daily advance of 13.5m.

In the section from Buji Station to Bushifeng Well of Shenzhen Metro Line 14, the left-line dual-mode shield began excavation in January 2020. In this case, EPB mode achieved an average advance rate of 3.6 rings/day, while the TBM mode achieved an average advance rate of 3.3 rings/day. Similarly, the right-line dual-mode shield started excavation in February 2020, achieving an average advance rate of 3.7 rings/day using the EPB mode and 4.7 rings/day using the TBM mode. During this period, the TBM mode encountered geological formations of light weathered schist with a compressive strength exceeding 100MPa, achieving a maximum daily advance of 18m and a maximum monthly advance of 294m.

2.3.2 Statistical analysis of cutter abrasion and replacement quantity

In the context of the sections on Shenzhen Metro Lines 12 and 14, this study performed a comparative analysis of cutter abrasion and replacement quantities in full cross-section hard rock strata. The analysis centered on two distinct tunneling methods: the EPB-TBM dual-mode shield and the traditional EPB shield. Furthermore, within the dual-mode shield tunnel boring, the study delved into the variations in cutter abrasion and replacement quantities between two different excavation modes.

As depicted in Table 3, in the Huai-Fu section of Line 12, the dual-mode shield averaged 6.9 rings per cutter replacement under normal abrasion conditions, one cutter replacement for every 29.6 rings under abnormal abrasion conditions, and an average of 5.6 rings per cutter replacement. In the Cui-Huai section, the EPB shield experienced an average of 1.1 rings per cutter replacement under normal abrasion conditions, one cutter replacement for every 4.4 rings under abnormal abrasion conditions, and an average of 0.9 rings per cutter replacement.

The tool consumption for the EPB shield is 6.2 times that of the EPB-TBM dual-mode shield. Cutter abrasion is significantly higher for the EPB shield tunnel boring machine, particularly under abnormal wear conditions.

Based on the data presented in the Table 4, it can be deduced that, in this specific section, the Dual-Mode shield demonstrates an average cutter consumption rate of 3.79 cutters per meter in TBM mode and 2.33 cutters per meter in EPB mode. The cutter lifespan in TBM mode is 1.6 times that observed in EPB mode.

According to the aforementioned statistical analysis, it is evident that in high-strength hard rock strata, both the EPB shield and the EPB-TBM Dual-Mode shield with EPB mode lead to the accumulation of rock debris at the soil bin and cutterhead bottom. This results in significant secondary abrasion on the cutters, reducing their lifespan, increasing the cutter consumption, and leading to a higher number of cutters exhibiting abnormal wear. The TBM mode of the EPB-TBM dual-mode shield proves effective in mitigating this issue.

2.3.3 Comparative analysis of main economic indexes of EPB-TBM dual-mode shield

In the context of the same hard rock strata, a comparative analysis was conducted between the Dual-Mode shield operating in TBM mode in the Huai-Fu section of Line 12 and the adjacent section employing a traditional EPB shield. The analysis focused on major economic indicators, including the construction period, labor costs, and electricity expenses.

Regarding the construction period, the length of this section is 2340m, and the Dual-Mode shield achieves a daily average excavation rate of 6.5m/d, resulting in a total construction period of 360 days.

$$2340\text{m} \div 6.5\text{m/d} = 360 \text{ days} \quad (1)$$

In contrast, the single EPB shield achieves a daily average excavation rate of 1.75m/d, resulting in a total construction period of 1337 days.

$$2340\text{m} \div 1.75\text{m/d} = 1337 \text{ days} \quad (2)$$

The former saves approximately 977 days compared to the latter.

Regarding labor costs, under normal construction organization with two shifts per day and a labor cost standard of 350 RMB/d, the Dual-Mode shield requires 65 personnel per day per machine, resulting in labor costs of 8.19 million RMB.

$$360 \text{ days} \times 65 \text{ people/d} \times 350 \text{ RMB/d} \\ = 8.19 \text{ million RMB} \quad (3)$$

On the other hand, the EPB shield requires 50 personnel per day per machine, resulting in labor costs of 23.40 million RMB.

$$1337 \text{ days} \times 50 \text{ people/d} \times 350 \text{ RMB/d} \\ = 23.40 \text{ million RMB} \quad (4)$$

The former saves approximately 1520.75 million yuan compared to the latter.

Based on the actual construction conditions in this section, the economic advantages of the EPB-TBM dual-mode shield TBM primarily stem from the higher excavation efficiency of the TBM mode in full cross-section hard rock strata. The longer the distance of TBM mode excavation, the more pronounced the economic advantages become.

3 TECHNOLOGY FOR MODE TRANSITION IN EPB-TBM DUAL-MODE SHIELD

3.1 Principles of mode transition in tunnel

According to the design and construction principles of the EPB-TBM dual-mode shield, and considering construction safety, the machine is brought to a stop for mode transition under specific conditions. When transitioning from TBM mode to EPB mode, the cutterhead should be halted for conversion when it is 10 ~ 15m away from the soil-rock interface, as seen in

Figure 7. Similarly, when transitioning from EPB mode to TBM mode, the cutterhead should be stopped for conversion after entering full cross-section hard rock formations at 20 ~ 25m, as seen in Figure 8.

Figure 7. Schematic diagram of transition point from TBM to EPB mode.

Figure 8. Schematic diagram of transition point from EPB to TBM mode.

3.2 Procedure for mode transition within dual-mode shield in tunnels

This section provides an overview of the mode transition process within tunnels, using the Central Belt Conveyor Dual-Mode Shield with the central belt conveyor as a case study.

3.2.1 Transition from EPB to TBM mode

The transition from EPB mode to TBM mode in the dual-mode shield with central belt conveyor involves the replacement of the muck removal equipment, namely the belt conveyor and screw conveyor. The main process includes preparatory work, removal of the screw conveyor, modification of the muck chute, installation of the belt conveyor, and modification of the chamber interior, as illustrated in Figure 9.

3.2.2 Transition from TBM to EPB mode

The primary process of transitioning from TBM mode to EPB mode includes preparatory work, modification of the soil bin, removal of the belt conveyor, installation of the screw conveyor, finalization, and debugging, as illustrated in Figure 10.

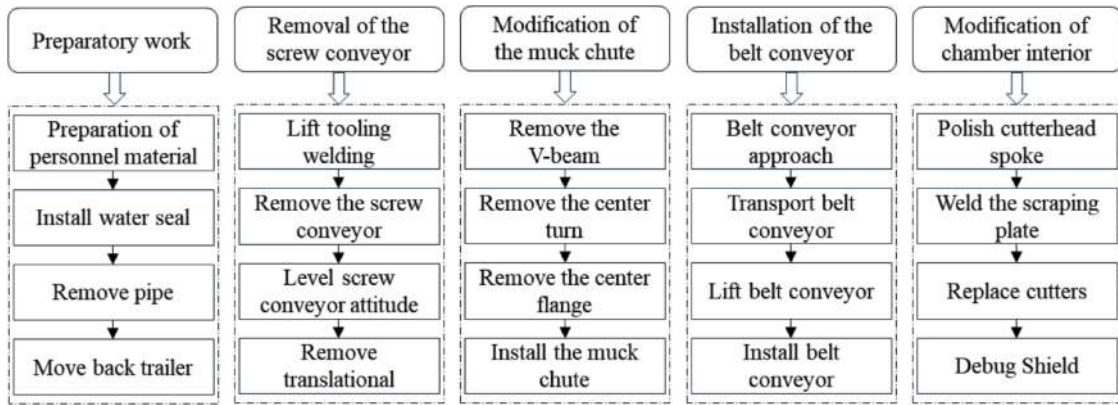

Figure 9. Flowchart of transition from EPB to TBM mode.

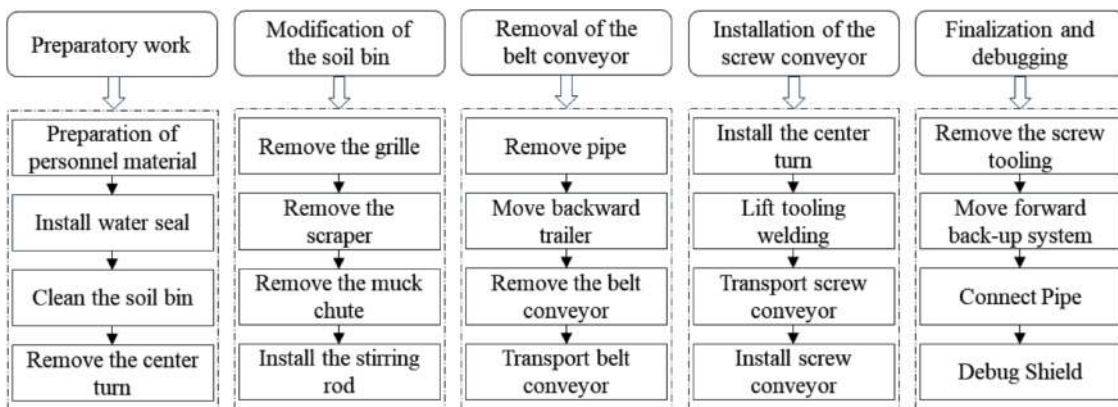

Figure 10. Flowchart of transition from TBM to EPB mode.

3.3 Duration of mode transition within tunnels

Based on the practical experience gained from 14 instances of in-tunnel mode transition in the EPB-TBM dual-mode shield utilized in the Shenzhen Metro, the typical duration for a single transition from EPB to TBM mode is 12-15 days, and from TBM to EPB mode is 11-15 days, with an average duration of approximately 13.5 days. Notably, the dual-mode shield tunnel boring machine CREC779 in the Liuyue to Baihe section of Line 13 achieved the shortest transition period, completing the TBM to EPB mode transition in just 11 days.

Taking the example of the EPB to TBM mode transition in the left-line of the Huai-Fu section of Line 12, the total duration was 12 days, with individual process times illustrated in Figure 11. Due to the confined operational space within the soil bin and the high welding process requirements, the welding operation during the mode transition process took a considerable amount of time, emerging as a critical step in controlling the overall transition period. Through technical enhancements and optimizations in the disassembly tools for the original screw conveyor, the operation safety was improved, and the transition efficiency was increased. As a result, the overall transition period was reduced by approximately 3 days compared to the pre-improvement duration.

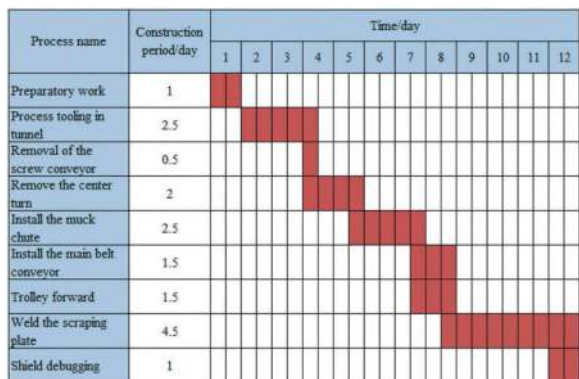

Figure 11. Gantt chart for the duration of EPB to TBM mode transition in the left-line of Huai-Fu section of Line 12.

4 MAJOR PROBLEM ENCOUNTERED FOR EPB-TBM DUAL-MODE SHIELD

In the excavation of high-strength and highly abrasive hard rock strata, encountering shield jamming against the surrounding rock mass becomes a significant operational risk for dual-mode shields. Similarly, such challenges have been recurrently encountered in the application of EPB-TBM dual-mode shields in the

Shenzhen Metro. For instance, during the excavation of an extremely hard rock stratum in a specific section, as seen in Figure 12, there was a notable deviation in tunneling parameters, with the cutterhead thrust increasing to 15000 kN, cutterhead torque decreasing to 800 kNm, and the penetration rate dropping to 4 mm/min. Upon conducting a cutterhead inspection, it was discovered that three disc cutters had experienced uneven wear, with the outermost edge cutters exhibiting varying degrees of deviation. This resulted in insufficient excavation diameter, causing the shield to become jammed against the surrounding rock mass.

Figure 12. The tunnel face of high-strength and highly abrasive hard rock formations.

Blasting excavation emerges as a highly effective method to address the challenge of shield jamming in tunnel boring machines, as seen in Figure 13. This technique involves strategically placing explosive charges at the cutterhead's muck discharge port and the location where the cutter tools are removed. After manually drilling boreholes and loading them with explosives, blasting is initiated. The sequence typically follows the order of “trial blast - groove excavation - section enlargement - reverse excavation”, resulting in high efficiency in surrounding rock mass excavation. However, due to the limited space within the soil bin and the need to protect the cutterhead and shell of the shield machine, careful precautions are necessary. Depending on the specific conditions at the site, the duration for resolving shield jamming using this method typically ranges from 15 to 45 days.

5 CONCLUSIONS

In the construction process of the Shenzhen Metro Phase IV project, the EPB-TBM dual-mode shield was successfully applied on a large scale for the first time. Tunneling under complex and variable geo-

Figure 13. Schematic diagram of explosive excavation method for dealing with shield jamming.

logical conditions and sensitive surrounding environmental conditions, the dual-mode shield has obvious advantages over the traditional single-mode shield. The application of dual-mode shield technology realized the concept of “one machine, two uses” in long-distance tunnels. This approach reduced the number of shield machine launch and retrieval shafts, as well as the quantity of different types of shield equipment, contributing to energy conservation, environmental friendliness, and low-carbon subway construction. Additionally, it significantly improved the efficiency of tunnel construction in long-distance, high-strength hard rock strata, generating substantial economic and social benefits.

Drawing on the practical application of nearly 30 instances of EPB-TBM dual-mode shields, improvement measures were proposed to address issues such as frequent problems with the cutterhead and cutters, as well as excessive shield vibration and torsion. The insights gained from this endeavor provide valuable guidance and reference for optimizing equipment and on-site construction in similar projects. The successful application has been extended to highway, water management, and intercity projects, serving as a model case for rail transit engineering construction both domestically and internationally. This achievement is of great significance in promoting the rapid development of the industry.

A newly developed reduced CO₂ backfill grout system for TBM operations

Mike A. Sposetti*

Master Builders Solutions Construction Chemicals LLC, Dubai, United Arab Emirates (owned by Sika AG)

ABSTRACT: The TBM Tunnelling industry has used two component grouts (A+B) as major backfill application for the last twenty years. Two component grouts have become so widely used that this conventional technology has become simple to handle in matter of specifications, performance expectations and application. However, being primarily focus on pricing, the TBM industry has lost the technical focus of backfill grouts, which is to primarily to avoid surface settlements and tunnel lining floating. Low quality cheap constituents significantly contribute to low quality grouts, in addition to the high carbon footprint. Conventional grout formulations contain a range of cement varying between 260 to 330Kg/m³ and they are responsible for an average of 300-340Kg of CO₂ eq./m³ emissions of injected grout. The newly developed Component A ensures net CO₂ emissions in the atmosphere in the range between 180 to 220Kg/m³, thus contributing to a decisive and substantial reduction of carbon footprint in the range of 45-55%. A good and performing annulus grouting is crucial for sustainability in mechanized tunnelling; more specifically, it should provide more durability to ensure a longer service life of the structures and reduce the cement content as the main source of CO₂ emissions.

Keywords: Tunnelling, TBM, Two components backfill grouts, reduced carbon footprint emissions, new technologies

1 HOW THE TBM INDUSTRY PERCEIVES THE BACKFILL GROUT TODAY

The TBM Tunnelling industry has lost the technical reasons why backfill grouts are pumped behind the tunnel lining during TBM advance.

Primary objective is the avoidance of ground settlements that can be automatically generated by the creation of the annulus void due to the passage of the TBM in the ground.

Secondary objectives, not less important, are:

- The avoidance of segment floating
- The prevention of water ingress into the tunnel, and
- The mild transfer of longitudinal and radial stresses from ground to lining

All backfill grouts objectives are strictly linked to raw material quality, TBM operations and the quality of the final tunnel as a product per se.

Unfortunately, in most of the cases, conventional two-components grouting methods do not fulfil the above basic requirements, thus jeopardizing the

quality of the final tunnel and putting at risk the life of people using the final tunnel on daily basis.

In this context, the backfill grout durability concept is still, anachronistically speaking, highly dominated by the concrete industry mentality where the Unconfined Compressed Strength (UCS) is measured at 28 days.

However, accountability on curing of laboratory samples and detailed procedures of testing, quality control is not yet properly addressed by the industry due to the lack of a proper tailored-made standard to regulate TBM backfill grouts.

The Global Warming Potential (GWP), defined as the impact of carbon footprint emissions (CO₂ eq. Kg) per cubic meter of grout, considering how long it remains active in the atmosphere, is however still rarely calculated.

In an average 300-340 GWP/m³, cement as binder of component A and sodium silicate as activator of component B are the major contributors of approx. 90% of the total CO₂ eq./m³.

This paper illustrates a new Component A backfill grouts solution with reduced carbon footprint emissions, that hopefully will be accepted by the industry.

2 THE CHALLENGES FACING CONVENTIONAL ANNULUS GROUTING METHODS

The major undisputable limitation in annulus grout injection methods is that after placement, they are located behind the concrete segments and are therefore not visible for quality inspection.

Under these circumstances, with the inability by stakeholders to review the final product, material quality has not been the focus of operations over the last decade.

For more sustainable results, annulus grouts should focus on quality, be more durable for longer lasting structures and reduce cement consumption to reduce CO₂ carbon footprint emissions.

Also, conventional logistics, mixing and placement pose several other operational challenges.

There are many influencing factors which contribute to supply chain complexity and overall quality fluctuations over project time.

A conventional formulation includes cement as binder, water, bentonite, other admixtures as component A, and sodium silicate as accelerator of component B. Each raw material requires its own storage tank with the materials procured and delivered separately by multiple suppliers.

These raw materials are stored and mixed at the site batching plant located outside the tunnel. There are many influencing factors which contribute (negatively) to supply chain complexity and overall quality fluctuations over project time. Cement, bentonite and accelerator are the raw materials that suffer the fluctuation of quality more than others.

3 THE REASONS FOR A NEW SUSTAINABLE, ECO-FRIENDLY FORMULATION

In a standard annulus grout, regardless the TBM excavation diameter the average percentage CO₂ emissions is around 20-22 range%.

Figure 1. CO₂ equivalent for segmental concrete and annulus grout per linear tunnel meter (Tunnelling Journal – April-May 2021).

Goal for a new environmentally sustainable formulation is to reach a total impact of 12-13% of CO₂ emissions in a TBM tunnelling project, reducing the overall impact to one third of the current one with conventional grouting methods.

4 THE ENVIRONMENTAL OPPORTUNITY

Conventional grout formulations contain between 260 to 330Kg of cement in every m³, being responsible for an average of 320Kg of CO₂ eq. emissions for every m³ of injected grout in the ground.

In order to reduce CO₂ emission to around 200Kg/m³, the challenges rest in retain all the key performance properties (density, viscosity, bleeding, gel time, compressive strength) and operational parameters (pumpability, flowability, stability leading to no segregation) and keeping the costs within the present range.

A significant reduction in cement content and overall CO₂ carbon footprint emissions represents an opportunity as long as negligible leeching by limiting free water and increased durability are ensured.

The solution the new grout has focused on is using unique admixture technologies, thanks to the mining backfill experience and the adoption of less reactive, inert materials.

5 THE NEW GROUT (COMPONENT A) AND HOW IT WORKS

With the new solution cement and water generate a stronger interbond between the binder and inert materials to reduce free water, reduce leaching, increase strength, control hardening behavior and reducing permeability.

Component A is a combination of binder, inert materials and admixtures delivered as a single dry powder which must be mixed at site with water, pumped into the TBM and then mixed at the injection point with sodium silicate as activator of component B.

Mixing benefits

- Component A mixing procedure follows the same protocol (and time) for standard grouts
- Only water is needed in the shear mix colloidal tank at the batching plant

Infrastructure & logistic benefits at batching plant & TBM

- Smaller batching plant with fewer tanks/silos for less complexity
- No retro fitting required
- No changes of pipes, pumps, tanks outside the tunnel and inside the TBM
- No changes in the injection points in TBM

Logistics and procurement benefits

- Single powdery material
- One supplier
- One point of contact for site technical support
- One supply contract

6 THE ROLE OF FREE WATER

Free water in backfill grout methods is very much linked to water volume losses in the surrounding grounds.

Critical argument for water volume losses is how much water is bonded in each component of the mix and, reversibly, how much water has a critical volume loss potential.

Free water in conventional backfill grouts goes over 60%, a huge factor that impacts on durability, affecting shrinkage and permeability of the final product.

In the new grout method there is significant less free water in net volume (overall 5-10% range, regardless the higher water/binder ratio).

Thanks to the high volume of inert aggregates, binder is bonded in the solids and aggregates are bonded in the water, reducing the net volume of free water by much.

In these conditions the net unbonded free water is better stabilized leading to a much better and more durable final product; anti washout properties are improved after gelling; leaching and shrinking are almost erased; early strength does contribute to lining stabilization.

How much water can potentially leach will heavily depend on the surrounding ground's porosity and water content.

Figure 2. Average Conventional raw materials distribution in conventional backfill two components grouts.

Why water?

- Water is needed to trigger the hydration process of cements
- Water is needed to ensure pumpability and flowability of Component A
- Accelerators need water to create the gelling matrix

What is the solution

The technical solution is the increase of solids in the mix to reduce the free water and, at the same time, to let the remaining water to continue doing its job at the same time

Less free water means:

- Shrinkage is insignificant with limited net water leaves the grout after placement
- Fewer cracks
- Improved waterproofing properties
- Increased durability
- Leaching is almost erased
- Anti Wash-Out properties are improved immediately after gelling
- No segregation, making the grout compatible with any ground

7 PROPERTIES COMPLIANCE WITH TECHNICAL PARAMETERS

In addition to the consistently reduced CO₂ carbon footprint emissions per m³, with the new backfill grout solution the pre and post injection technical performance of main parameters can still be ensured.

- Ensured pumpability, flowability and stability of Component A
- Very limited bleeding of Component A @T24hrs
- Sodium silicate with low solid content dosage as Component B
- Limited shrinkage @T24hrs for reduction of free water and leaching capacity
- Fewer cracks, improved waterproofing and increased durability
- No segregation, allowing the new solution to be compatible with any ground
- Improved anti washout properties

7.1 Quality control

In order to ensure a positive reception in the market, we have kept unchanged all the laboratory tests in use for the qualitative assessment of the grouts. The Table 1 below summarizes these tests.

8 CO2 CARBON FOOTPRINT EMISSIONS SOURCES OF INFORMATION

When calculating GWP, it's important to list the source of information to give credibility to the work.

GWP needs also to be formally stated in EPD (Environmental Product Declaration (EPD) drafted in accordance with EN15804+A2 & ISO14025/ISO21930 standards.

Generic (global) dataset from Ecoinvent 3.6, Generic (European) dataset from CEPE database v3.0 (2016) and EFCA Model EPD: EPD-EFC-20150091-IAG1-EN (Europe) are just some of these sources.

Table 1. Summary of lab tests.

Property	QC Test	Average Conventional Grouts	The New Grout
Flowability	Marsh Cone @T0 hour	30 – 45 seconds	35 – 55 seconds
Stability	Marsh Cone @T24 hrs	45 – 55 seconds	35 – 70 seconds
Bleeding	Bleeding Test @T24 hrs	3 – 8%	1 - 3%
Gel Time	Beaker by Beaker Test Method @T0 hr	It depends on Accelerator dosage	It depends on Accelerator dosage
Early Strength	Penetration Test @T1 hr	0.05 – 0.10 MPa	0.10 – 0.15 MPa
Was-Out	Anti Wash-Out test @T0 hr	Seldom required	3 - 5% max weight loss
Shrinkage	Volumetric Test @T24 hrs	Never required	1 - 2%
Late Strength	UCS Test @T24 hrs	0.20 – 0.50 MPa	0.40 – 0.80 MPa
Late Strength	UCS Test @T28 days	2.0 – 3.0 MPa	1.50 – 2.0 MPa
Elastic Deformation	E-Modulus @T28 days	Seldom required	0.70 – 1.20 GPa
GWP (Global Warming Potential)	Calculation based on Sources	Never measured or required	Net 170 – 230 CO ₂ eq. Kg/m ³ (30 – 45% reduction on raw materials)

Figure 3. Conventional grout @T24hrs after 15 strokes on Hagermann flow table at room temperature.

Figure 4. Conventional grout @T28days at room temperature.

Figure 5. The new grout solution @T24hrs after 15 strokes on Hagermann flow table with improved rheology & no cracks.

Figure 6. The new grout solution @T28days at room temperature with improved durability, no segregation.

9 THE BENEFITS OF THE NEW, INNOVATIVE ANNULUS GROUT

9.1 *Environmental benefits*

- Reduced CO₂ emissions on raw materials by 35-45%
- Reduced CO₂ emissions from transport – one only source to supply Component A
- Insignificant leeching levels into the surrounding ground/water table

9.2 *Benefits for operators and contractors*

- More predictable outcome
- Less risk of secondary grouting
- One supply contract
- Use of present plant infrastructure
- Less logistic complexity
- Mixing and injection unchanged
- Costs comparable to conventional solutions

9.3 *Benefits for employers and end users*

- Increased durability
- Less chance of water ingress in tunnels
- Fewer water leak repairs
- Less downtimes
- Longer, uninterrupted service operation

10 CONCLUSIONS

The new sustainable technologies introduced in this paper are brand-new solutions designed to work in

the industry for very long time, compatible with the new Green TBM concept but also with any type of TBM currently serving the market.

The benefits are particularly advantageous for the environment, in terms energy and water reduction, and carbon footprint emissions.

The advantages of the new technology of foaming agents and backfill grouts match with the constant increase of the diameter of final tunnels (tunnel ID) that leads to a corresponding increase of the volume of soil to be excavated and, ultimately, the volumes of chemicals to be used during TBM operation.

Contractors have now a new way to approach the protection of the environment; with these new technologies they are now able to contribute to a substantial reduction of environmental pollution in grounds and into the atmosphere.

Successful tunnelling in the desert, Wakrah and Wukair Drainage Tunnel, Doha, Qatar

J.B. Stypulkowski* & Khalid Saif F S Al-Khayareen
Public Works Authority (ASHGHAL), Doha, Qatar

ABSTRACT: The Wakrah and Wukair Drainage Tunnel is a 13km-long and 4.5m-ID sewer tunnel which includes several adits with provisions for future connections as well as four work shafts, four intermediate access shafts and ancillary hydraulic structures. Two TBM drives with a length of 5877m and 7198m were both mined using two CREG TBMs with an excavated diameter of 5.9m. The tunnel is supported with a 300mm-thick precast segmental lining made from Fiber Reinforced Concrete (FRC). The tunnel is also lined with a secondary cast-in-place Corrosion Protection Lining (CPL) consisting of sacrificial concrete and a HDPE membrane to cope with an aggressive sewer environment for the next 100 years. The ground surface levels along the alignment range from approx. +5 to +25 m above the Qatar National Height Datum 95 (QNHD95) with shaft depths ranging from 50 to 60m thus making this the deepest and most challenging TBM tunnelling project in Qatar to date. Connecting branches and a new sewage treatment plant will be delivered under different contracts. The authors will link the design considerations and results of the geotechnical data collection system for weak/soft rock mass commonly found in Doha, Qatar presented in the previous papers with the results of performed geological mapping and show how they correlate with the actual TBM performance. The recent advancements in research related to TBM performance and how they relate to the mechanized tunnelling in the Rus Calcareous (RUS) and Rus Gypsum (RUSGY) formations will be assessed as well.

Keywords: Tunnelling, EPB TBM, Performance prediction, weak/soft rocks, deep shafts, durability

1 INTRODUCTION

The Wakrah and Wukair Drainage Tunnel (WWDT) is 13 km long with 4.5 m ID sewer water tunnel about 50 to 60 m below ground surface which is part of a bigger sewer scheme serving Doha's growing population in the years to come. The Owner (or Employer), PWA-ASHGHAL, is the designated Engineer, who is represented by the Engineer's Representative Parsons International (PIL). PIL design team provided engineering design review, verification and approval services for all the design produced by the Contractor's team PORR-HBK-MIDMAC (PHM). PIL was also the Construction Manager on this project. Authors of this article expect the readers to refer to introductory publication by Stypulkowski et al. (2023) on the same subject for omitted details. The basic statistical terminology used is explained in www.cuematch.com. The author's preference is to use "mode" to find the most common value, average is used only if mode can't be calculated.

2 PROJECT OVERVIEW

Integral to the project are several adits with provisions for future connections as well as four work shafts, four intermediate access shafts, ancillary hydraulic structures and an Odour Control Facility. The shaft depths range from 50 to 60m, which will make this the deepest and most challenging TBM tunnelling project in Qatar to date, with water pressures potentially reaching 6 bars. Connecting branches and a new sewage treatment works will be delivered under different contracts.

Two TBM drives with a length of 5,877m and 7,198m respectively were mined using two identical CREG TBMs with excavation diameter of 5.9m. The tunnel is supported with a 300mm-thick precast segmental lining made from Fiber Reinforced Concrete (FRC). The tunnel is currently lined with a secondary cast-in-place Corrosion Protection Lining (CPL) consisting of sacrificial concrete and a HDPE membrane.

Logistics and launch tunnels were excavated using NATM/SEM technology (bench & heading) with a cross section area between 31.2 m² and 43.8 m².

*Corresponding author: jstypulkowski@ashghal.gov.qa

The project site is mostly undeveloped with sparse desert vegetation and is surrounded by Qatar Energy (QE) lines, overhead high-voltage transmission lines, and other utility services, as well as expressways. The ground surface levels along the alignment range from approx. +5 to +25 m above the Qatar National Height Datum 95 (QNHD95).

Figure 1. WWDT project layout/progress.

Access Shafts WS10 and AS09 were used to launch two Tunnel Boring Machines (TBMs) mining upstream provided access for tunnel construction. Access Shaft AS09 is centralized along the alignment and is a launching shaft as well as receiving shaft. List of all the shafts is in Table 1. After completion of construction a smaller diameter permanent shafts will be constructed within the temporary shaft and the excess space around is backfilled. Two shafts are intended as TBM reception shafts: WS07 and AS09. The shafts intermittently served as tunnelling shafts and after TBM passed it facilitated CIP liner installation in already completed sections (Figure 1).

Table 1. Shaft summary.

Shaft	Temporary shaft		Permanent shaft		Permanent shaft ID
	ID	OD	(m)		
	Conical		Conical		
	Base	Top	Base	Top	
WS08	10.2	14.5	10.2	11.1	7.8
AS10	10.2	14.0	10.2	11.1	7.8
WS09	15.2	19.5	15.2	16.1	12
AS11	15.2	19.5	10.2	11.1	7.8

3 ALIGNMENT CONSIDERATIONS

The tunnel horizontal alignment has been confined to the assigned utility corridors. For additional consideration please refer to Stypulkowski et al. (2023).

4 GEOLOGY

An extensive ground investigation works has been performed along the alignment. For detailed description please refer to Stypulkowski et al. (2023).

The project area is geologically a part of the Arabian Gulf Basin as described in detail by Cavelier et al. (1970) and Sadiq and Nasir (2002). Only two underlying lower geological units: the Rus Calcareous (R) and Rus Gypsum (RG), (Karagkounis, 2016) were encountered during tunnelling.

The encountered R can be described as fine-grained calcarenite characterized by chalky and bioclastic limestone with occasional nodules of gypsum and beds of laminated shale, siltstone, claystone, and clayey silt. Very closely to medium-spaced fractures were reported, as well. RUS was encountered in different colours, including greyish brown, grey, brownish grey, and white.

The encountered RG can be described as fine-grained gypsum and calcareous siltstone with beds of fine- to medium-grained bioclastic limestone, calcareous siltstone, soft to stiff silty clay and claystone, with very closely to widely spaced fractures. RG was encountered in different colours, including grey, brown, brownish grey, bluish grey and brownish grey.

5 INTACT ROCK PROPERTIES

Laboratory tests were conducted on rock samples obtained from borings before construction. For the Rus unit Uniaxial Compressive Strength (UCS) test results (Figure 2) range between 1 – 51 MPa (mode 4.1MPa). For the Rus Gypsum unit Uniaxial Compressive Strength (UCS) test results range between 2.2 – 31 MPa (mode 16MPa). While the maximum values are lower the USC in mode terms for RG is almost 4 time larger. Tensile strength from Brazilian tests (Figure 3) range between 0.1 – 11MPa (mode 3MPa) for R and for RG range between 0.1 – 12MPa (mode 2MPa). While the maximum values are similar the Brazilian in mode terms for R is 38% higher. $I_{s(50)}$ from point load testing (Figure 8) ranges between 0 – 4MPa (mode 0.2MPa) and 0 – 3MPa (mode 0.5MPa) for R and RG respectively. While the maximum values are higher the $I_{s(50)}$ in mode terms for RG is almost 3 time larger. Young's modulus from UCS testing (Figure 7) range between 0.4 and 39GPa (mode 12GPa) for R and between 0.8 and 47.5GPa (mode 23.5GPa) for RG. The maximum values are 21% higher for RG and the

Young's modulus in mode terms for RG is 2 times larger. Poisson's ration in mode terms is 0.36 for both units. Slake Durability Index (SDI) (Figure 4) ranges between 10 and 99 (mode 75) and 32 and 99 (mode 97) for R and RG respectively. The SDI in mode terms for RG is 30% higher. Schmidt Rebound Hardness (SRH) (Figure 5) is similar for both rock units, however in mode terms it is 35% higher for RG. Maximum Swelling Strain Index (Figure 6) values are 4 times larger for RG.

Figure 2. Rus & Rus Gypsum all tests UCS in MPa and MN/m².

Figure 3. Rus & Rus Gypsum all tests, Tensile Strength σ_t (MPa).

Series of Triaxial Tests were carried out on 241 Rus samples and 209 Rus Gypsum samples. Resulting Angles of Friction ϕ (°) were similar yielding 38 to 40 deg mode terms and average cohesion was from 2 to 2.4 MPa.

Figure 4. Rus & Rus Gypsum all tests, slake durability index.

Figure 5. Rus & Rus Gypsum all tests, schmidt rebound hardness.

Figure 6. Rus & Rus Gypsum all tests, swelling strain index.

Figure 7. Rus & Rus Gypsum all tests young's modulus E_i (GN/m²).

Figure 8. Rus & Rus Gypsum all tests, $I_{s(50)}$ (MPa).

The RMR system (Bieniawski, 1989) while it was developed for hard rock tunnels it is commonly used by designers since it is related to GSI which in turn is often used as an input for the Hoek-Brown failure criterion. Its inapplicability to soft/weak rocks has been discussed in detail by Stypulkowski et al, 2014, 2016, 2018, Pathak et al 2015, Vucemilovic, H. 2021. Since extensive triaxial testing has been conducted yielding Mohr-Coulomb (M-C) criteria parameters the authors decided to omit it.

6 EXAMINATION OF THE TBM DATA

6.1 General

The excavation is still carried out by one of two CREG TBMs with rotating cutter-head which was fitted with cutting tools (disc cutters, scrapers, rippers). TBM drives AS09 to WS07 with a length of 5,877 m started 2/28/22 with a breakthrough 5/4/23 and WS10 to AS09 with a length of 7,198 m started 1/27/22 with expected breakthrough in October 2023. Both TBMs have an excavation diameter \varnothing 5,9m. The permanent lining of the tunnel consists of doweled, pre-cast concrete segments reinforced with steel fibres. For additional details please refer to Stypulkowski et al. (2023).

6.2 TBM performance and utilization

Five earth pressure sensors in the bulkhead were used for controlling the stability of the tunnel face. Continuous measurements of the earth pressure in the excavation chamber allowed control of the face support pressure. The contractor estimated in its Plan for Advance of Tunnels (PAT) maximum supporting pressure of 5.22 and assumed 1.2 bar as a minimum.

Figure 9. TBM Earth Pressures – Invert (bar).

Face pressures calculated using methodology described in Anagnostou et al.(1994) is commonly used for estimation. Since most of the measured results in mode terms are about 1.14 bar there is no correlation between soil type of materials and weak rocks of Doha (Figure 10).

The excavated material was measured via the belt scales installed on the conveyor belt and compared to the theoretical volume.

Since the rate of advance mainly depends on geological conditions, ground stand-up time, stability, mode of advance, condition of cutters, etc. the authors looked at the collected data (Figure 11). These boundary conditions have a direct influence on the cutter head torque and the contact force, which limit the advance rate.

Figure 10. TBM Earth Pressures – Crown and σ_{tot} (bar).

The maximum speed designed for this TBM was 80 mm/mi (Figure 11). The advance speed associated with cutter head rotation speed, was well below expected maximum 5.5 rpm (Figure 12).

Figure 11. TBM Advance Rate (mm/min).

Figure 12. TBM Rotational Speed (rpm).

The cutter head rotation speed and thrust force were adjusted during the TBM excavation for optimized advance rate (Figure 14). The contractor estimated in PAT expected maximum thrust forces from: ground face resistance, water pressure, shield friction, cutter tools, drag forces from back up systems and tail skin seal to be 27,715kN and minimum 12,478kN. What was recorded during tunnelling is shown on Figure 12. Maximum thrust recorded was 17,389kN with a mode of 8,453kN which is about 30% of what was anticipated.

Figure 13. TBM Thrust (kN) with 12 high values eliminated out of 3649.

There were 12 interventions at the face, 3 involved double disc replacement (Table 2).

6.3 Ring building

The tunnel was lined with segments immediately after the TBM advance under the protection of the

shield. The segments were moved into position by an erector, a remote-controlled crane arm, which picked them up mechanically and then put in place. In TBM tunnelling it is the most important operation which when it is done efficiently contributes greatly to overall success of tunnelling operations.

The ring build time has been filtered and after elimination of stoppages longer than 8 hrs it has been established that installation time in mode terms was 75 minutes (Figure 16 and Figure 15).

Detailed description of typical installation process has been presented in Stypulkowski et al (2018).

6.4 EPB face pressure effect on TBM performance

The authors looked at how different face pressure may affect tunnelling parameters after Bilgin (2023).

The results were split into four pressure intervals of 0.5bar each. As shown in Table 3 and of figures Figure 16 and Figure 17. Contrary to the findings made by Bilgin (2023) thrust and torque were not linearly related to the face pressure.

Figure 15. TBM Ring Build Time (min).

Figure 16. Ring installation time shorter than 480 min (99 instances out of 3649 eliminated).

Figure 17. Ring Advance time (min) & Thrust Force (kN) vs EPB face pressure.

Figure 18. Cutter Head Torque (kNm) & Advance Rate (mm/min) vs EPB face pressure.

Table 3. EPB face pressure effect on TBM performance.

TBM#2	Ring Advance time - mode	Thrust Force - mode/ave	Grout Pressure - mode/ave	Cutter Head Advance rate - mode/ave	Cutter Head Advance Rate/ Penetration - mode/ave	Total Grout Volume Ratio (Actual/Theoretical) - mode/ave	Total Grout Volume	Cutter Head Torque - mode/ave
Face Pressure	[min/Ring]	[kN]	[bar]	[mm/min]	[mm/rev]	[%]	[m ³]	[kNm]
0 to 0.5	58	5,018	0.98	23	10	106	4.98	615
0.5 to 1	34	7,502	2.01	52	18	127	5.01	1,234
1 to 1.5	28	8,931	2.06	54	17	115	4.94	1,153
1.5 to 2	27	7,745	3.44	57	23	142	5.02	1,044

notes: correlations don't follow published patterns, EPB face pressure increase doesn't automatically result in proportional increase in tunneling parameters for both TBMs

6.5 TBM penetration considerations

Since UCS test results concluded that Rus Gypsum is 4 times stronger than Rus and $I_{s(50)}$ is 3 times higher, the authors decided to look if the difference in strength affected TBM performance in those units. Most of the tunnelling was done along the boundary between those units with significant portion in the mixed face condition. In addition, tensile strength for Rus Gypsum is 38% higher and young's modulus values are 2 times larger supporting trends in other data. However, triaxial test results show very similar results for both units.

6.6 Torque and thrust

When comparing thrust forces recorded in both units in mode terms, we have 8,249 and 9,565 (kN) in R and RG respectively (Figure 12) which is 16% higher for RG. When comparing advance rates, we have units in mode terms 47.3 vs. 37.7 (mm/min) which is which is 29% lower for RG (Figure 20).

Figure 19. Thrust force in Rus vs Rus Gypsum.

When looking at torque recorded in both units in mode terms, we have 1,211 and 1,196 (kNm) in R and RG respectively which are similar indicating constant driving parameters for the TBM.

In general no in-crease of penetration can be associated with thrust and torque increase.

Figure 20. Advance rates in Rus vs Rus Gypsum.

6.7 Boreability

The boreability have been used in rock tunnelling to express ease or difficulty of TBM tunnelling. Most frequent input parameters in hard rock models are: UCS, data on discontinuities, thrust per cutter and cutter diameter. Applicability of this approach for weak/soft rocks of Doha was addressed by Stypulkowski et al (2016).

The authors used Boreability Index (BI) to analyse the variations of rock mass conditions along the alignment. BI also known as FPI is the thrust force per cutter (kN) divided by penetration rate (mm/rev). The

Figure 21. Correlations made with Boreability Index (BI) were not observed with thrust and torque.

authors looked at this relationship before in Stypulkowski et al (2018). The index again shows similar characteristics for weak/soft rocks of Doha.

6.8 UCS and penetration in weak/soft rocks

The relationships between UCS and penetration, torque and thrust are shown on Figure 22 to Figure 27 for R and RG separately. Unlike previously UCS test results from tunnelling horizon do not correlate well.

Figure 22. TBM Penetration (mm/rev) vs UCS in tunnelling horizon (MPa) in R.

Figure 23. TBM Penetration (mm/rev) vs UCS in tunnelling horizon (MPa) in RG.

Figure 24. TBM Torque (kNm) vs UCS in tunnelling horizon (MPa) in R.

Figure 25. TBM Torque (kNm) vs UCS in tunnelling horizon (MPa) in RG.

Figure 26. TBM Thrust (kN) vs UCS in tunnelling horizon (MPa) in R.

Figure 27. TBM Thrust (kN) vs UCS in tunnelling horizon (MPa) in RG.

7 CORRELATIONS OF TBM DATA WITH ROCKMASS

Forecasting of excavation behaviour in tunnelling using classification systems rely on previous case histories.

7.1 QTBM

Penetration rates were used to calculate Q_{TBM} using well known empirical approximation after Barton,

2006 ($Q_{TBM} = (5/PR)^5$). Figure 28 shows distribution of Q_{TBM} with median 19 yielding good to very good tunnelling for most of the drive in Q_{TBM} terms.

Figure 28. Q_{TBM} less than 100 with 87 high values eliminated.

8 CONCLUSION

Since the project is still ongoing with the second TBM mining in the same geology the authors intended this paper to provide a second “progress report”.

ACKNOWLEDGMENTS

The writers acknowledge PHM for all the construction and design effort and Volkan Salepciler from PII for actively managing the project. A special acknowledgement is owed to Murat Canpolat of PHM for providing and reviewing all geotechnical information included herein.

TBM design for operation in gassy formation

Laura Tafuri* & Omar Bonfanti
Webuild, Milan, Italy

Andrea Lisardi
Collins srl, Fiumicino, Italy

ABSTRACT: The Italian railway new network system at present under construction in south of Italy foresees the excavation of several long tunnels to be bored by TBMs in clayey sedimentary formations in presence of gas. The inflows of gas along most of these tunnels are foreseen to be frequent if not continuous in some area. The standard TBM design features and predispositions adopted to deal with the presence of gas are instead suitable for formations in which the presence of gas is only possible or occasional. Consequently, the systems installed on these “standard” TBMs are oriented, according EN16191, towards measuring the gas concentration and, in the event of critical thresholds being exceeded, to automatically shutdown the power supply, evacuate the tunnel and leave the TBM in standby until the dilution of the gas concentration by the ventilation system. The expectation of frequent gas inflows for long stretches of tunnel in projects to be carried out in Southern Italy required a different approach, and more advanced systems to increase the workers safety and at the same time allow, within certain limits, the advancement of the TBM even in the presence of gas inflows, using a safety system that adopt ATEX equipment, procedures, compartmentation, ventilation, drainage and monitoring system. Starting from the guidelines (NIR 44), developed in Italy for large diameter TBMs excavating in gassy formations and adopting EN1127-2 and EN80079-38 for guidance, Webuild has developed, in collaboration with specialist consultants, university institutes and TBM manufacturers, the design, the technical characteristics and the specifications of the TBMs to be used in these projects. The article describes the philosophy behind the design of these TBMs, how this design was developed, the associated procedures and the specifications of the auxiliary equipment and systems supporting the TBM for muck transport and services along the tunnel.

Keywords: Tunnelling, TBM design, gassy formations, ATEX, underground, safety

1 INTRODUCTION

The new Italian railway network currently under construction in the southern part of Italy, utilizing mechanized excavation, is part of a complex and heterogeneous geological context, specifically involving clayey sedimentary formations. In addition to these geological challenges, there is a significant presence of gas, which is not occasional or discontinuous, as observed in other contexts, but continuous and characterized by high quantities and pressures.

Furthermore, the new foreseen railway network, include several projects, located in Campania and Sicily regions, as following indicated:

- *Napoli-Bari HV*, with the lots of Hirpinia-Orsara, Orsara-Bovino and Apice-Hirpinia, for a total tunnel length of 71km
- *Palermo-Catania HV*, that include the lots:
 - Lot 4B Enna-Dittaino
 - Lot 4A – Caltanissetta-Xirbi-Nuova Enna
 - Lot 3 – Lercara-Caltanissetta-Xirbi
 - Lots 1&2 – Fiumetorto-Lercara

for a total tunnel lengths of 124 km

The various tunnels to be realize, which involve the use of more than 20 TBMs, challenging construction timelines, in addition to the difficult geological context, the strong and continuous gas presence mentioned earlier, and the primary need to ensure the highest safety standards for all individuals

*Corresponding author: l.tafuri@webuildgroup.com

involved, while allowing for the continuity of excavation, have led to the necessity to revolutionize the traditional ATEX concept. The article will describe, starting from the classic ATEX concept, the approaches and improvement interventions undertaken to define the new explosion-proof design of the TBM.

2 ATEX CONCEPT: EVOLUTION AND IMPLEMENTATIONS

Essentially, the reference for the design of ATEX TBMs is based on the Best Practices recommended by the NIR 44 regulation, typically defined and applied to large-diameter TBMs. In these TBMs, the design is primarily focused on measuring gas concentration, and in the event of critical thresholds being exceeded, automatically interrupting the power supply, evacuating the tunnel, and placing the TBM on standby until the gas concentration is diluted by the ventilation system. In the specific context of projects in Southern Italy, this standard design and working approach are not sufficient and need to be implemented. Specifically, the design of the TBMs for transformation into ATEX includes the following macro-intervention areas:

- Compartmentation of volumes/work areas;
- Use of suitable equipment certified for use in gas environment.
- Implementation and optimization of operational activities on board the machine.

The objective was to improve the continuity of excavation while prioritizing safety; the evolution of this specific aspect has been a focal point in conceptual development over the years. To achieve these goals, a suitable machine configuration has been established, starting from NIR44 and drawing upon previous Italian experiences (Sparvo tunnel, Santa Lucia, COCIV). Additionally, by studying and subsequently implementing new technologies, specific procedures have been devised for workers to follow during the operational phase. This ensures the proper utilization of these innovations and, consequently, maximizes excavation efficiency.

There has been an increased emphasis on machine design, aiming to establish a design methodology that, regardless of variations across projects, can provide a universal approach to ATEX design. In the following sections, starting from the overarching concept of ATEX, all the implementations developed to achieve the new concept of explosion-proof TBM design will be outlined.

2.1 *TBM main concept and previous implementations*

The design of TBM-EPB in gassy formations is based on the concept of managing emission sources and confining the air-methane atmosphere within an ATEX volume.

General TBM concepts comply to EN 16191 that, for use TBM in potentially explosive atmospheres, require EN 80079-38 (*Equipment and components in explosive atmospheres in underground mines*) for guide, and comply the Italian guideline NIR44.

Consequently, the risk assessment is performed according EN 1127-2 and equipment are Ex Group I. Analyses of previous experience in gassy formations like Sparvo tunnel (Bandini et al, 2017), Santa Lucia e Pavoncelli tunnels (Bandini et al, 2020) have provided know-how, implemented and tested in Radimero tunnel in a gassy formation, where emissions are quite ordinary.

The new TBM design is an evolution of all previous experience; solutions are provided to avoid both presence of explosive atmosphere and ignition sources, by technical innovations, monitoring, procedures, ventilation system, avoiding potential emission source by increasing sealing of shield elements, and using a drainage system from the excavation chamber.

A confined ATEX volume, designed with specific ventilation, are built around screw conveyor discharge, considered an effective and almost continuous emission source.

2.1.1 *TBM volumes -NIR44*

TBM volumes concept is realized according NIR44 criteria, using a new solution for compartmentation and ventilation of Volume 3. The main conceptual layout is depicted in Figure 1. General NIR44 criteria (Bandini et al, 2017) establish four distinct volumes characterized by different risk assessments and varied solutions aimed at risk mitigation:

- **Volume 1** – always full of muck or material during the advance,
- **Volume 2** – Non ATEX Volume, around Volume 3 housing, where are implemented ATEX solution to monitoring and increase sealing of shield elements and emergency system.
- **Volume 3** – ATEX volume confined by an air proof housing and aspiration ventilation system, from screw conveyor discharge (Figure 2) to last gantry.
- **Volume 4** – ATEX Volume from the end of Volume 3, extended for 500 m
- **Volume 5** – Non ATEX Volume. It is a new implementation respect to NIR44, managed by monitoring and alarms procedures.

2.1.2 *Emission source*

The first step of analysis is to characterize the emission source on the TBM. These can be categorized into two groups:

- Potentially continuous, that can't be avoided during advance;
- Discontinuous, emissions resulting from a temporary malfunction or inefficient of sealing systems adopted to compartmentalize the machine's volumes and to segregate them from ground.

Figure 1. Main Concept Layout and Ventilation concept in normal and SD1 alarm conditions.

Full ATEX volumes are associated to the first type of emission. For the second type of emissions have been implemented solutions, to avoid emission, by developing new sealing system, managed by ATEX control systems, improving their efficiency and managing emergencies. In the volumes where there are second type of emission source, all emergency and control system are ATEX, while other equipment are standard, with temperature control procedures and automatic shut-down managed by methane monitoring system.

2.1.3 Maintenance in hyperbaric conditions

In hyperbaric condition is not possible to use ATEX equipment to eliminate ignition source: ATEX

Figure 2. Compartmentation between volume 1 and 3 (Photo and scheme courtesy of CREG).

standard are applicable only in normo-baric conditions. The working procedure adopt a system to realize a cake, by slurry or cement grout, or clay-shock method (Shao-Hui Tang et al, 2021). Pressure and air flow rate are monitored, managing alarm conditions. Methane sensors are in normo-baric atmosphere connected by a probe to a suction point inside excavation chamber. If methane is detected inside excavation chamber alarm condition are activated. In alarm condition, due to pressure drop or air flow rate variation or methane concentration detected, all equipment are turned off, people leave excavation chamber, closing the door, reaching man-lock. Special lights are used to communicate alarm condition in excavation chamber. These equipment are tested by a specialized laboratory in 5 bar methane-air atmosphere, to ensure that they haven't ignition source in working conditions (5 bar). Lights protections dedicated solutions are developed improving ATEX protection method Ex M (encapsulation - EN 60079-18).

2.1.4 Alarm shut down concept

All emergency and monitoring equipment in TBM and tunnel are ATEX, allowing emergency managing during alarm condition. According En 1127-2, in an explosive atmosphere (concentration greater than LEL), Ex I M2 (Mb) equipment needs to be capable of being disconnected or made safe. During evacuation and for a short time, it might be necessary to operate M2 equipment in an explosive atmosphere.

According to the risk assessment, in tunnel and on TBM, equipment and plants are both ATEX or standard. Methane monitoring system manage two shut-downs: SD1 for non ATEX equipment in alarm condition and SD2 for ATEX Ex I M2 (Mb) equipment, if explosive atmosphere is present on for a longer time than evacuation time from TBM. In the Figure 3 is showed the electrical line concept, in which one ATEX line (armored high voltage cable and ATEX junction box) from portal reaches the ATEX cable reel on TBM. This cable reel is then connected to the high voltage junction box from where start two lines: the first to the ATEX transformer cabinet and the second to the switchgear cabinet for standard line. In SD1 condition is activated the braker on TBM to shut down from safe volume

standard line. In SD2 condition is activated the switch gear present on the portal and all the tunnel equipment are automatically turned off.

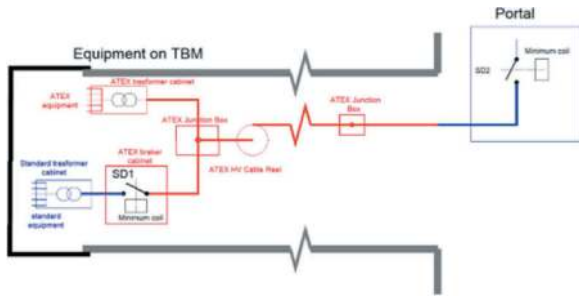

Figure 3. Electrical line concept.

According to the emergency plan and risk analysis, monitoring system, telephones, SOS system and rescue chamber on TBM are not turned off both in SD1 and SD2 condition: all these equipment is energized by backup-UPS.

In SD1 condition still work ventilation system and emergency equipment, like lights, dewatering pumps, tail and articulation sealing systems, and second crane mechanical protection system.

In SD2 condition, ATEX line is shutter down from portal, after short time. Ventilation fan on TBM, both blower and aspiration one, are switched off. In these conditions remain blower ventilation system by portal fan, blower ventilation flow up fresh air to the shield while the secondary fan is off, by closing valve before secondary fan. Proportional valve for blower ventilation in volume 3 is fully opened to maximize flow rate. The ventilation concept changes to the layout showed in the Figure 4. The ventilation inside Volume 3 (belt conveyor housing and duct) changes direction, blowing from screw conveyor discharge. Different threshold limits are defined for each volume, according to the risk assessment and the NIR44 guideline. Table 1 shows the percentage methane volumes that trigger the various situations.

Figure 4. SD2 Alarm condition – ventilation procedure.

The same conditions are activated for different threshold limits. In alarm condition all standard (not ATEX) equipment are shutter down (SD1) from a safe volume and it is activated evacuation procedure using the ATEX evacuation vehicle, always available on the TBM. On the TBM there are several

Table 1. Threshold limits.

Alarm condition	C % methane in air			
	Volume 3	Volume 4	Volumes 2 and 5	
Normal	< 0,3	< 0,3	< 0,15	
Attention	0,3	0,3		Reduce advance Pump grease articulation and brushes
Pre alarm	3	0,7	0,15	Stop advance Increase ventilation Close guillotine
Alarm	3,5	1	0,35	Shut down standard equipment evacuation

alarm lights and trumpet managed by gas monitoring system. These alarm stations are even along tunnel every 500 m, connected by optical fiber to TBM monitoring system. At the portal there is a control room with PC with real time display, data logger, alarm log and managing system to operate, by password, to the gas monitoring system.

2.2 New implementations/optimizations for ATEX

Based on the previous operational experiences, it has been studied new aspects and/or implement and improved previous adopted solutions for increasing the safety and the continuity of the excavation. These aspects are all oriented to extend the operativity on TBM board, and are listed below:

- Ventilation Concept
- Gas Drainage Concept
- Upgrading of gas monitoring system
- Solution for parking and use of ATEX emergency vehicle
- Other improvement and applications
 - Shield articulation and tail brushes
 - Extension of Volume 4

In the following paragraphs are described in details.

2.2.1 Ventilation concept

Ventilation plant is a “safety device” according to ATEX; it is compliance to a risk-based approach considering Safety Integrity Level, SIL1 level according to EN 61508.

The main features are:

- UPS station,
- Flow rate and pressure monitoring system with associated safety procedures,
- portal fan station redundancy

For this last aspect typically are provided two fans coupled, considering a degraded mode due to failure. All control and monitoring system are compliance to a SIL1 level.

On the TBM the ventilation system is made by two different plants, that working together and in a balanced way: blower ventilation from portal with a secondary ATEX fan on TBM, and aspiration system dedicated to Volume 3.

In the Figure 5 is showed the schematic detail.

Figure 5. Ventilation concept.

Blower ventilation is provided to the shield area and to working chamber, to excavation chamber during maintenance in normobaric conditions, and to Volume 3, by blowing line close to screw conveyor gate to move and dilute emission from screw conveyor. All lines are managed by a proportional valve.

Volume 3 flow rate is defined by balancing all flows in TBM and considering minimum air speed in the belt conveyor housing of 1,5 m/s.

Main ventilation design parameters are:

- Air speed inside the belt conveyor housing,
- distance between suction line end section and Volume 3 end section,
- avoid air recirculation,
- emergency gate on the front of housing to be opened if ventilation inside Volume 3 is off,
- minimum air speed in TBM is 0,5 m/s.

2.2.2 Gas drainage concept

To increase the continuity of the excavation, one of the main aspects considered is the removal of gas presence to avoiding any ignition source. For this reason has been developed various operative procedures and technical implementation that combine ventilation and new systems. These implementations consist in:

- Procedures that allow the gas reduction during TBM advancing;
- Procedures that allow the intervention in the excavation chamber;
- Systems that permit the gas removal from the excavation chamber and the evacuation through the tunnel

The first aspect is illustrated in the Figure 6

Figure 6. Void detection system (photo on CREG courtesy)

This system is installed on the top of bulkhead and permit to monitor the voids presence. Normally the advance of the TBMs is possible only in “Closed” mode, with excavation chamber always full. The absence of void volumes into the excavation chamber shall prevent the release of gas from the excavated material and consequently the formation of potentially explosive gas bubbles.

The second aspect is depicted in Figure 7a and 7b, illustrating the two phases, one before and the other after the intervention in the excavation chamber. As shown in the pictures, the presence of additional air lines allows interventions in hyperbaric conditions with a higher level of safety. This is because they enable the introduction of clean air into the excavation chamber, thereby reducing the methane concentration to safe levels.

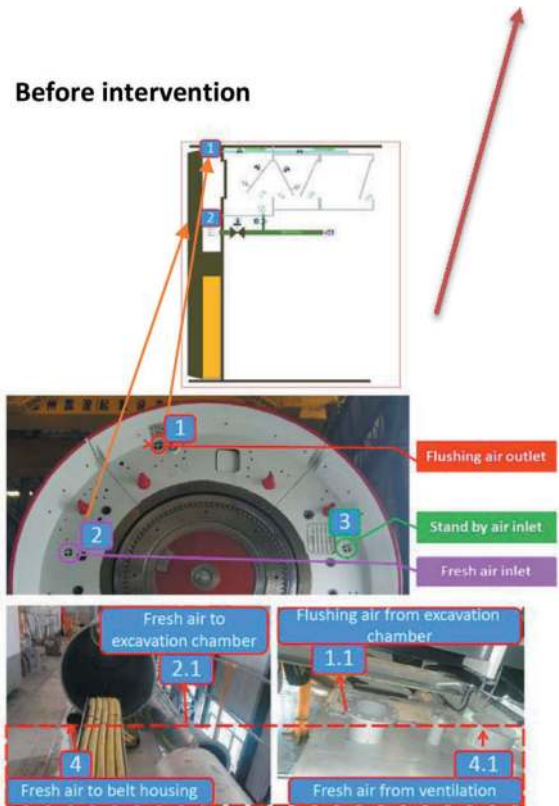

Figure 7a. Procedures for interventions in excavation chamber in atmospheric conditions – Before the maintenance (on CREG courtesy).

During intervention

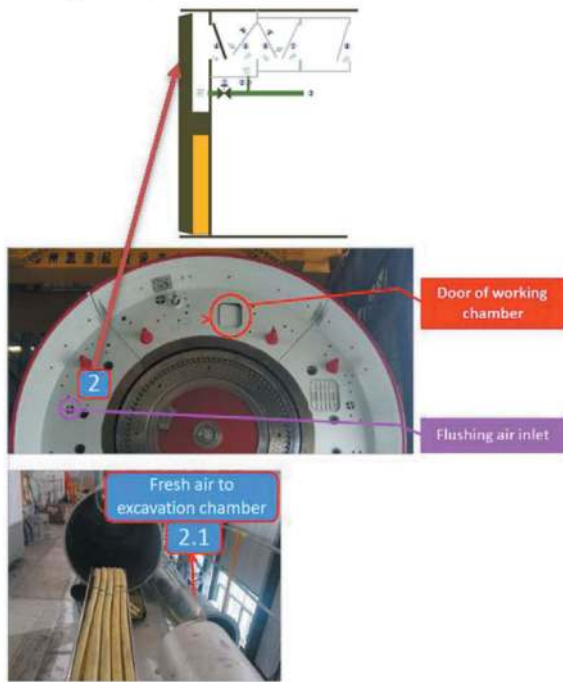

Figure 7b. Procedures for interventions in excavation chamber in atmospheric conditions – During the maintenance (photo on CREG courtesy).

Furthermore, considered the third aspect mentioned before, a drainage system has been designed to allow the discharge of the gaseous volumes from the excavation chamber to the surface through a dedicated conduit (Figure 8 for schematic and Figure 9 for details).

Figure 8. Drainage system Schematic.

The primary objectives are as follows: to reduce the pressure within the excavation chamber, expel exhaust air from the excavation chamber during the flushing procedure, eliminate air bubbles from the excavation chamber during excavation, and facilitate the drainage of methane to the surface. The design has been developed with due consideration of past experiences in the Pavoncelli tunnel (Bandini et al, 2020) and requirements described in EN 14983:2007, (*Explosion prevention and protection in underground mines - Equipment and protective systems for firedamp drainage*).

Figure 9. Drainage system Details (photos on CREG courtesy).

This system is designed to reduce the occurrence of an explosive atmosphere within the tunnel and the TBM back-up during operations. It achieves this by maintaining operational pressure limits for all sealing systems and minimizing impulsive emissions from the screw conveyor. The entire system and its components operate under hyperbaric pressure in an air-methane atmosphere, in compliance with the Pressure Equipment Directive (PED) and the ATEX directive.

A separator, designed in accordance with the ATEX directive, is installed near the excavation chamber. To prevent frictional ignition, the internal surfaces and filters are constructed using non-sparking materials. The objective is to segregate solids and mud (clasts, foam, muck) from gas and water, facilitating their passage into the second section of the drainage system. Procedures have been established for flushing the entire line and separator using inlet water and compressed air, managed by

valves. A hose reel on the TBM ensures continuous line integrity during advancement, with dedicated procedures developed for maintenance.

It is possible to flush the entire line by filling it with water propelled by compressed air to the portal. The water will travel from the reel to the surface through the separator, the second section of the line, and the hose. A water seal drum with a flame arrester on the discharge line is installed at the surface. Emissions from the line are intermittent, and the flow can consist of air or a methane-air mixture at various concentrations, with no flame being utilized.

2.2.3 Methane monitoring system

The monitoring system functions as a pivotal safety device, designed in adherence to the ATEX standard, achieving a Safety Integrity Level (SIL) 1 in accordance with EN 61508. Monitoring sensors align with the specifications outlined in EN 60079-29-1:2016 (Explosive atmospheres - Part 29-1: Gas detectors - Flammable gas detector performance requirements). The strategic positioning of sensors, illustrated in Figure 10, is carefully defined to oversee emission sources and the gas path on the TBM.

Figure 10. Sensor Positioning concept (on CRCHI courtesy).

In this specific application, a deliberate augmentation of the sensor count has been implemented, further fortifying the monitoring capabilities and safety levels.

The sensors for the excavation chamber and the work chamber are located in Volume 2 within a safe area and are connected to a sampling point in the excavation chamber during maintenance. This is due to the fact that the sensors do not function properly under hyperbaric conditions, and direct installation is not feasible. The schematic representation is provided in Figure 11.

Figure 11. Sensors for working and excavation chamber (on CREG courtesy).

2.2.4 Emergency vehicle and solution for evacuation

An emergency vehicle is consistently present on the TBM to facilitate the evacuation of the entire crew from the tunnel at any given moment. To accommodate this requirement, a dedicated gantry has been implemented.

In an ATEX configuration, the system is designed to enable evacuation at any time, and, for this purpose, a specific system has been developed to facilitate this in emergency situations. In Figure 12, the hoisting system used to transfer the vehicle from the platform to the ground is depicted. The entire system, comprising hoisting and hydraulic components utilized for moving the emergency vehicle, adheres to a Safety Integrity Level (SIL) of 1 according to IEC 61508.

The evacuation procedure is initiated in alarm conditions at SD1. Upon activation at SD2, personnel commence the evacuation of the tunnel. If gas concentration rapidly rises to the Lower Explosive Limit (LEL) level, the emergency vehicle system remains operational even after power shutdown from the portal, allowing the relocation of the vehicle from the parking area by personnel.

A semi-manual system employing compressed air, sourced either from a bottle or supplied by the tunnel line, is utilized to relocate the vehicle from the platform even under SD2 conditions.

2.2.5 Other improvements and applications

2.2.5.1 Shield articulation and tail brushes

To enhance the tightness of shield articulation, seals and cameras have been incorporated, along with an

Figure 12. Emergency Vehicle Platform in ATEX configuration (on CREG courtesy)

ATEX control system and ATEX grease pumps. A redundant injection procedure is in place to seal the articulation. In the event that local sensors of the methane monitoring system or grease flow monitoring indicate a malfunction in the shield articulation sealing, an emergency gasket can be deployed (refer to Figure 13).

The sealing system for tail brushes is equipped with three cameras and an ATEX tail grease system. Additionally, it features ATEX pressure monitoring, an ATEX grease distribution system, valves, and ATEX pumps.

Figure 13. Articulation sealing system (on CRCHI courtesy).

The entire grease pumping system automatically activates for a predetermined duration in alarm conditions to ensure the sealing of the tail brushes system.

2.2.5.2 Volume 4 extension

The ATEX volume 4 extension is defined to ensure that a potentially explosive atmosphere introduced into volume 4 reaches volume 5 only when hot surfaces are cooler than 300°C (Bandini et al, 2013). Similar monitoring on dumpers or excavators has indicated that the maximum cooling time is approximately 11 minutes. Including these times, along with alarm activation and the shutdown procedure performed by the operator, results in a total

cooling time of about 14 minutes. Considering a tunnel flow rate of 0.6 m/s, the safety cooling system can be calculated over 500m. The cooling time for electrical equipment may be shorter than that for engine hot surfaces; however, after shutdown, they require several minutes to cool. This procedure can operate efficiently only if an effective monitoring system is installed, and cooling tests are conducted on all equipment operating in Volume 5.

2.2.5.3 Specialized people and procedures

All the implemented solutions cannot overlook the presence of trained personnel and expertise, and the meticulous adherence to detailed and specific procedures for all excavation and maintenance phases. A constant presence of a technician responsible for on-board monitoring and verification of the adopted solutions for compartmentalization and ventilation is anticipated.

The team is led by a manager who examines and analyzes issues, identifying technical and procedural solutions. Personnel working in the tunnel receive training from the responsible technician at the beginning of excavation and during continuous site inspections. Each operator, according to their role, undergoes dedicated training covering general risks, the management of alarm conditions, and specific working methods for their tasks.

Risk minimization is achieved through the adoption of technical and technological solutions, but it cannot disregard the method of advancement. Experiments conducted have confirmed the ability to contain impulsive emissions that trigger alarm conditions through careful management of advancement methods and material conditioning.

3 CONCLUSIONS

The innovative approach to the TBM design and the further implementation of the ATEX setup concept, as described in preceding chapters, were necessitated by the need to establish a comprehensive and systematic approach to the challenge. This need arose due to the considerable number of machines involved and the length of the tunnel to be constructed. The overarching objective was to enable the construction of the involved tunnels in a reasonable and systematic manner, specifically addressing the following aspects:

- Ensuring continuity of excavation, which would otherwise not be feasible.
- Enhancing TBM efficiency.
- Elevating the safety standards for the workforce.

Operational implications and all implementations were executed drawing on experiences from past construction projects, and more critically, through the engagement of sector experts and the close, robust collaboration with TBM suppliers.

The achieved results have facilitated and continue to support a systematic approach to design, offering the potential for replication across a broad spectrum of cases that encompass different machine groups.

ACKNOWLEDGMENTS

The authors extend their sincere appreciation to Collins consultants and TBM manufacturers CREG and CRCHI for their unwavering support throughout the development of solutions and for facilitating the practical realization of the studied concepts.

Successful steering control with partial soil excavation for station crossing of a 13.08 m diameter EPB TBM in Lodz, Poland

Marcin Tomaszewski* & Soren Nortoft
PBDiM, Mińsk Mazowiecki, Poland

Fabrizio Bove & Marco D'Ambrosio
Seli Overseas, Rome, Italy

ABSTRACT: The Lodz Railway Node project in Poland, includes the excavation of an approximately 2.7 km tunnel in a densely urbanised area with an earth pressure balance (EPB) tunnel boring machine (TBM) of 13.08 m in diameter. To optimize the project schedule, the TBM crossing through Polesie station has been carried out with only a partially excavated face. Considering the geometrical station constraints, such as the slabs already in place, and the lack of face pressure, controlling the steering of the machine within the small tolerances allowed by the alignment required the application of special measures. The task has been particularly challenging due to the features of the large diameter TBM employed, not provided of any active articulation, the alternance of layers of very different soil and the low area accessibility. The paper highlights the difficulties encountered and the solutions adopted, providing a valuable numerical reference of the actual TBM parameters through the back-analysis of the data recorded during the advance. Additionally, the correctness of the theory and assumptions, that had been previously developed before the execution of this challenging task, is demonstrated.

Keywords: station crossing, partial soil excavation, TBM guidance, alignment

1 INTRODUCTION

The tunnel boring machine (TBM) tunnel from Odolanowska chamber to Fabryczna Lodz railway station is a section of the Lodz Railway Node (TEN-T) Stage II – Section Lodz Fabryczna – Lodz Kaliska/Lodz Zabieniec which, when completed, will constitute a new modern junction between the terminal station of Fabryczna and the existing railway line between Kaliska and Zabieniec (see Figure 1).

Figure 1. General layout of Lodz Railway Node.

*Corresponding author: m.tomaszewski@pbdim-obt.pl

DOI: 10.1201/9781003495505-290

The tunnel, excavated with a 13.08 m diameter earth pressure balance (EPB) TBM, is 2660 m long with an overburden ranging between 14 and 18 m.

To date, approximately 40% of the complete length of the TBM tunnel has been bored, including the 885 m stretch of the tunnel from Odolanowska up to Polesie station, the 165 m of Polesie station crossing with partial soil excavation, and further 100 m underneath the ancient historical buildings of the city of Lodz.

For the excavation, a refurbished EPB TBM manufactured by Herrenknecht was employed, with the features relevant for the station crossing summarized below:

- Boring diameter 13.08 m
- No active or passive articulation
- No applicable tilting for steering of the cutterhead

The tunnel lining is designed with 500 mm thick precast segments wide and 1.6 m long, with an 8+0 configuration (i.e., without a small key segment) and a 11.7 m internal diameter.

Moreover, a summary of the main events of the whole drive to date are shortly presented hereby:

- The first 100 m of the TBM has been carried out with an umbilical configuration, with the backup gantries preassembled at the top of the launching shaft and extracting the muck by a temporary de-mucking system.
- The TBM experienced severe steering difficulties in the first meters of the alignment, following a narrow horizontal curve radius of 600 m. Thus, they have been solved by the rearrangement of thrust cylinder groups and a full ripper configuration instead of disk cutters, to adapt tool configuration to actual soil conditions, where at the beginning it has been faced a majority of clay face that later became mostly sand.
- Due to the shallow overburden (slightly more than one diameter), the variable soil characteristics, and the urbanized area above, tighter control on the settlements has been carried out.
- A massive activity of consolidation (as well as evacuation, demolition, and reconstruction of already damaged buildings where possible and needed) is currently still ongoing in the old city in the proximities of the tunnel.

Further details related to the above have been already shown by Bove et al. (2022).

2 BEFORE THE STATION CROSSING

At the beginning of 2022 the partial execution of the first station Polesie (see Figures 2 and 3) required consideration of an alternative crossing with a partially excavated section, as TBM excavation was on the critical path of the overall project. Hence, a new study for the station crossing has been conducted to advance through the station safely and avoid jeopardizing the project's construction schedule.

Figure 2. Plain view of Polesie station and TBM alignment.

This led to the conclusion that a theoretical “static condition” for TBM excavation should be applied, with a minimum theoretical thrust force of roughly 15 MN, to be carried out according to the following actions:

- Excavating along an 8 m high partial face (5 m missing on the top), similarly to a single shield TBM advancing in open mode through soft material with a small cavity on top of the section.

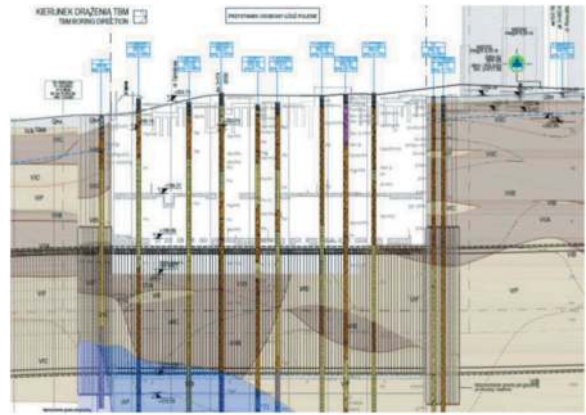

Figure 3. Polesie station longitudinal profile: silty clay and clayed sand.

- Reducing the cutter-head revolution speed (to about 1 rpm) as well as penetration rate during the advance, to achieve a continuous advance in a quasi-static process and equilibrium.
- Limiting the pressures on thrust cylinders during ring assembly.
- Installing the full ring to allow the steering of the TBM in all directions.
- Reducing the TBM cutterhead boring diameter, by removal of gauge rippers and disc cutters, to limit the undercutting below the shield and the tendency of the machine to dive.
- Tight control of the TBM alignment and adherence to the threshold limits for stopping the advance, according to the previously set limitations on excavation, due to the small gap between the TBM and the already existing slab (see Figures 4 and 5).

Eventually, previous successful station crossings already recorded (Concilia et al., 2021, Goodboy et al., 2021, Maccan et al., 2011) speeded up the process of decision-making toward this challenge.

Figure 4. Polesie station crossing: the TBM advances with limited gap on the top.

Figure 5. Polesie station crossing: general overview of the TBM, in situ soil and concrete walls.

3 THE “CROSSING CONCEPT”

According to what has been practically carried out, a model for station crossing is presented in Figure 6.

Conversely to typical EPB mode, where there is a clear cylindrical symmetry among tunnel, TBM and ring alignment, during the excavation in the station this obvious concept has been twisted, thus creating a misalignment between the tunnel axis and TBM axis, that is now positioned approximately 15 mm lower. In such a case it is almost clear that the advance is more similar to a hard rock TBM, asymmetric with respect to the tunnel alignment and with the shields lowered toward the bottom of the excavation, whose reaction is totally borne and balanced by the natural soil underneath.

4 DATA ANALYSIS

The station crossing, for a total length of 165 m, has been carried out in 52 days between October 13th (break-in into the station) and December 6th, 2022 (completion of Polesie station crossing), i.e. 3,2 m/day of advance on average, including all the following stops:

- Removal of unsafe concrete blocks and mud (mixture of soil, reactivated crushed cement, foams and water) after the break-in.
- Adjustment of the checks in situ, i.e. identification of the actual TBM position and relative maneuvering spaces between level -2 and level -3 with forecast of any possible interference with structural elements, like steel anchors already present inside the Polesie Station: just 27 cm of gap has been detected as minimum tolerance value!
- Ad hoc reconfiguration of the cutting tools configuration for the station crossing.
- One high voltage cable extension.
- Maintenance and reconfiguration of the cutterhead for the break-out.
- Mechanical overhaul, including the replacement of any damaged tail brush.

The peak of advance during the station crossing was reached on November 29th with 11 meters excavated within 24 hours.

Starting with an analysis of the main relevant parameters during the station crossing, it can be observed as follows:

- The average height of ground not removed by TBM is approximately 4,3 m with a muck

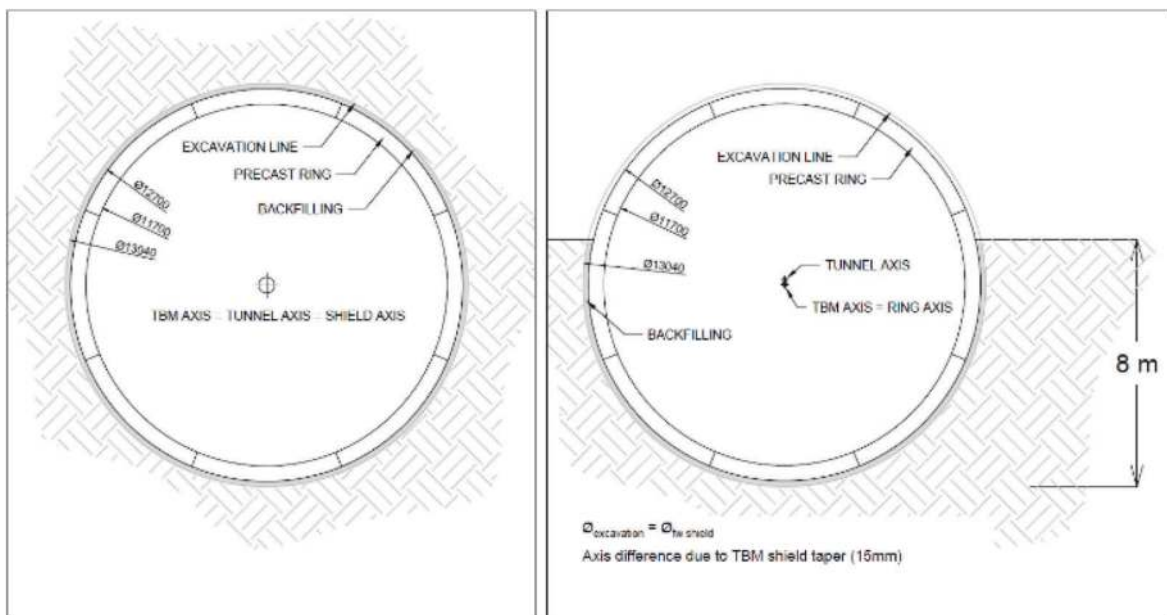

Figure 6. EPB mode (left) vs. station crossing mode (right).

Figure 7. Horizontal deviation along the Polesie station.

extracted of 219 tons per ring, approximately the 61% of the full excavation

- The deviations can be summarized hereby:
 - Horizontal deviation: 0.41 mm on average with peak value of 12 mm (see also Figure 7)
 - Vertical deviation: 0,5 mm on average with peak value of 20 mm

Thus, the maximum value of deviation with respect to the diameter of excavation is no more than 0,11%, that is totally neglectable, confirming the successful expectations.

Further to the above, the following average parameters are significant:

- penetration rate: 20 mm/min
- RPM: 0,8
- Cutterhead Torque: 10 MN
- Thrust force: 26.000 kN

Focusing on the thrust, the distribution of the forces among the thrust cylinders' groups (see Figure 8) is significant, with approximately 51% of the total thrust applied on the bottom (Group D), since the TBM has the natural tendency to dig, moreover considering that the soil changed to "softer" during the ongoing advance. Going into deeper details, the thrust applied in the lower part (Groups C, D and E) sums up to 79% of the total thrust (see Table 1), with an asymmetric variation between Group C and F, most likely due to the direction of the TBM rotation.

Figure 8. Arrangement of the thrust cylinders' groups.

Table 1. Average distribution of the thrust force.

Position	Thrust cylinders' groups	Total thrust (kN)	Total thrust (%)
Top	Group A	5.633	21,10
	Group B	1.268,57	4,75
	Group F	2.396,14	8,98
Bottom	Group C	21.066	78,90
	Group D	2.819,26	10,56
	Group E	13.620,76	51,02
	Group E	4.625,82	17,32

Additionally, a proper partial backfilling has been carried out with grout injection of bicomponent of around 7,6 m³ per ring, roughly 60% of the value injected during standard EPB operation.

Eventually, the total thrust force used has been higher than the one expected by theory, thus meaning that most likely the friction between shields and natural soil, as well as the reaction of the back-up, had been underestimated.

5 ADJUSTMENTS DURING THE STATION CROSSING

In this paragraph, it is also important to mention some practical adjustments that have been carried out during the advance like:

- Segments that have been connected each other through temporary steel supports instead of designed connectors, pins and bolts: this in order to simplify the future dismantling of the rings into the station (see Figure 9).
- A window created on the top of the segments to smooth the access.
- Instead of using sealing rings at break-in and break-out into the station, it was preferred to lower the piezometric level by the use of drainage shafts all around the station, thus pumping out the water.

Figure 9. Temporary supports for rings to simplify their future removal.

6 MONITORING

A sound net for monitoring (see Figure 10) with tachymeter prisms and inclinometers has been used in order to assess and promptly act in case of any problem. In any case the maximum settlement value recorded was less than 5 mm, i.e. neglectable.

Moreover, particular care has been carried out regarding the risk due to the narrow gap between the slab already in place and the TBM, by a continuous control during the advance. To ensure that no damage will occur to the permanent structures of the

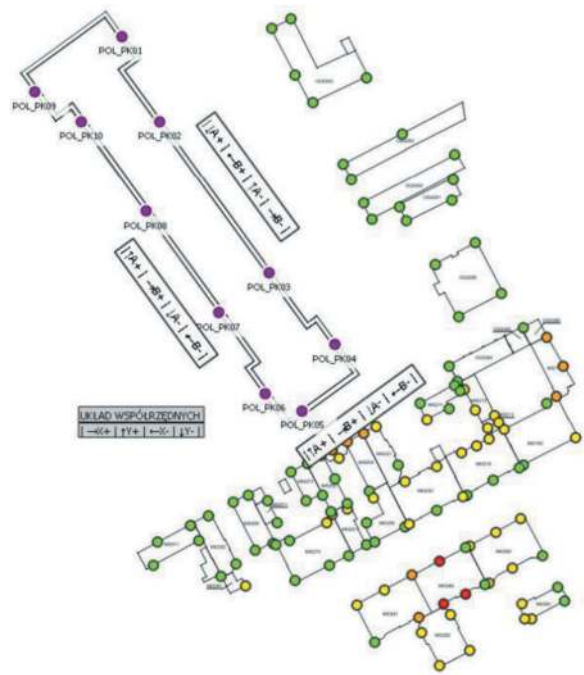

Figure 10. Monitoring points positions of Polesie station (level 0).

stations, the following trigger values have been established (Bove et al., 2022):

- Bottom: right and left: max misalignment allowed 200 mm.
- Top: max misalignment allowed 100 mm (reduced due to the proximity of the slab).

It is worth pointing out that during the full run into the station, the maximum deviation values were no more than 10% of the aforementioned threshold values, as shown in Figure 11, where the higher values have been automatically read by tachymeters.

Figure 11. Polesie station (level -2): tachymeter prism values.

7 CONCLUSIONS

The safe passage through Polesie station presented unique challenges, that was possible to overcome by adjusting thrust force, excavation method, and cutterhead configuration while adhering to strict alignment controls and settlement limitations. Data

analysis reveals that the TBM, maintained impressive performances during the station crossing, including neglectable deviations, high penetration rates, and effective force distribution. In summary, the way of execution of the TBM tunnel, especially the complex station crossing, through the diligent monitoring and strategic adjustments to the excavation process, have collectively contributed to the overall success of the project. As the Lodz Railway Node Stage II progresses, the experiences and insights gained from this experience can guide future projects of similar magnitude and complexity.

ACKNOWLEDGMENTS

Special thanks to PKP Polish Railway Lines for their cooperation in the implementation of this demanding project, which is a pilot project in TBM technology in railway Poland market. This project paves the way for series of future challenging projects planned by PKP PLK, for implementation in the upcoming close future.

Furthermore, an additional acknowledgement to Mr. Mariusz Serzysko, PBDiM Director, for the overall experience and support provided.

ABSTRACT: Cross passages between twine bored tunnels are typically provided at regular interval to allow people to evacuate from one tunnel to the other in the event of an emergency. Constructing these cross passages is considered as a high-risk construction activity particularly in soil and water bearing ground. Traditionally, ground treatments (such as jet grouting and ground freezing) are conducted before opening of the main tunnel lining for cross passage construction. Mechanised method by mini-TBM and pipe jacking machine is developed and have been used in several projects around the world. CREG's Cross Passage (CP) Machine is specifically designed and manufactured for cross passage construction between two mainline TBM tunnels. The CP Machines have been successfully adopted in several projects in China and valuable knowledge are consolidated. This paper will discuss the key considerations during the planning stage, design of special tunnel segments and cross passage opening, temporary works design to facilitate launching and retrieval of CP Machine, permanent CP lining and impact assessment to the main tunnel segmental lining. In addition, detailed construction methodology and experienced gained in several projects will be summarised.

Keywords: Tunnel Boring Machine (TBM), Cross Passage (CP), Cross Passage Machine

1 INTRODUCTION

Cross passages between twine bored tunnels are typically provided at regular interval to allow people to evacuate from one tunnel to the other in the event of an emergency. Constructing these cross passages is considered as a high-risk construction activity particularly in soil and water bearing ground. Traditionally, ground treatments (such as jet grouting and ground freezing) are conducted before opening of the main tunnel lining for cross passage construction. The quality of ground treatment highly depends on the ground conditions and skill of specialist ground treatment contractor. Even though ground treatment is provided however in some cases, ground collapses are reported during the CP construction. In addition, the construction of CP by traditional method need several months to complete and it will significantly affect the programme of the project. Mechanised method by mini-TBM and pipe jacking machine is developed and have been used in several projects around the world. CREG's Cross Passage (CP) Machine is specifically designed and manufactured for cross

passage construction between two mainline TBM tunnels. The construction of CP by mechanised method takes a few weeks to complete both excavation and permanent lining installation. It also eliminates safety and health concerns associated with manual excavation for workers under exposed ground. The CP Machines have been successfully adopted in several projects in China and overseas.

This paper will discuss the key considerations during the planning stage, design considerations of special tunnel segments and cross passage opening, temporary works design to facilitate launching and retrieval of CP Machine, permanent CP lining and impact assessment to the main tunnel segmental lining. In addition, detailed construction methodology and experienced gained in several projects will be summarised.

2 TRADITIONAL CP CONSTRUCTION

The construction of CP, especially in soft ground, between the twin bored TBM tunnel is one of the most high-risk construction activities for

*Corresponding author: ck.tsang@smec.com

tunnelling projects. The CP is generally constructed using traditional mining techniques to create a link between two tunnels as shown in Figure 1. Depending on the ground conditions and site constraints, different ground treatment methods such as TAM grout, jet grout or ground freezing can be implemented. The overall sequence of works is described below:

- Carry out ground treatment works for the ground surrounding the CP
- Opening of main tunnel segmental lining
- Excavation of CP by mined method, generally not more than 2m advance.
- Shotcrete the excavated roof and walls and provide temporary support as necessary
- Continue excavation, shotcrete and temporary support, stage by stage, until reaching the receiving end
- Apply smoothing shotcrete before the installation of waterproofing membrane
- Spray permanent shotcrete or cast in-situ concrete to form the CP permanent structure
- Construction of collar structure between the CP and main tunnel

Figure 1. Typical construction of cross passage.

There are mainly two types of risk for traditional CP construction which need to be considered during the design. The first one is the stability of tunnel segment opening and CP excavation. The second one is the CP induced settlement and its impact on surrounding assets. Some of key risks are summarised below:

- Geotechnical design parameters not reflecting the condition observed on site, or unforeseen ground conditions encountered.
- Instability of segmental lining during opening (before CP excavation)
- Damage to existing tunnel structure near the opening
- Instability of segmental lining at the receiving tunnel (near completion of the CP excavation)
- Unforeseen ground conditions causing unsuccessful ground treatment
- Higher than expected water ingress leading to excessive ground loss.
- Excessive ground movement affecting nearby existing building, structures and utilities.

In addition to the high risk associated with CP excavation, the construction programme usually takes several months to complete. The health and safety issue are also a concern for CP construction. Therefore, mechanised method by mini-TBM and pipe jacking machine are developed to minimise the risks and to improve the production rate compare to the traditional method.

3 PLANNING FOR MECHANISED CP EXCAVATION

The key concerns for using mechanised CP excavation is the available working space inside the mainline TBM tunnels. The launching and receiving devices, TBM and backup equipment, precast segments/pipes, TBM launching frame, grouting pipelines, slurry pipelines, water supply and power supply need to be fit within limited space. The diameter of CP machine needs to satisfy the functional requirements for the CP. Detailed space proofing of the CP need to be carried out for approval by the Authorities. Since the construction of the CP by mechanised method will fully occupied the mainline tunnel and will obstruct any construction activity inside the tunnel. Careful construction planning needs to be carried out to minimise the impact of the overall construction programme of the project.

4 DESIGN CONSIDERATIONS

The use of the mechanised method for CP construction highly depends on the equipment developed by the machine manufacturer. The designer of the mainline TBM tunnel segmental lining and cross passage lining need to have very good understanding on the construction methodology and sequence of works developed by the machine and equipment manufacturer. Based on the experience of using CREG's CP machines for metro projects in China, the typical arrangement of the machine and the special tunnel segments are shown in Figure 2 and Figure 3 respectively.

Figure 2. Typical arrangement of CREG CP machine.

Figure 3. Typical arrangement tunnel and CP segments.

The following special design and assessment need to be carried out:

- Permanent Steel Segmental Lining for CP opening
- Temporary glass fibre reinforced concrete segments at CP opening
- CP permanent linings
- Temporary structures
- Launching frame and receiving frame
- Launching sleeve and receiving sleeve
- Waterproofing details
- Carrier & work platform
- Impact assessment of the permanent lining structural capability and deformation
- Ground movement induced by cross passage construction

5 MECHANISED METHODS FOR CP CONSTRUCTION

The mechanised method for CP construction can be classified into TBM method and pipe jacking method. These methods will be described in the following sections.

5.1 TBM method

TBM method is a fully mechanized construction method to cooperate excavation, mucking out and segment erection in sequential process.

5.1.1 Case study

The first TBM method for CP excavation was adopted in Ningbo Rail Transmit Line 3 in 2017. The project locates between the Southern Business District Station and Yinzhou Government Station with a total section length of about 733.7m. There are a lot of sensitive buildings and structures along the tunnel alignment. The CP is under the greenery of a park at the intersection of Yinzhou avenue and Tiantong south road, with an overburden of 17.8m. The distance between the centers of the two main metro tunnels is 17.4m and the geology is mainly muddy clay and silty clay. The two main metro tunnels are lined with 5500mm I.D. segmental lining, and the cross passage is also lined with circular segmental lining. The segmental lining of CP is designed with 3150mm

OD, 2650mm I.D with segment thickness and width of 250mm and 550mm respectively. The general arrangement of the CP is shown in Figure 4.

Figure 4. CP general arrangement.

5.1.2 Machine configuration and key features

The TBM method for CP construction consists of main machine (including cutter head, shield structure, main drive, screw conveyor, segment erector, thrust system, etc.), back-up system, launch and receiving devices, and other auxiliary construction systems. The arrangement of the machine is shown in Figure 5. The TBM key parameters are shown in Table 1.

Figure 5. Cross passage TBM configuration.

Table 1. Cross passage TBM key parameters.

Item	Description	Parameters	unit
1	Excavation diameter	Φ3290	mm
2	Cutter head rotation speed	0-3.8	r/min
3	Maximum thrust	10500	kN
4	Drive power	200	kW
5	Maximum torque	862	kNm

Different from the conventional TBM design, the cross passage TBM will be launched and received in the concave and convex shape of main tunnel segments respectively. Therefore, the cutter head of cross passage TBM is designed with big and small arc structures (see Figure 6). This is to allow the diameter of the big convex arc structure of cutter head to fit to the inner diameter of main tunnel segment so that the force on the cutter head is evenly distributed across the opening. This can also enhance

a better tilt control of the machine during the launching operation. The diameter of the small concave arc structure of center cutter is similar to the outer diameter of main tunnel segment so as to allow a better tilt control of machine during receiving.

Figure 6. Design of tapered cutter head and center cutter.

To deal with the main tunnel segment deformation caused by the thrust of cross passage TBM during launching, advancing and receiving. Stabilizing support devices are designed in the main tunnels as shown in Figure 7. The stabilizing support device consists of the outer gripper system, inner trolley system, hydraulic system and electrical control system. During construction, the jacking force on the main tunnel segments can be adjusted to prevent over stressing the main tunnel segment.

Figure 7. Stabilizing support and seal devices at launch and receiving.

To deal with possible water inflow at the CP opening during launching and receiving of TBM, the use of steel sleeve for launching and receiving is developed. Traditionally ground treatment is required to prevent groundwater inflow however under this construction method, minimal ground treatment and even without ground treatment is needed. This can significantly reduce the construction risks, cost and programme.

5.1.3 Construction sequence and key technical issues

Construction sequence

The construction sequence includes preparation, launching, excavation, receiving and T-joint treatment.

During preparation, the main tunnel is clear for installation of rails for cross passage TBM and rolling stocks. The assemble the cross passage TBM will be

carried out in the surface and it is transported to the CP location. The TBM can then be connected to the launch sleeve and the launching portal set up in the main tunnel. The launching sleeve will be filled up with slurry and pressurised for TBM to start boring. After cutting the segmental lining, the TBM will continue boring, mucking out, installation of CP segmental lining and back grouting will be carried out progressively. At the same time, the receiving device is set up in the opposite side of CP. The receiving sleeve is filled up with slurry and pressurised to receive the TBM. After the whole main machine of cross passage TBM enters the receiving sleeve, the TBM will be disconnected for water and electricity connection. Removal of the receiving device together with the main machine out of the main tunnel. Finally, T-joint treatment will be carried out between the finished cross passage and the main tunnel.

Key technical issues

(1) Special tunnel segments for the CP opening

The CP opening at the main tunnel is lined with special segments. As shown in Figure 8, the special segments include steel segments surround the CP opening, fibre reinforced concrete segments at the CP opening and steel ring at the junction to enable even distribution of load after the CP opening is cut. This can also facilitate the connection of launch and receiving sleeves.

Figure 8. Cross passage portal.

(2) Segment erection

The segments of cross passage adopt stagger-jointed erection with circumferential joints and longitudinal joints connected with M24 curved bolts. A segment ring consists of 5 segments as shown in Figure 9 and a photo showing the completed CP is shown in Figure 10. The details of CP segment are shown in Table 2.

Figure 9. Cross passage segments.

Table 2. Details of cross passage segments.

Details	Dimensions	Description	Remarks
I.D.	2650mm	Erection method	Staggered
O.D.	3150mm	Joint connection	M24 curved bolt
Thickness	250mm	Segment type	Five segments (one 64°key segment + two 68°adjacent segments + two 80°standard segments)
Width	550mm	Erection method	Staggered

In order to facilitate the installation of CP segments in the congested space, the segment erector adopts the main beam with rotary erector installed in the center of machine to allow longer axial movement stroke to pick up segments. A simple trolley runs on the steel rail at the bottom of cross passage to transfer segments of cross passage from the back-up gantry to the area below segment erector.

Figure 10. CP after segment erecting.

(3) Treatment at the CP opening

Steel segment rings are used at the CP opening in both the launching and receiving ends. This is used to facilitate the construction of CP opening structure that normally constructed by cast in-situ reinforced concrete. The completed CP opening structure and is connected to the steel segment is shown in Figure 11.

Figure 11. CP opening structure.

5.2 Pipe jacking machine

The pipe jacking machine for CP construction is very similar to the TBM method. For the two methods, the machines can usually adopt similar designs in the excavation and drive systems, and thus their systems are convertible. The major difference is the installation method of lining. For the TBM method, segments will not move forward along with the TBM, which are erected by segment erector and then follow with back grouting. For pipe jacking method, pipes are pushed forward along with the main machine until the completion of cross passage. Back grouting will be carried out

Table 3. Summary of projects using pipe jacking machines for cross passage construction.

Project	Characteristic	Machine type
Cross passage of Mexico's Emisor Oriente Tunnel	Geology: sand and clay; Pipe I.D.: 1800mm.	Slurry pipe jacking machine
Cross passage of Hong Kong Tuen Mun - Chek Lap Kok Link	Geology: granite and alluvium; Pipe I.D.: 3000mm; CP length: about 13m.	Slurry pipe jacking machine
Cross passage of East Gaolang Road Station - Zhoujingxiang Station section of Wuxi Metro Line 3 Phase 1	Geology: clay	EPB pipe jacking machine

after completion of excavation and installation of pipes. Table 3 shows a summary of the projects with cross passages excavated by pipe jacking machines in China and overseas.

5.2.1 Case study

The project is located at East Gaolang Road Station - Zhoujingxiang Station section of Wuxi Metro Line 3 Phase 1 Project. The overburden of tunnel is about 17.5m and the TBM tunnel has O.D. and I.D. of 6200mm and 5500mm respectively. The tunnel lining thickness of 500mm and segment length of 1500mm. The distance between the center of two main tunnels is 14m with overburden of 19.2m. The geology at the CP location is mainly in clay. The O.D. and I.D. of CP is 3260mm and inner diameter of 2760mm respectively. The length and thickness of pipe is 900mm and 250mm respectively. There are totally 10 numbers of pipes installed to complete the CP.

5.2.2 Machine configuration and design features

The earth pressure balance (EPB) pipe jacking machine for the CP of Wuxi Metro Line 3 is composed of main machine (including cutter head, shield structure, main drive, screw conveyor and steering system, as shown in Figure 12), jacking system, back-up system, launch and receiving devices and support system. The technical details of the CP pipe jacking machine are shown in Table 4.

Figure 12. Main features of EPB pipe jacking machine.

Table 4. Technical details of the CP pipe jacking machine.

Item	Parameter	Unit
Excavation diameter	3290	mm
Cutter head rotation speed	0-1.8	r/min
Maximum thrust	12000	kN
Drive power	180	kW
Maximum torque	1100	kNm

Compared with the TBM method, the pipe jacking method has the advantages of simple construction process, low costs and high applicability in a narrow space. But it also has the disadvantages that it is only adapted to short and straight CP alignment.

5.2.3 Construction sequence and key technical issues

Construction sequence

The pipe jacking method shares the similar construction process with the TBM method, which also includes preparation, launch, excavation, receiving and T-joint treatment. The major difference is the excavation and pipe installation process. Figure 13 shows the launching of CP pipe jacking machine for Wuxi Metro Line 3 project.

Figure 13. Launching of the pipe jacking machine in the cross passage of Wuxi Metro Line 3.

Key technical issues

The CP is constructed by an EPB pipe jacking machine. Similar to the TBM method described in Section 2, special segments in the main tunnel are required at the CP openings.

Due to the limited working space within the main tunnel, the pipe is divided into upper pipe and lower pipe with angular degree of 150° for the smaller pipe. The general arrangement of the pipe is shown in Figure 14. This arrangement is different from conventional construction by pipe jacking machine.

Figure 14. The upper and lower rings arrangement of pipe.

The pipe is erected in a staggered arrangement and its technical details are shown in Table 5. Generally, when using a pipe jacking machine to bore a cross passage with single pipe, the power cable of main machine will be disconnected during pipe installation process. For the upper and lower rings arrangement, the power cable is kept connected during the pipe installation process.

The pipe jacking machine equipped with a single beam structure with double hoists that allow the two

Table 5. Technical Details.

Item	Parameter	Description
Pipe diameter	O.D. 3260mm and I.D. 2760mm	Precast reinforced concrete
Pipe thickness	250mm	Joint connection with 10 M24 longitudinal bolts
Pipe length	900mm	Joint connection with 4 M24 circumferential bolts

hoists move independently or simultaneously. This allow easy adjustment of the lifting point and orientation of the pipe. The whole erection procedures are as follows:

- lift the lower pipe by changing the height of lifting hooks and position of lifting points.
- move the power cables to the inside of the pipe.
- lift the upper pipe and connect to the lower pipe by controlling the gap between the pipes

Figure 15 And Figure 16 show the installation of the lower and upper pipes respectively.

Figure 15. Installation of lower pipe.

Figure 16. Installation of upper pipe.

6 CONCLUSIONS

6.1 *Pros and cons of mechanical excavation method*

In general, the mechanised CP construction has a high degree of automation such that excavation and lining installation can be carried out concurrently. In addition, the machine can be reused for all CP construction if the dimension of CP is the same. It will significantly reduce the costs and shorten construction

period. It also provides a better health and safety control over traditional mined excavation and cast in-situ lining construction. The risks associated with ground settlement and water inflow are significant reduced by the mechanised CP construction with special segment installed in the main tunnel.

On the other hand, the mechanical equipment also has some disadvantages over traditional mined method. This is less flexible for different dimensions of CP. More sets of CP machines need to be manufactured for different dimensions of CP and consequence the cost will be increased. Due to limited working space within the main tunnel, the logistic for installation of the CP machine is quite challenge that need a proper planning. Since special segments in the main tunnel need to be designed and installed at the CP locations, the design of steel segments, fibre reinforced segment and steel ring need special design and assessment based on the equipment features and construction sequence. The T-joint treatment between the main tunnel steel segment and cross passage lining need special connections against water leakage.

6.2 *Future development*

The mechanical equipment for cross passage construction has been adopted for several projects in the world. Different projects have different requirements and the developed CP machines have different unique features. New equipment leading to new construction methods has become a new approach for the innovative development of underground space. This paper provides some insights potential new developments of the mechanical equipment for cross passage construction.

(1) Intelligent TBM construction

Intelligent TBM technology is a development that deeply integrates the new generation of information technology and intelligent data analyses. Based on current TBM technology development, the modern TBM has the functions of self-prediction, self-judgment, self-learning, self-decision-making and self-control system. These form an important part of future industrialized development for TBM tunnel construction. It will provide a safer and energy saving construction with less man-power input.

Since cross passages are generally short in length, the excavation machine after launching and will be ready for retrieval. The control of CP machine alignment is therefore challenging. Moreover, the main machine needs to break through the special segment and the pre-installed steel ring at the receiving end, which requires high construction accuracy. The application of intelligent TBM technology in cross passage construction can overcome these difficulties. In addition, the main tunnels construction are completed with better understanding of the geological conditions at the CP locations. This provides important geological information for CP machine to develop automatic operation

parameters for precise construction control and to reduce construction risks.

(2) Application under extreme conditions

Subsea tunnel is developing rapidly in China and oversea. The construction of proposed sub-sea tunnels such as Qiongzhou Strait Tunnel and Bohai Strait Tunnel will face significant technical challenges such as safety of tunnel drives for super long distance and super high water pressure. Under such circumstances, the application of slurry TBM/pipe jacking machine for cross passage construction can reduce the risks water inflow by use of sealing of shield structure, main drive, launch sleeve and receiving sleeve.

(3) Application in more construction fields

In addition to common cross passages of metro tunnels, the mechanical equipment can also be widely used for the construction of underground fire exits and escape routes, cross passages between underground shopping malls, cross passages between utility tunnels and sewage tunnels., short underground passages with small cross-sections mainly for personnel passing, and underground structures with limited launch and receiving sites.

A study on intelligent assembly technology for Mid-partitions in shield tunnels and application

Hua Wang

China Railway Tunnel Group Co., Ltd., Guangzhou, Guangdong, China

China Railway Tunnel Consultants Co., Ltd., Guangzhou, Guangdong, China

Guangdong Provincial Key Laboratory of Intelligent Monitoring and Maintenance of Tunnel Structure, Guangzhou, Guangdong, China

ABSTRACT: In order to solve great construction interference, complex construction procedures, backward construction techniques and difficulty to guarantee construction quality in the integral or partial cast-in-situ construction of mid-partitions inside the shield tunnels, key intelligent assembly technologies such as multi-sensor information fusion vision camera recognition and positioning, dual 6-axis mechanical arm and active visual posture control, heavy-duty servo displacement feedback control, etc. were developed by adopting the construction concept of intelligent equipment design and prefabricated assembly and manufacturing one-button intelligent assembly robots based on Lot JCXSG-11 of the Shanghai Airport Connecting Line, ensuring the assembly posture and control accuracy of mid-partitions, and realizing the intelligent assembly of prefabricated mid-partitions. The results show that: 1) The control and synchronization accuracy of the mid-partition assembly robot system reaches 0.5mm, and the assembly accuracy of mid-partitions reaches ± 2 mm, resulting in high-precision assembly; 2) With the aid of intelligent control technology, one-button operation is realized for mid-partition assembly. Each cycle takes 38min and the efficiency is more than 10 times higher than that of the traditional cast-in-situ construction, bringing about intelligent, efficient and green assembly of mid-partitions.

Keywords: shield tunnel, mid-partition, intelligent prefabricated assembly, high precision, synchronous construction, gantry-type, assembly robot

1 INTRODUCTION

With the rapid development of traffic construction in China in recent years, shield tunneling has become an important method for tunnel and underground engineering construction due to its advantages such as high efficiency, fast speed, safety and reliability. The internal structure of a shield tunnel is usually constructed by the cast-in-situ and prefabrication methods. According to the construction organization mode, the internal structure can be constructed synchronously with shield tunneling or after shield cut-through. In general, mid-partitions of the internal structures of the tunnels are of a semi-prefabricated and semi-cast-in-situ structure, with cast-in-situ bases and partial walls prefabricated, and will be constructed after shield advancement. The mouth-shaped prefabricated components are installed synchronously with shield advancement, and the arched bottom plates and rail bearing plates are cast-in-situ structures and will be constructed synchronously after shield advancement for a certain distance.

At present, some progress has been made in the research of prefabrication and assembly technology for mid-partitions in the internal structures of the shield tunnels. Scholars Zhou Junli[1], Jiang wenxing[2],

Yang Chenglong[3], Wang Zhihua[4], Shen Yongping [5], Wu Kui[6] studied the installation machine for pre-cast middle partition wall in the practical shield tunnel construction projects in China and explored systematically the key technology of assembling and synchronous construction, etc., and a series of research results has been achieved.

It can be seen from the above studies that the following problems are involved in the prefabrication and assembly of mid-partitions of internal structures of tunnels in China: 1) Prefabrication has not been completely realized, and many components are still cast in situ; 2) Synchronous progressing of mid-partition construction and shield tunneling has not been fully realized, resulting in great construction interference; 3) The degree of automation is low, and intelligent assembly has not yet been realized. The assembly equipment is modified with special mechanical arms or designed with special “sucker-type” cranes, and operated manually. The performance, structure and intelligence of the equipment need to be further improved. Therefore, for the construction technology for prefabricated mid-partitions of underground structures in China, a corresponding system or specification has not yet been established, the application scope is relatively single, the assembly

technology is fragmented, and the construction process and technology are not mature enough. In terms of assembly equipment, the special assembly machine for internal components of shield tunnels features low construction efficiency, low intelligence, low assembly accuracy and great construction interference.

In order to solve the problems in the prefabrication and assembly of mid-partitions in shield tunnels, such as great construction interference, complex construction procedures, backward construction techniques and being difficult to guarantee construction quality, it is of great significance to carry out systematic and in-depth research on the assembly technology and equipment of mid-partitions in the internal structures of the tunnels, so as to enhance the intelligent level of construction technology and equipment, thus ensuring that the assembly quality of finished products of prefabricated components is controllable, improving the construction environment and realizing intelligent, efficient and green construction.

2 TECHNICAL BACKGROUND

2.1 Project overview

This paper is based on the tunnel works of Lot JCXSG-11 of Airport Connecting Line of Shanghai Rail Transit Regional Line Project, which is located in Pudong New Area, Shanghai, including 1 transfer shaft and 1 section. The transfer shaft is a shield launching shaft, 209m long, 15.6~30.5m wide and 26.4~28.5m deep, with two underground box frame structures. The total length of the transfer shaft section is 4,721.099m, and the sectional tunnel is of single-tube double-track layout. A slurry shield with a diameter of $\Phi 14.04\text{m}$ is used for construction. The internal structure mainly includes arc members, mid-partitions, top connectors, evacuation platforms and cable trenches. See Figure 1 for the schematic diagram of cross-section design of the internal structure of the tunnel.

Figure 1. Cross-section design of internal structure of tunnel.

2.2 Design scheme of mid-partition

The mid-partition is designed to be 9.116m high, 0.4m thick and 2m wide. It is made of C40 concrete, and the structural outline of the mid-partition with each section weighing 22.65t is shown in Figure 2.

Figure 2. Structural outline of Mid-partition.

As shown in Figure 3, a 30mm thick cushion is provided between the mid-partition and the substructure, with a flatness of not less than 3mm. The gap is filled tightly with fine aggregate mortar and 20 Grade 8.8 M36 bolts are adopted for connection. As shown in Figure 4, Grade 8.8 M30 bolts are used for longitudinal connection of the mid-partition; 33*100mm cross bolt holes are set up for connection of adjacent walls, and the joint surface is assembled in an “L” shape, with required assembly caulking of 20 mm.

Figure 3. Connection between substructure and Mid-partition (Unit: mm).

As shown in Figure 5, the top of the mid-partition and the segment are fixed with brackets, and the steel plate bracket and the segment are fixed with bolts by using bolt holes embedded on the segment. Sealing strips are designed between the mid-partitions to block gaps and prevent air leakage. The top connectors of the mid-partitions are metal brackets, which have the characteristics of lateral restraint of the mid-partitions and vertical relative movement.

Figure 4. Connection between Mid-partitions (Unit: mm).

Figure 5. Connection between Mid-partition and segment.

2.3 Assembly accuracy requirements for mid-partition

For the assembly accuracy of the mid-partitions, the bolt connection and the control of the gap between the mid-partitions shall be taken as the control objectives and the smoothness and aesthetics of the tunnel shall be taken into account. See Table 1 for the installation quality control indicators.

Table 1. Quality control indicators for Mid-partition installation.

S/N	Control item	Control deviation	Control density
1	Elevation angle α	$\pm 0.15^\circ$	Per piece
2	Maximum gap difference at the bottom	$\leq 5\text{mm}$	Per piece
3	Inclination β	$\leq 0.06^\circ$	Per piece
4	Side verticality	$\leq 10\text{mm}$	Per piece
5	Corner γ	$\pm 0.15^\circ$	Per piece
6	Centerline deviation between mid-partition and arc member	$\leq 5\text{mm}$	Per piece
7	Gap between walls	$\leq 7\text{mm}$	Per piece
8	Filling the gap	20-30mm	Per piece

3 GENERAL DESIGN OF INTELLIGENT ASSEMBLY ROBOTS FOR MID-PARTITIONS

3.1 General design concept

The general design of intelligent assembly robots for mid-partitions aims to achieve the basic functions for stable operations of procedures such as grabbing, rotating, walking, fine adjustment and assembling of mid-partitions, and ensure high precision and intelligent control of assembly. In order to ensure the normal passage of construction transport vehicles, the gantry of the erector is provided with a walk-through design with large clearance to meet the requirements for the passage space of construction vehicles; it has the function of fine adjustment for 6 degrees of freedom in various postures to ensure installation accuracy, efficiency and safety. The gantry-type intelligent erector for mid-partitions features posture adjustment with 6 degrees of freedom, with the installation trolley having fine adjustment functions such as longitudinal back and forth movement, transverse back and forth movement, upward and downward expansion, rotation and swing, and it also features automatic walking and positioning; it has intelligent construction functions such as automatic detection and perception, automatic calculation and analysis processing, automatic decision-making and action execution, human-machine interaction and information storage.

The main design concept of the intelligent control systems for mid-partition assembly robots is as follows: project the structured light onto a reference mid-partition and that to be installed in a visual guidance mode with the aid of two 6-DOF mechanical arms of the erector, an integrated laser rangefinder, a limit switch and other detection elements, as well as the active binocular vision camera module to calculate position and posture parameters; complete the closed-loop control of the visual servo through multi-sensor information fusion to provide basis for subsequent fine adjustment of mid-partitions; finally control the hydraulic cylinder and drive motor through software calculation and analysis to complete such 4 procedures as parallel posture adjustment of partitions, mid-partition grabbing and turning, fine posture adjustment and assembly of mid-partitions, and erector return posture adjustment.

3.2 Main structural composition and parameters

3.2.1 Main structure of assembly machine

According to the construction space characteristics and robust structural requirements in the tunnel, the intelligent erector for mid-partitions is designed with a double-span gantry structure, with supporting structures at both ends and an assembly working mechanism in the middle. The intelligent erector for mid-partitions is mainly composed of a gantry system, a rotating system, a traversing system, a walking system, an electronic control system, a hydraulic system and an intelligent control system. See Figure 6 for the conceptual design of the gantry-type intelligent erector for mid-partitions.

Figure 6. Conceptual design of gantry-type intelligent erector for Mid-partitions.

3.2.2 Technical parameters of erector

According to the assembly requirements, the main technical parameters of the gantry-type intelligent erector for mid-partitions are shown in Table 2.

Table 2. Main technical parameters of Gantry-type intelligent erector for Mid-partitions.

Technical parameter	Value
Overall dimensions of the erector (mm)	11576×6350×6185
Total weight of the erector(t)	80
Degree of freedom in installation	6-axis control
Operating pressure of the hydraulic system (MPa)	18
Lifting height of the gantry column (mm)	1600
Lateral traversing distance (mm)	1400
Longitudinal displacement distance (mm)	600
Lateral angle adjustment distance(mm)	±50
Longitudinal angle adjustment distance (mm)	±50
Turning distance of the mid-partition (mm)	800
Laser ranging sensor (mm)	Measurement accuracy: 0.02, 0.5
Photoelectric sensor (mm)	Measuring range: 0-800
Active vision camera (mm)	Measurement accuracy: 0.5
6-DOF mechanical arm (mm)	Repeated positioning accuracy: ±0.02
Walking method	Frequency converter + electric drive
Walking speed(m/min)	6.7
Assembly time of a single mid-partition (min)	38
Operation mode	Gantry-type
Control mode	One-button intelligent control + remote control

4 PROCESS OF INTELLIGENT ASSEMBLY OF MID-PARTITIONS

4.1 Process of intelligent assembly of mid-partitions

In accordance with the multi-sensor information fusion positioning system, an erector coordinate system is established. The coordinate transformation is carried out with the mechanical arm vision positioning system as the core. With the aid of the closed-loop control of the visual servo and the laser ranging redundancy information, real-time positioning of the mid-partitions during installation is realized through strong robust visual feature selection for accurate position and posture adjustment.

The assembly process with intelligent assembly robots for mid-partitions mainly includes 4 procedures: parallel posture adjustment of mid-partitions, grabbing and turning of mid-partitions, fine posture

adjustment and assembly of mid-partitions, and erector return posture adjustment. It takes 2,280s (38min) in total, including 1,800s for the erector and 480s for manual installation of bolts. See Figure 7 for the assembly process flow of mid-partitions.

4.2 Workflow of intelligent assembly robots for mid-partitions

4.2.1 Step 1: Parallel posture adjustment of mid-partitions

As shown in Figure 8, the erector moves to the zero working position and communicates wirelessly with the mid-partition. The 4 laser ranging sensors installed with the aid of the grabbing pin shaft of the erector is used to adjust the vehicle carrying platform device to make the mid-partition relatively parallel and transverse to the grabbing mechanism. The grabbing mechanism and pin shaft are aligned with the five center holes of the mid-partition through visual recognition cameras and laser ranging sensors. See

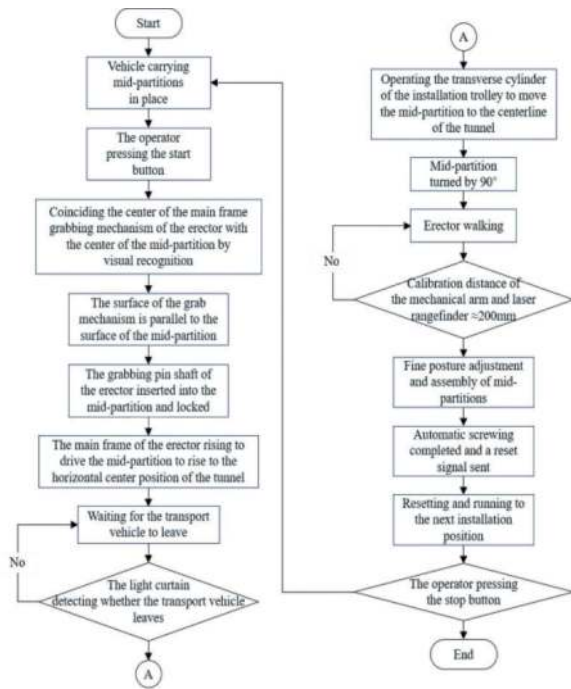

Figure 7. Flow chart of intelligent assembly of Mid-partitions.

Figure 9 for the alignment of the grabbing mechanism and pin shaft with five center holes of the mid-partition.

Figure 8. Erector moving to the zero working position.

Figure 9. Alignment of the grabbing mechanism and pin shaft with five center holes of the Mid-partition.

4.2.2 Step 2: Grabbing and turning of mid-partitions

As shown in Figure 10, the laser ranging sensor for positioning is used to insert the grabbing pin shaft into the mid-partition and lock it; according to the set procedure, the transport vehicle leaves after the mid-partition is lifted; the transverse cylinder retracts, and the mid-partition moves transversely to the centerline of the tunnel; the main frame lifting cylinder rises, and the mid-partition rises to the horizontal center position of turning. The mid-partition is rotated 90° to reach the vertical state, as shown in Figure 11.

Figure 10. Grabbing pin shaft Inserted into the Mid-partition and locked.

Figure 11. Mid-partition rotating 90° to reach vertical state.

4.2.3 Step 3: Fine posture adjustment and assembly of mid-partitions

As shown in Figure 12, two 6-DOF mechanical arms of the erector and laser ranging sensors are used to detect the distance from the installed mid-partition; when the distance is 200mm, the erector stops and the fine adjustment position is reached; as shown in Figure 13, with the aid of active vision cameras of the two mechanical arm systems, the structured light is projected onto the reference mid-partition and that to be installed and then identified, and the relative position and posture parameters between the mid-partitions are calculated, all posture positions of the mid-partitions are adjusted through the closed-loop control, and then, fine adjustment and assembly are completed.

Figure 12. Schematic diagram of two 6-DOF mechanical arms and laser ranging sensors.

Figure 15. Erector automatically moving to the zero working position.

Figure 13. Projecting structured light onto reference Mid-partition and that to be Installed and identifying status.

4.2.4 Step 4: Erector return posture adjustment

As shown in Figure 14, after the assembly of the mid-partition is completed, the bottom is temporarily fixed with appropriate metal gaskets and the bolts at the bottom and between walls are tightened. The operator presses the reset button; and then, the grabbing pin shaft is separated from the mid-partition, and the erector automatically moves to the zero working position for the next procedure. The erector automatically moves to the zero working position, as shown in Figure 15.

Figure 14. Grabbing pin shaft separated from the Mid-partition.

5 KEY TECHNOLOGIES FOR INTELLIGENT ASSEMBLY OF MID-PARTITIONS

5.1 Multi-sensor information fusion positioning technology

The intelligent installation of mid-partitions is based on multi-sensor information fusion data, and the mechanical arm vision positioning system of the erector as well as the strong robust visual feature, high-precision displacement sensors, laser range-finders, optical sensors and other detection elements are used to measure and detect actual relevant data. The hydraulic cylinder is finally controlled through software calculation and analysis.

As shown in Figure 16, key information data are extracted with the aid of multi-sensor information such as laser ranging information, vision information, cylinder stroke information and structured information of the equipment; the structured light is generated by a point cloud camera generator, the vision camera extracts point cloud data information to form an image characteristic value of the target mid-partition, which is compared with the expected characteristic value of the fixed mid-partition image, and the visual servo loop control is used to calculate their relative positions and postures.

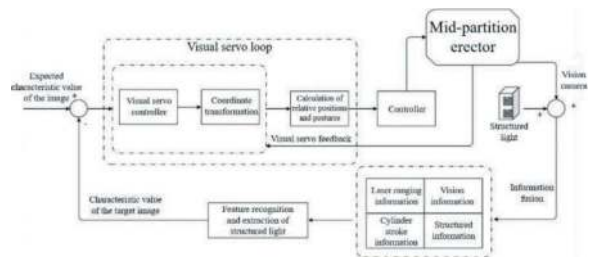

Figure 16. Block diagram of intelligent control system for Mid-partitions.

An erector coordinate system is established. The coordinate transformation is carried out with the mechanical arm vision positioning system as the core. With the aid of the closed-loop control of the visual servo and the laser ranging redundancy information, real-time positioning of the mid-partitions during installation is realized through strong robust visual feature selection for accurate position and posture adjustment.

5.2 Center hole positioning by vision camera recognition

In the center hole alignment stage, a visual recognition camera is used to identify the round hole for center positioning reserved at the center of the prefabricated slab of the mid-partition, and it is necessary to feed back the coordinate position of the circle center for adjusting the center of the grabbing mechanism of the erector to align with the center of the prefabricated slab.

As shown in Figure 17, the grabbing pin shaft is aligned with the hole of the mid-partition. The industrial vision camera positioning technology and the built-in deflection angle of the vision camera are adopted to compare the coordinate information of the hole image taken with the standard image and feed back the coordinate position of the circle center for adjusting the center of the grabbing mechanism of the erector to align with the center of the mid-partition. The identification and positioning process of the round hole for center positioning includes image loading, image pre-processing, edge detection of the center hole, hough-circle transform, and output of coordinates of the fitted circle and circle center, aiming to obtain the rotation angle, height difference and horizontal difference, control the relative movement of the rotating cylinder, lifting cylinder and longitudinal horizontal cylinder of the erector, and insert the grabbing pin shaft into the mid-partition. See Figure 18 for the application effect of recognition of the center hole of the mid-partition by the vision camera.

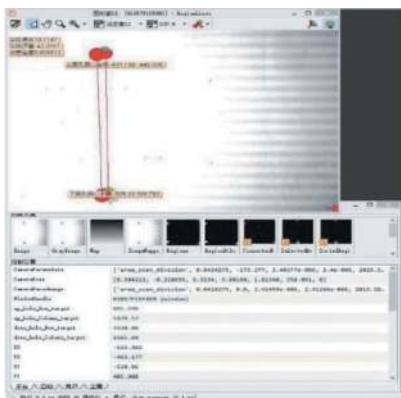

Figure 17. Recognition results and adjustment of current grabbing hole and standard positions and postures.

Figure 18. Effect of recognition of the center hole of the Mid-partition by the vision camera.

5.3 Dual Six-axis mechanical arm and active visual posture control technology

After the mid-partition reaches the fine adjustment position, with the aid of two mechanical arm systems with active vision cameras (see Figure 19 and Figure 20), the structured light is projected onto the reference mid-partition and that to be installed respectively and then identified, so as to calculate the relative position and posture parameters between the mid-partitions and adjust the postures and positions of the mid-partitions through the closed-loop control.

The dual six-axis mechanical arm guides the camera to accurately obtain the position and posture coordinates of the mid-partitions, converts the image coordinates into the erector coordinates that can be recognized by the erector, and issues instructions according to the coordinate system calculation and PLC calculation of the erector. The hydraulic control system adopts a load-sensitive electrical proportional control scheme to complete the automatic centering and grabbing of the intelligent assembly robots for the mid-partitions, the automatic rotation of the mid-partitions by 90°, the automatic walking of the erector to the installation position, the fine adjustment of the mid-partitions, the installation of the mid-partitions and other procedures, and then guides the hydraulic cylinder of the erector to complete the positioning, grabbing and posture adjustment of the mid-partitions.

Figure 19. Upper active vision camera and structured light generator in working.

Figure 20. Lower active vision camera and structured light generator in working.

5.4 Heavy-duty servo displacement feedback control

The hydraulic system adopts the combination mode of the load sensitive pump and the proportional multi-way valve to realize the flow control technology with constant output of system flows and independent of load changes; the proportional valve adjusts the speed curve of the cylinder according to requirements to ensure stable actions; when integrated with displacement sensors, the cylinder realizes multi-cylinder compound action control with accuracy of millimeter level to meet the action accuracy requirements of the erector.

The intelligent assembly robot for mid-partitions obtains external information through the multi-sensor information fusion positioning system based on the measured data and analysis of the current and target positions of components. The high-performance industrial personal computer makes calculations and judges whether the perception meets the working conditions in real time, and imports the collected position and posture errors into PLC to calculate the current control amount in accordance with the coordinate system analysis information of the erector, so that hydraulic cylinders and other actuators can execute the current drive amount, calculate the displacement of each actuator and send it to the hydraulic control system, so as to achieve the required working condition.

6 FIELD APPLICATION EFFECT

6.1 Assembly efficiency of erector

From June 2022 to July 2023, after factory test and field application, a total of 2,361 mid-partitions were assembled on site, with a cumulative assembly length of 4,722 m. The intelligent assembly robot for mid-partitions completed four procedures, with a total duration of 38min (including 5 min for fastening bolts and removing lock pins). The field application of the intelligent assembly robot for mid-partitions is shown in Figure 21.

Figure 21. Field application of intelligent assembly robot for Mid-partitions.

6.2 Quality control effect of assembly

The assembly quality of the intelligent assembly robot for mid-partitions is mainly reflected in the control of assembly accuracy, which refers to the relative deviation from the previous mid-partition. If the assembly accuracy of the mid-partitions reaches $\pm 2\text{mm}$, high-precision assembly is realized, and the installation quality control indicators of the mid-partitions are shown in Table 3.

Table 3. Statistics of quality control eviations for Mid-partition assembly.

Control item	Design deviation	Measured deviation	Control density
Elevation angle α	$\pm 0.05^\circ$	$\pm 0.05^\circ$	Per piece
Maximum gap difference at the bottom	$\leq 5 \text{ mm}$	$\leq 0.5 \text{ mm}$	Per piece
Inclination β	$\leq 0.06^\circ$	$\leq 0.01^\circ$	Per piece
Side verticality	$\leq 10 \text{ mm}$	$\leq 2 \text{ mm}$	Per piece
Cornery	$\pm 0.15^\circ$	$\pm 0.05^\circ$	Per piece
Centerline deviation	$\leq 5\text{mm}$	$\leq 1\text{mm}$	Per piece
Gap between walls	$\leq 7\text{mm}$	$\leq 0.5 \text{ mm}$	Per piece
Filling the gap	20-30mm	20-30mm	Per piece

7 CONCLUSIONS AND DISCUSSION

Based on the problems that need to be solved urgently for intelligent assembly of prefabricated mid-partitions for shield tunnels, and in combination with the assembly process, equipment intelligence degree and status of the resource organization mode, this paper studies the design scheme of the gantry-type intelligent erector for mid-partitions and key technologies for one-button intelligent high-precision assembly, and draws the main conclusions as follows:

- 1) The conceptual design of the intelligent control system for the intelligent assembly robot for mid-partitions: An erector coordinate system is established. The coordinate transformation is carried out with the mechanical arm vision positioning system

as the core. With the aid of the closed-loop control of the servo of the double-sided vision camera module and the laser ranging redundancy information, real-time positioning of the mid-partitions during installation is realized through strong robust visual feature selection for accurate position and posture adjustment, resulting in the assembly accuracy $\leq \pm 2\text{mm}$.

- 2) The posture measurement technology of mid-partitions based on the dual six-axis mechanical arm and active vision servo technology: The structured light image is recognized by a vision camera, and the position difference between two mid-partitions is identified and calculated by an algorithm, thus realizing accurate position and posture adjustment of parallelism of mid-partitions. The efficiency is more than 10 times higher than that of the traditional cast-in-situ process.
- 3) The application of full prefabrication and assembly technology and intelligent equipment for the internal structures of shield tunnels has great technical and practical significance and provides a reference for construction technologies and new equipment in the field of full prefabrication and assembly. In the next step, it is recommended to carry out systematic and in-depth research on the connection between mid-partitions and bottoms, design forms of mid-partitions, connection between mid-partitions and top brackets, intelligent

assembly application function integration and intelligent fastening of circumferential and longitudinal bolts, etc. to standardize construction and improve construction efficiency.

ABSTRACT: The Jiangyin Jingjiang Yangtze River Tunnel Project has a total length of approximately 11.825 kilometers, of which 6,445 meters cross the Yangtze River using the TBM tunnelling method (with a TBM tunnelling length of 4,952 meters), and the outer diameter of the tunnel segment is 15.2 meters. The TBM used in this project has a long one-time excavation distance, and the strata it crosses are mainly composed of cohesive and sandy silt, with the sand layer containing a high quartz content and contains high-strength calcareous nodules. The tunnel has deep overburden, high water pressure, and noxious gases in the formation, making it very challenging project.

This article elaborates on the innovative design of the Herrenknecht TBM used in right line of this project, which was aimed at addressing the challenges of the project including the long excavation distance, high water pressure, strong wear from soil, the presence of noxious gases in the formation and high construction quality requirements.

The TBM used on this project has an excavation diameter of 16.09 meters, a working pressure of 1 MPa and is equipped with a large opening ratio accessible soft ground cutting wheel, a displaceable main drive and an automatic pressure-regulating main drive sealing system. It is also equipped with a SSP-E geological forecasting system, a tailskin two-components synchronous grouting system, an adaptive tailskin sealing grease injection system, a tailskin grouting quality scanning system, a telescopic camera in the excavation chamber, and a high-flow flushing system among other customized features.

Thanks to all these TBM design innovations, the right line tunnel excavation was successfully completed on May 17, 2023.

1 INTRODUCTION

In recent years, with the development of economy and society and the progress of engineering technology, the shield tunnelling method has been widely used in the construction of highway tunnels due to its advantages such as fast construction speed, good safety, and low environmental impact. Due to the functional requirements of highway tunnels, the diameter of shield tunnelling machines used in highway tunnel construction is usually over 10m, with the diameter greater than 14m being the majority. According to statistics, there are currently 50 ultra- large diameter

shield tunnelling projects with a diameter of >14m in China, most of which are underwater tunnels.

The shield tunnelling machine applied to ultra-large diameter underwater tunnels needs to be designed, manufactured, and used in accordance with the characteristics of ultra-large diameter underwater tunnels, such as long excavation distance, high underground water pressure, large excavation section, complex geological changes, and high requirements for tunnel forming quality. A targeted design should be carried out to ensure the safety and efficiency of the tunnel construction. This article takes the design of the Herrenknecht shield machine for

*Corresponding author: wang.hai@herrenknecht.com

the right line tunnel of the Jingjiang Yangtze River Tunnel in Jiangyin as an example to explain the application of shield machine design tailored to the characteristics of the project.

2 PROJECT OVERVIEW

The Jiangyin Jingjiang Yangtze River Tunnel Project is located in Jiangsu Province, starting from the intersection of Jingjiang Gongxin Highway and Chengxi Avenue, crossing the Yangtze River south and ending at the intersection of Jiangyin West Outer Ring Road and Furong Avenue. The total length of the route is approximately 11.825 kilometres, and the entire line adopts the construction standard of a two-way, six-lane expressway with a design speed of 80 km/h and a roadbed width of 33 meters; three interchanges are set up along the entire line, including Jingxi, Jiangyin West, and Qingshan.

The main tunnel of the Jiangyin Jingjiang Yangtze River Tunnel Project starts from about 300m north of S356 in Jingjiang City, passes south through S356 and Binjiang 1st Road before entering the Yangtze River. After reaching Jiangyin City, it passes down through Jiangfeng Road, Binjiang Road, and Tongfu Road, and is grounded at about 270m south of Tongfu Road. The total length of the tunnel is about 6445 meters (the main tunnel is calculated based on the left and right lines, with chainage YK2+720-YK9+170 on the right line, and 6450 meters long; the chainage ZK2+720-ZK9+159.238 on the left line, and 6439.2 meters long).

The tunnel crossing the river section is constructed using the shield tunnelling method. The inner diameter of the tunnel segment lining is 14.2 meters, and the outer diameter is 15.5 meters. The shield tunnelling section on the right line is 4952 meters long (chainage YK3+433-YK8+385), and the shield tunnelling section on the left line is 4937.19 meters long (chainage ZK3+432.396-ZK8+369.590).

Figure 1. Overview of jiangyin jingjiang yangtze river tunnel project.

The strata crossed by the tunnel mainly consist of soft plastic to hard plastic silty clay, muddy silty clay, loose to dense silt, silt, fine sand, dense gravel medium coarse sand, etc. The quartz content of the silt layer is about 55-75%, the quartz content of the fine sand is about 55-85% and the quartz content of the medium coarse sand is about 80-90%. There are high strength calcareous nodules sandwiched in the sand layer. Noxious gases are present in the muddy silty clay.

The main characteristics of the project are:

- “Large cross section”, with an outer diameter of 15.5m for the segment, and the excavation diameter of the shield machine will exceed 16m;
- “Long distance”, with a one-time tunnelling distance of approximately 4.95km for the shield tunnelling machine;
- “High pressure”, refers to the tunnel crossing the Yangtze River with a large burial depth and high water pressure. The maximum soil and water pressure at the tunnel axis exceeds 0.9Mpa;
- “Difficult geology”, the tunnels pass through various strata, and hard plastic silty clay can easily lead to clogging and blockage on the cutting edge; dense powder fine sand and medium coarse sand have a high quartz content, are highly abrasive, and in some areas are also mixed with calcareous nodules, which can easily cause wear of the cutting tool; there are also noxious gases present in the formation.

Figure 2. Geological longitudinal section of jiangyin jingjiang yangtze river tunnel engineering.

3 TARGETED DESIGN AND INNOVATION OF SHIELD TUNNELLING MACHINES

3.1 Overview of overall design of shield tunnelling machine

Based on the engineering geological and hydrogeological conditions and difficulties of the Jingjiang Yangtze River Tunnel in Jiangyin, the overall design concept of the shield tunnelling machine was determined through theoretical analysis and calculation, as well as summarizing the design experience of similar projects in the past. The shield machine adopts a MIX shield with the following main technical parameters:

- Working pressure of the shield tunnelling machine: 1Mpa
- Cutter head excavation diameter: 16,130mm
- Front shield diameter: 16,100mm
- Middle shield diameter: 16,070mm
- Tailskin diameter: 16,040mm/16,020mm
- Main drive power: 4,900KW
- Cutting wheel speed: 0-2r/min
- Nominal torque: 37,593KNm
- Maximum torque: 46,991KNm
- Breakout torque: 50,751KNm
- Total thrust: 28,7064KN
- Theoretical maximum advance speed: 45mm/min

3.2 Cutting wheel

The geology of this project is complex and the fine sand, coarse sand and calcareous nodules can cause wear on the cutting tools. Under the working conditions of deep overburden and high water pressure, if the cutting tools are worn out to the point where they cannot be used and need to be replaced, using the conventional way to enter the chamber with compressed air to replace the cutting tools will result in high construction risks and low tool replacement efficiency. Therefore, in the design of the cutting wheel, a targeted design of an accessible cutting wheel was adopted, and the safety of the cutting wheel and cutting tools during long distance excavation is ensured by tool configuration, wear resistance design, and tool wear monitoring.

The cutting wheel structure adopts an accessible type, consisting of 6 accessible main arms and 6 small spokes. The cutting wheel is equipped with accessible ripper tooth holders and sealing gates, accessible scraper holders and sealing gates, and conventional scraper holders, which can facilitate the replacement of the cutting tool.

Figure 3. Cutting wheel for the right line tunnel of Jiangyin Jingjiang Yangtze River Tunnel.

The cutting wheel opening ratio is approximately 45%. 12 DN100 flushing ports are set in the center area of the cutting wheel, and a separate P0.1 flushing pump is used for flushing. The flushing of each nozzle has been optimized and designed to concentrate the flushing at two of the flushing points. The flow rate is concentrated for a short period of time, the flushing pressure is increased, and the central area of the cutting wheel is washed in time to prevent clogging formation at the cutting wheel center.

The layout of the shield tunnelling tools is shown in Figure 5. The height of the accessible center tool is 245mm, the height of the front welded rippers and the accessible rippers is 225mm, the height of the accessible scraper on both sides of the main arms is 185mm, and the height of the bolt fixed scraper and bucket lips on both sides of the main arm is 165mm. The reasonable height difference configuration of the cutting tools can effectively meet the requirements of cutting strata and fully utilize the service life of the tools.

Figure 4. Center flushing of cutting wheel.

Figure 5. Cutting tool configuration.

When excavating in dense powder fine sand, medium coarse sand, and formations containing calcareous nodules, the cutting tools are prone to wear. Once excessive wear occurs, it will greatly reduce the service life of the cutting tools and even endanger the structure of the cutting wheel, causing irreparable losses. In response to this phenomenon, the cutting wheel is equipped with an accessible scraper/ripper wear monitoring device at key positions, which can display the tool wear status in the shield machine control cabin, as shown in Figure 6.

Figure 6. Wear monitoring of cutting wheel and cutting tools.

3.3 Main drive and sealing system

Considering the geological conditions of the shield tunnelling in this project and the uncertainties encountered in the geological conditions (such as boulders, dead wood, and sunken ships), the main drive adopts a variable frequency motor drive, equipped with 14 gearboxes, with a total power of 4900kW, a nominal torque of 37,593KNM, a maximum torque of 46,991KNM, and a breakout torque of 50,751kNm.

Considering the main excavation in clay and sand layers, the maximum speed is 2.0rpm. The torque curve of the driving part is shown in Figure 7.

Figure 7. Main drive torque curve.

The main drive of the cutting wheel is shown in Figure 8. The main drive adopts a 7.6m diameter three row roller heavy-duty main bearing produced by Rothe Erde in Germany, equipped with 18 pieces of Φ 400/280-400mm telescopic cylinders.

Figure 8. Main drive structure.

The inner and outer seals of the main drive sealing system are composed of four lip-shaped rubber seals. The outer seal is equipped with an automatic pressure regulating device, which can adjust the sealing back pressure according to the changes of the slurry pressure in the excavation chamber, and the pressure resistance can reach 1.2MPa. The structure and installation method of the main seal can ensure that the external seal can be replaced inside the tunnel in emergency situations.

3.4 Synchronous grouting system

In order to reduce the phenomenon of segment stepping and joint leakage, and to ensure the quality of the formed tunnel, it is necessary to use shield tail

Figure 9. Automatic pressurizing system for main bearing sealing.

grouting in a timely manner to stabilize the segment ring after it comes out of the shield tailskin, thereby reducing the floating of the segment ring. In response to the characteristics of this project, the shield tailskin grouting adopts a synchronous bi-components grouting system, which greatly shortens the setting time of the grout, timely and effectively controls the floating of the ring segments, avoids the occurrence of segment stepping, joint leakage etc., and the quality of the formed tunnel is high.

The structure of the shield tailskin synchronous bi-components grouting system is shown in the Figure 10. Equipped with component A pipe, component B pipe, cleaning piston, and cleaning water circuit, the structure is exquisite, the piston action is reliable, cleaning is convenient, and the two-component mixing position is close to the end of the shield tailskin, making it difficult to block the pipe.

Figure 10. Layout of Bi-component grouting system in tailskin.

The capacity of the component A and B screw pumps equipped in the system can meet the grouting volume requirements at the maximum advance speed of the shield machine, accurately control the mixing ratio of component A and B, and effectively control the grout setting time. In the grouting mode, component A and component B enter the mixing zone at the end of tailskin of the shield through their respective pipelines and mix before injecting into the annular gap between the outer wall of the segment and the inner wall of the excavation tunnel. At this point, the cleaning piston is in the retracted position, blocking the cleaning circuit.

In the cleaning mode, the cleaning piston extends, and the slurry injected into the annular gap is blocked by the piston and will not flow back into the shield tailskin. The cleaning water enters the component A and B pipelines through the space around the cleaning piston to clean the

pipelines. The cleaning water flows back to the waste water tank to ensure the cleanliness of the environment inside the tunnel.

3.5 Grouting quality inspection system

After the segment is moving out from the tailskin and grouted, whether the grout timely and completely fills the annular gap outside the segment directly affects the stability of the structure and the buoyancy of the segment. It also has an important effect on controlling soil deformation and prevention of ground settlement. In order to confirm the quality and effectiveness of grouting behind the segment wall, and to ensure the stability and quality of the formed tunnel, it is necessary to test the quality of grouting behind the segment wall in order to take timely measures to compensate for the adverse effects of insufficient synchronous grouting at the shield tail during the shield tunnelling process.

The shield tunnelling machine of this project is innovatively equipped with an independent segment grouting quality detection system behind the erector. The system mainly consists of an arc arch structure, a geological radar that can move on the arc arch, and the associated data processing laptop and software.

After the segments have been assembled, as the shield tunnelling machine advances, the segments gradually detach from the shield tailskin and reach the area where the grouting quality detection system is located. At this time, the system is activated to scan the wall of the segments using geological radar. The data obtained is automatically processed by the corresponding data processing software and presented in the form of a graphical report. The operator can visually see the thickness and uniformity of the grouting behind the segment wall, determine whether the synchronous grouting at the shield tailskin is sufficient, and whether secondary grouting behind the segment wall is necessary.

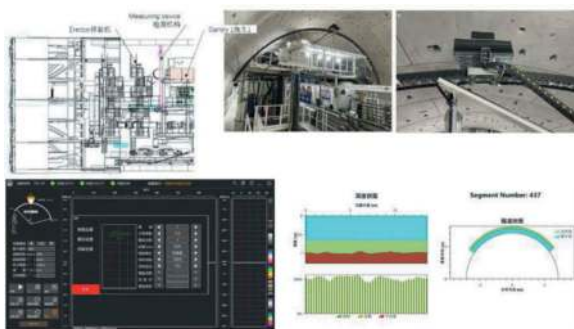

Figure 11. Grouting quality inspection system.

3.6 Shield tailskin grease injection system

The shield tailskin sealing system consists of 4 rows of shield tailskin brushes, 1 row of steel plates, and 1 row of grout extruders. During the advancing process of the shield tunnelling machine, the shield tailskin

sealing system plays a role in isolating the water and soil pressure and grouting outside the shield tailskin, to ensure tunnel safety. It is necessary to continuously inject shield tailskin sealing grease during the advancing process to ensure the sealing ability of the shield tailskin sealing brush and extend its service life.

Figure 12. Layout of shield tailskin sealing.

In the past, traditional shield tailskin grease injection systems, although equipped with automatic and manual modes, often experienced excessive grease injection in actual use, affecting the effectiveness of shield tailskin sealing and wasting shield tailskin grease. The shield tunnelling machine of this project innovatively adopts a new adaptive shield tailskin grease injection system. The system can automatically adjust the injection amount of shield tailskin grease into each sealing chamber based on the physical characteristics of the shield tailskin sealing grease, the required amount of shield tailskin sealing grease per square meter of segment surface area and the pressure of different shield tailskin sealing brush chambers, ensuring that the grease is evenly injected into each shield tailskin brush sealing chamber and applied to the shield tailskin sealing brush. After practical use, it has been proven that the system has a good control effect on the injection of shield tailskin grease, ensuring the sealing effect of the shield tail sealing system and effectively saving the amount of shield tail grease injection, demonstrating good effectiveness.

3.7 Video monitoring system for excavation chamber and air cushion chamber

During the advancing process of the shield tunnelling machine, most of the cutting tools on the cutting wheel can be easily inspected using the relevant functions of the accessible cutting wheel, but the wear of the bolt mounted scrapers and bucket lips cannot be perceived. In addition, sometimes when the shield machine is stopped, it is necessary to check the excavation surface in front of the cutting wheel to observe whether there are any foreign objects inside the excavation surface and whether the excavation surface is stable. When carrying out maintenance work on the shield tunnelling machines in the excavation and air cushion chambers, it is also necessary to monitor the operation of personnel in the excavation and air cushion chambers to ensure safety. Therefore, the shield tunnelling machine of this project is equipped with

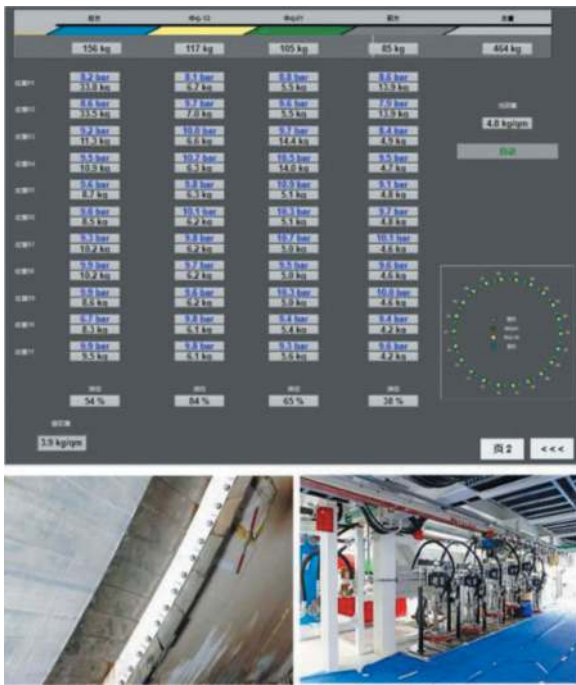

Figure 13. Adaptive tailskin grease injection system.

a set of pressure-resistant, waterproof and self-illuminating telescopic cameras above the excavation chamber and a set of pressure-resistant, waterproof, and self-illuminating fixed cameras are installed above the air cushion chamber. The telescopic camera can extend to the back of the cutting wheel to observe the steel structure of the cutting wheel, the side tools of the main arm of the cutting wheel, the bucket lips, and the tunnel face. The fixed camera observes the air cushion chamber.

During the construction process of this project, the telescopic camera was used to observe the structure of the cutting wheel, the tunnel face, and the clogging situation on the cutting wheel. The camera image was clear and the effect was good. As shown in Figure 14.

Figure 14. Snapshot from telescopic camera.

3.8 Geological advance prediction system

Due to the long distance of the tunnel crossing the Yangtze River in this project, there are certain uncertainties in the geological conditions and the geological conditions encountered (such as boulders, dead wood, and sunken ships). In addition to the reserving advance drilling channels, the shield tunnelling machine is also equipped with a soft soil sonic geological advance prediction system (SSP-E), which can detect the soil in front of the shield tunnelling machine through geophysical exploration.

The system includes a transmitter located below the side of the shield, receivers located on the front of the shield, and corresponding data transmission and processing software. When the shield tunnelling machine stops to assemble segments, the system is activated and the transmitter extends to touch the tunnel wall, emitting sound signals. The receivers extend to touch the excavation surface through the cutting wheel opening to receive signals. The system collects the reflected waves of the sound waves and processes and analyses the data, recording the magnitude of the reflected wave reflectivity. Subsequently, the same steps will be carried out again when the shield tunnelling machine stops and assembles the segments. Through the accumulation of a certain amount of measurement data, abnormal reflectance sections can be discovered, which can help determine if there are foreign objects or voids in the soil ahead and provide support for making construction plans.

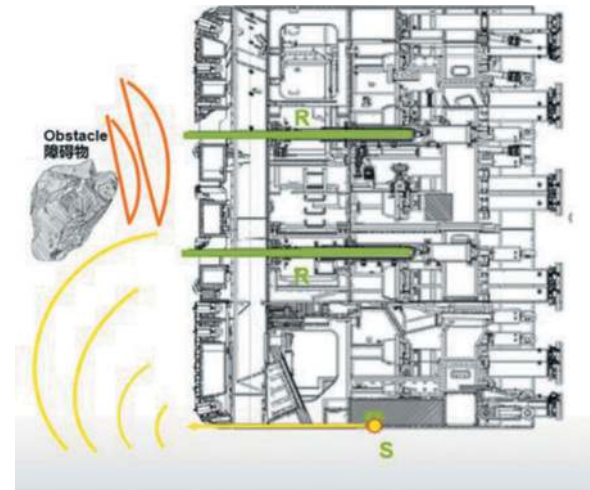

Figure 15. Geology forecasting system.

In the actual operation process, due to a leakage of a gate valve in front of one receiver and the need for compressed air intervention to repair completely, the contractor ultimately gave up on repairing the system considering the cost and time needed. The system was not actually used.

3.9 Slurry circuit and flushing system

This project adopts a MIX shield machine which relies on the slurry circuit to provide bentonite slurry

to maintain stable support pressure and ensure the stability of the excavation surface, and to ensure that the relevant parts of the cutting wheel, excavation chamber and air cushion chamber are flushed and the excavated materials from the cutting wheel is transported to the ground slurry treatment system.

The slurry circuit includes P1.1, P1.2 feed pumps, P2.1, P2.2, and P2.3 discharge pumps, P0.1 center flushing pump, P0.2 air cushion chamber bottom flushing pump, P0.3 excavation chamber bottom flushing pump, feed and discharge pipelines, valves, flow meters, density meters, etc. The diameter of the slurry feed and discharge line is DN500, with a slurry inlet flow rate of 2600m³/h and a slurry discharge flow rate of 2800m³/h. Considering the long tunnelling distance of the shield tunnelling machine and the high ground abrasiveness, the slurry circuit pipelines of the entire machine adopt more wear-resistant tri-base composite material wear-resistant pipes, and the tri-base wear-resistant layers in the straight jet area inside all the flushing pipelines and slurry discharge pipeline bends have been thickened.

Figure 16. Thickened three base composite material wear-resistant pipe.

The slurry circuit has various operating modes, such as excavation, stoppage, pipe extension, weekend and equipment maintenance, to ensure smooth excavation of shield tunnelling in complex geological conditions.

4 TARGETED DESIGN APPLICATION EFFECT

The shield machine started excavation on December 31, 2021 and successfully breakthrough on May 15, 2023. Throughout the entire tunnelling process, the performance of the shield machine was stable, with a maximum daily advance of 11 meters and a maximum monthly advance of 234 meters. The targeted designs have basically played a full role, among which the accessible cutting wheel works normally, the tool has no abnormal wear, the main drive torque reservation and the main drive sealing pressure resistance are sufficient, the shield tailskin bi-components synchronous grouting and adaptive shield tailskin grease effect are well used,

the grouting quality detection system, excavation chamber & air cushion chamber video monitoring system, and slurry circuit work normally, providing technical support for the final tunnel connection.

Figure 17. Performance of shield machine of right line tunnel of jiangyin jingjiang yangtze river tunnel.

5 CONCLUSION

Based on the geological and hydrogeological conditions of the right line of the Jiangyin Jingjiang Yangtze River Tunnel Project, especially when crossing the Yangtze River, the tunnel has a large overburden depth, a large excavation diameter, high water pressure, complex geological conditions, and the presence of adverse geological conditions such as calcareous nodules and harmful gases. There are many uncontrollable factors and Herrenknecht has innovatively designed the shield tunnelling machine. The main technologies include accessible cutting wheel, telescopic main drive, and automatic pressure regulating main drive sealing system, shield tailskin bi-components synchronous grouting, adaptive shield tailskin grease injection system, grouting quality detection system, excavation chamber and air cushion chamber video monitoring system, geological advance prediction system, and slurry circuit have achieved good application results in construction, ensuring the safe and smooth tunnel construction according to plan, and playing a good demonstration role for the design and application of shield tunnelling machines in similar projects.

ABSTRACT: Ground subsidence is a common geological hazard generated during shield tunneling construction, and if not controlled, it can have a catastrophic impact on the safety of existing buildings. Due to the large shield face and shallow burial depth from the ground, large-diameter shallow buried shield tunnels are more prone to ground deformation. Therefore, the study of the impact mechanism and deformation control of large-diameter shallow buried tunnels on ground deformation is of great engineering significance. This study is based on model experiments and on-site measurement methods to conduct targeted research on deformation caused by large-diameter mud water balance shield tunneling through railways, reservoir embankments, and surface uplift and settlement, including indoor scaled model tests that can simulate the shield tunneling process and grouting behind the wall. The study is based on the actual engineering of the Jinan Yellow River North Extension Tunnel. The model test results show that the surface deformation first experiences uplift, followed by settlement, with a maximum settlement of 10mm, and the settlement trend conforms to the Peck formula prediction results; And compared with the on-site measurement results, a control technology for railway and reservoir embankments using large-diameter shallow buried shield tunnels is proposed, which is to reinforce railway tracks through D-beams or control surface deformation through controlling grouting pressure combined with real-time monitoring, in order to provide guidance and reference for engineering practice and reduce the impact of ground settlement and uplift on existing buildings.

Keywords: Shield tunneling method, Reservoir embankment, Railway subgrade, Settlement control, Model test

1 INTRODUCTION

With the development of society and urban expansion, more and more tunnel projects are being planned for construction. Among them, large-diameter shield tunnels are widely used due to their high construction efficiency and automation level. However, at the same time, as the diameter of shield tunnels increases, construction risks also increase synchronously. It is crucial to explore the impact mechanism of large-diameter shield tunneling on the surface.

Scholars at home and abroad have conducted some research on this section. Regarding the aspect of shield tunneling through existing railways, Lv Peilin^[1] et al. found based on observation data that during the process of shield tunneling under railways causing line settlement, subsequent settlement accounts for a relatively large proportion of the total settlement, and it takes a long time for settlement to reach stability; Du Hu^[2] used a combination of finite

element analysis and on-site practice to study and found that sleeve valve pipe grouting can be used to treat railway roadbed, set up pile isolation protection, and closely implement secondary grouting during shield tunneling through existing railways, which can effectively reduce the impact of shield tunneling; Huang Long^[3] et al. conducted a study on the shield tunneling under the newly built railway of Ningbo Metro Line 1 and found that the shield tunneling construction had a relatively small impact on the deformation of the pile plate structure roadbed. The settlement of the pile plate structure after shield tunneling construction can meet the requirements of the specifications; Gao Zhigang^[4] et al. conducted numerical simulation analysis based on the S8 line of the Nanjing Metro, and adopted foundation grouting reinforcement measures for the railway roadbed and dynamically adjusted construction parameters during shield tunneling, achieving the role of ensuring construction safety; Li Qi^[5] et al. introduced the

*Corresponding author: sduyan_sh@163.com

use of D-beam reinforcement schemes and excavation parameter control techniques to control the settlement of shield tunneling through existing railways. Throughout the monitoring process, the settlement was less than the control value, proving the feasibility of the control technology; Sun Bo^[6] et al. used the example of Qingdao Metro Line 2 crossing the Jiaoji Railway, and used ABAQUS to dynamically simulate the process of crossing the existing railway. They analyzed the settlement of ballasted and ballastless railways, and proposed that setting up a reinforcement area for grouting can reduce settlement by about 50% and reduce ground disturbance.

In terms of shield tunneling through reservoir embankments, Yuan Dajun^[7] et al. relied on the Nanjing Yangtze River super large diameter mud water shield tunnel to study the disturbance mechanism and laws of mud water balance shield tunneling on soil at various stages; Cheng Xuewu^[8] conducted research on the mud water balance shield tunneling through the Haihe River, summarizing the lateral and longitudinal settlement laws of the overlying soil layer of the tunnel, as well as settlement control methods; Zhu Muyuan^[9] et al. analyzed the settlement law and characteristics of the large embankment section during the shield tunneling process, and proposed settlement control methods based on the Jinan Jiluo Road Yellow River Crossing Tunnel Project; Huang, J^[10] et al. used ABAQUS to numerically simulate the settlement caused by construction and study and control construction measures based on the Luoyang Metro Line 2 Undercrossing Luohe River Project; Zhang Xiaoyong^[11] et al. analyzed the displacement law of the Yellow River embankment surface when the mud water balance shield tunneling passes through it, and studied the influence of different mud support pressure ratios on the stability of the excavation surface; Zhang Longbo^[12] combined three-dimensional finite element analysis and Peck formula calculation, comprehensively considering factors such as tunnel burial depth and grouting, and introduced a correction coefficient α and β , The modified Peck formula obtained can more accurately predict the surface lateral settlement of large-diameter shield tunneling tunnels; Wang Xin^[13] et al. used a finite difference program to conduct a three-dimensional model analysis of a super large diameter shield tunnel crossing a large embankment, and found that the shield tunneling had the greatest impact on the soil settlement of the embankment before reaching it. The main impact area of the embankment was from 1D outside the dam foot on the back surface (D represents the outer diameter of the tunnel) to 1.71D outside the dam foot on the upstream surface. However, there is still a lot of research space for the construction of double

track tunnels with burial depths less than the diameter of shield tunneling studied in this article, as well as the impact of shield tunneling on existing railways and embankments.

This article first uses indoor model tests to explore the surface deformation situation, and compares and analyzes the experimental data with on-site measurements. The two are combined to study the control methods of surface deformation during large-diameter shallow buried shield tunneling construction, providing control methods and technical references for surface deformation caused by future large-diameter shallow buried shield tunneling projects.

2 PROJECT OVERVIEW

This study is based on the Jinan Jiluo Road North Extension Tunnel Project, which is a double track large-diameter slurry shield tunnel designed as a public rail joint construction. The double track tunnel starts 50 meters from the north bank of the Yellow River and crosses the Handan Jinan Railway. Then, less than 100 meters of excavation begins to penetrate the south bank embankment of the Queshan Reservoir, entering a continuous water section of 1550 meters. The total length of the shield tunnel section is 2040m. The project uses a shield tunneling machine with a diameter of 15.76m and an outer diameter of 15.2m for the shield tunnel segments. When crossing railway and reservoir embankments, the burial depth is 11.7m, and the distance between double track tunnels is about 12m. The geological conditions at the construction site are complex, mainly composed of silty clay and silt, accompanied by sand layers, calcareous nodules, etc. The reservoir area was once a village, and there are unexplored abandoned wells along the route, which poses a threat to shield tunneling construction. The reservoir embankment is 6-8 meters above the ground, with the highest water level about 6 meters above the ground. The bottom of the reservoir area is a thick layer of cohesive soil, and the surface of the reservoir embankment is covered with composite geomembrane. The dam foundation has a vertical plastic layer to cut off seepage. However, after 20 years of operation, the anti-seepage material of the dam body is partially damaged, resulting in varying degrees of leakage. Queshan Reservoir is an above ground regulation and storage reservoir, covering an area of 7.4 square kilometers with a net water supply of 400000 cubic meters per day. It is a centralized drinking water source for the Yellow River regulation and storage reservoir as well as Jinan City. The water source is a first-class protected area, so shield tunneling through railways and reservoir embankments requires extremely high settlement requirements.

Figure 1. Engineering plan diagram.

Figure 2. Schematic diagram of engineering profile.

3 TEST SIMULATION

This study used a 100:1 similarity ratio to scale down the engineering situation. The model experiment designed similar soil layers and tunnels, and used laser displacement meters to monitor and simulate surface deformation during shield tunneling. The size of the model test box was $1550 \times 900 \times 1000\text{mm}$, the soil layer is taken by on-site small diameter earth pressure balance shield tunneling machine, the shield tunneling machine is made of 157mm outer diameter steel pipe, and the pipe segments are made of 152mm outer diameter PE material pipe. Based on the similarity ratio of size similarity ratio: $C_L = 100:1$ and bulk density similarity ratio: $C_\gamma = 1:1$, achieve full similarity in controlling various physical and mechanical parameters within the elastic range: similarity ratio of elastic modulus: $C_E = 100:1$, similarity ratio of bending stiffness: $C_{EI} = (100:1)^5$, similarity ratio of tensile stiffness: $C_{EA} = (100:1)^2$, Poisson's ratio, similarity ratio of internal friction angle: $C_\mu = C_\phi = 1$. Permeability coefficient similarity ratio: $C_K = 10:1$. Given actual segment weight $\gamma_p = 25\text{kN/m}^3$, elastic modulus $E_p = 31\text{GPa}$, elastic modulus PE (polyethylene) pipe $E_p = 0.55\text{GPa}$, acrylic elastic modulus $E_p = 2.7\text{GPa}$, then: (1) Simulate the similarity ratio of actual elastic modulus of shield tunnel: $C_E = 31:0.55 = 56$, outer diameter similarity ratio: $1570:15.7 = 100$, inner diameter similarity ratio: $1390:13.9 = 100$, pipe thickness similarity ratio: $650:6.5 = 100$; (2) Model soil bulk density similarity ratio: $C_\gamma = 1:1$.

The shield tunneling adopts a casing pipe jacking method, using a large diameter pipe to simulate the cutter head of the shield tunneling machine. The pipe is pushed forward by hydraulic pressure, and a small diameter pipe is placed behind the large diameter pipe to simulate the tunnel lining. During the process of small diameter circular pipe jacking, rubber pipes are tied between the soil layer and the pipe segments, and water is injected into them. The grouting pressure can be controlled through water pressure simulation to simulate the deformation of the soil during the grouting process.

Figure 3. Model testing device.

Figure 4. Schematic diagram of the layout position of the model test soil box and laser displacement meter.

The experimental process mainly includes: filling the soil box with on-site soil and compacting it, measuring the density of the soil layer to meet the requirements of similarity ratio; After the soil layer reaches its height, make an earth dam on the surface of the soil layer, and conduct a water storage test after compaction; Install laser displacement meters at the top and bottom of the dam; The reservoir area is filled with water, and after waiting for the water in the reservoir area to slowly seep into the formation, shield tunneling is started and real-time monitoring is carried out. Firstly, the drill bit is used to extract soil 50mm forward, then the shield cutter is used to insert 50mm into the top of the head, and finally the PE pipe tunnel model is pushed forward 50mm until the tunnel is fully penetrated.

4 TEST RESULTS AND ON-SITE MEASURED VALUES

4.1 Model test results

The monitoring results of the laser displacement meter at the dam crest during the model test are shown in Figure 5.

Figure 5. Model test results.

The model test results show that as the shield tunneling progresses, a partial uplift occurs at the top of the dam, and after the shield tunneling machine passes through, a settlement of about 0.1mm is generated, corresponding to a settlement of about 10mm on site. During the shield construction process, it is necessary to strictly control the shield tunneling speed and grouting amount, which will be discussed in detail in the following text.

4.2 Dam monitoring results

An electronic level is used for settlement monitoring on site, and a new method is adopted for on-site monitoring and testing, which is based on the micro pressure ground deformation area surface monitoring system and method. Multiple measuring lines including micro pressure sensors are laid on the surface to collect real-time water pressure values at each measuring point. After processing the pressure change data monitored by the micro pressure sensors, differential settlement values are obtained. The settlement rate and settlement trend curve, based on the absolute coordinate elevation information of the initial point, calculate the relative settlement uplift deformation displacement of each measuring point based on the initial point, and then obtain the absolute deformation displacement value. The on-site monitoring points are arranged horizontally along the dam foot and crest, the on-site monitoring results of the embankment are shown in Figure 6.

The on-site monitoring results are similar to the model test results, with a protrusion of about 10mm first, followed by a settlement of 10mm. Finally, through settlement control measures, the overall settlement is about 1mm. The monitoring data of the electronic level deployed along the axis of the dam crest is shown in Figure 7, and the settlement trough caused by the single line shield tunnel conforms to the theoretical solution of the Peck formula.

4.3 Railway monitoring results

Due to the extremely high requirements of railways for surface subsidence, detailed monitoring and

Figure 6. Dam monitoring results.

Figure 7. Comparison between the monitoring results at the top of the embankment and the Peck formula.

control areas have been set up in the vicinity of the railway on site. The location relationship between the railway and the originating well, embankment, and Queshan Reservoir is shown in Figure 8.

Figure 8. Schematic diagram of railway protection area.

On site monitoring of the railway protection line using an electronic level, the deformation monitoring results of the railway track are shown in Figure 9.

The trend of railway monitoring results is similar to that of embankment settlement, with about 5mm uplift occurring first, followed by about 4mm settlement. The surface gradually rises over time, with a total uplift of about 1mm within 20 days. The overall settlement is smaller than that of embankments,

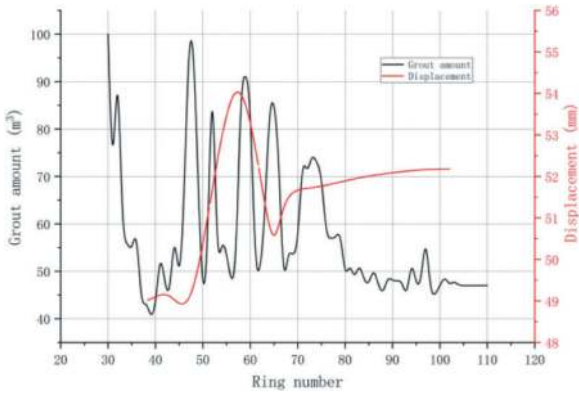

Figure 9. Monitoring results of railway settlement.

due to the use of more stable rail reinforcement methods by the railway to control surface uplift and settlement caused by shield tunneling.

5 SHIELD TUNNELING CONTROL METHOD

5.1 Control of shield tunneling machine construction parameters

The construction site adopts a 15.76m outer diameter mud water balance shield machine, which monitors real-time excavation parameters such as thrust, speed, torque, rotational speed, steering, rolling angle, as well as grouting parameters such as grouting amount and grouting position during the excavation process. At the same time, it monitors axis deviation and soil cover thickness. At the same time, real-time monitoring of the dam traversed by the shield tunneling is carried out on the construction site to adjust the construction strategy based on this.

Figure 10. Settlement and excavation parameters at the top of the embankment.

According to on-site construction records, the crossing of the south bank of the reservoir embankment starts around 25 rings, which is about 50 meters from the start of the shield tunneling, and is completed around 150 rings, which is about 300 meters from the start of the shield tunneling. As the shield tunneling machine advances, due to the increase in tunnel burial

depth and changes in soil layer, the thrust and torque of the shield tunneling machine gradually increase. Subsequently, due to the gradual fixation of burial depth, the shield tunneling machine moves forward parallel to the ground, and the thrust and torque of the shield tunneling machine gradually stabilize. During the process of crossing the embankment, the speed of the excavation machine is an average of 15mm/min, which is adjusted appropriately according to the soil layer situation.

During the shield tunneling process, two steps are mainly used for surface deformation control, namely synchronous grouting and secondary grouting. According to the trend of the change in grouting amount, it can be seen that during the process of shield tunneling machine passing through the dam, from ring 25 to ring 150, the grouting amount is significantly larger. By controlling the deformation of the dam top through grouting, excessive settlement can be prevented from causing the dam to collapse, leak, and other situations.

5.2 Railway foundation reinforcement methods

Due to its sensitivity to deformation, railways require special reinforcement. On site, the reinforcement of the cross section between the railway and shield tunnel was completed before the shield tunneling under the Handan Jinan Railway. The reinforcement of the strata was carried out using sleeve valve pipes and rotary jet grouting piles. The boundary of the reinforcement area is perpendicular to the railway line, with a minimum distance of 5m from the outer side of the shield tunnel, and the reinforcement depth is up to the arch of the shield tunnel. The specific reinforcement method is shown in Figure 11.

Figure 11. Schematic diagram of railway track reinforcement.

At the same time, in the reinforcement area, D-shaped temporary beams are used to erect railway tracks to prevent excessive settlement during shield tunneling through the railway, affecting railway traffic and even threatening the safe passage of trains. D-shaped temporary beams can ensure that shield tunneling does not interrupt the operation of the railway business line when passing under it. The relationship between D-shaped beam and fulcrum pile is shown in Figure 12. After actual testing, the deformation of the railway during the shield tunneling process has not

affected the opening of vehicles. At the same time, in order to prevent safety accidents, trains need to slow down during construction. The design speed of the Hanji Railway is 120km/h, starting from 800m away from the construction site. When it reaches the deceleration landmark, it slows down to 45km/h. After the tail of the train departs from the deceleration landmark on the other side, it starts to accelerate to the design speed.

Through the reinforcement of rotary jet grouting columns, the joint reinforcement of temporary beams and support piles, and the control of train speed during the passing process, various measures

Figure 12. Layout plan of temporary beam and support Pile.

can be implemented together, which not only does not affect the normal operation of the railway, but also achieves the purpose of settlement control.

6 CONCLUSIONS

Based on model testing and on-site monitoring, combined with construction technology methods, the following conclusions have been drawn from this study:

- (1) For surface settlement caused by large-diameter mud water balance shield tunneling, the deformation of the ground conforms to the concave settlement groove calculated by the Peck formula. The maximum settlement is located at the tunnel axis, and the settlement gradually decreases towards both sides. This proves that the indoor simulation method is more accurate and can accurately reflect the working conditions;
- (2) Large diameter mud water balance shield tunneling, due to its significant disturbance to the soil and the tunnel depth being smaller than the diameter of the shield tunnel, has a significant impact on the surface without control, which can easily cause deformation and collapse of surface buildings. Therefore, it is necessary to reinforce the foundation of existing buildings. For example, in this study, the railway track is reinforced with rotary jet grouting in advance, and D-shaped beams are used to reinforce the railway track, which can control surface deformation, Simultaneously ensuring the normal passage of railways;
- (3) For existing reservoir embankments, especially those discussed in this article that were

constructed earlier and lacked soil information, settlement control can be achieved through monitoring and dynamic adjustment of grouting. By controlling the grouting pressure, monitoring the deformation of the dam, reducing the grouting pressure when the surface rises, and increasing the grouting pressure when the surface settles, surface deformation can be controlled and the risk of shield tunneling through the dam construction can be reduced.

ABSTRACT: Shield clogging is a common issue when tunneling through cohesive soil layers. Dispersants are frequently employed to disintegrate and disperse the clay adhered to the cutter head and cutters. This paper uses slaking tests to investigate the slaking characteristics of a mixed soil composed of kaolin and montmorillonite with different void ratios under the influence of dispersants and pure water. The results indicate the following: (1) Surface slaking is the primary process in mixed soil slaking, resulting in a slightly turbid solution and continuous peeling of clay debris from the clay block surface; (2) Influenced by the extent of the water-soil interaction area, the slaking percentage over time displays an “S” shaped curve; (3) The equivalent slaking thickness of clay blocks can better evaluate clay slaking characteristics in terms of size change. The equivalent slaking thickness gradually increases over time, followed by a steady acceleration, and it can be divided into the initial stable and rapid development periods. (4) With an increased void ratio, the initial stable period of mixed soil gradually shortens, and the slaking rate in the rapid development period first increases and then decreases. Dispersants can significantly shorten the initial stable period of mixed soil.

Keywords: Clay, Slaking characteristics, Void ratio, Dispersant

1 INTRODUCTION

When shield tunneling in cohesive soil, clay easily adheres to the cutterhead and cutters' surfaces. If not dealt with in time, under the influence of high temperature and consolidation, the clay will quickly solidify into tough mud cakes, blocking the cutterhead openings and seriously affecting the tunneling efficiency of the shield machine. To mitigate this issue, dispersants or dispersible foam agents are commonly injected into the shield machine's cutterhead and soil bin. These agents help disintegrate and disperse the mud cakes, detaching them from the cutterhead and cutters' surfaces (Du et al., 2022; Fang et al., 2022). An in-depth analysis of the slaking characteristic of clay is helpful for better carrying out the prevention and control of shield clogging.

In recent years, many scholars have researched the slaking characteristics of clay. Moriwaki and Mitchell (1977) conducted the slaking experiments on kaolin, illite, and montmorillonite, pointing out that soil slaking can be divided into four modes: swelling slaking, dispersion slaking, surface slaking, and body slaking. Swelling slaking is manifested as excessive expansion leading to loose clay structure and slaking; dispersion slaking is displayed as the dispersion of clay particles without macroscopic cracking; surface slaking is manifested as the continuous falling of debris and fragments on the surface of clay blocks; body slaking is displayed as the overall fracture of clay blocks. The mass variation curve of clay during the slaking process can be derived by monitoring the changes in the mass of clay blocks. Typically, this curve exhibits an 'S' shape. Li et al. (2019) and Wang et al. (2019) divided the slaking

*Corresponding author: zhuhanbiao@csu.edu.cn

process of loess into three stages: immersion, softening, and slaking, based on the variation curve of slaking. The softening stage is the main stage of clay slaking. According to the variation law of the slaking curve, multiple evaluation indicators of clay slaking can be obtained, such as the slaking rate in the middle section of the slaking rate curve(Wang et al., 2019), the slaking rate at 8 hours(Große et al., 2015), the time required for 30% of the soil mass to disintegrate(Große et al., 2015), the initial slope of the slaking rate curve(Lim, 2006), the average slaking rate(Yin et al., 2020; Ze et al., 2019), the relative surface area of the aggregate at 10 minutes of slaking(Jones et al., 2021), and the ratio of the final slaking rate to the slaking time(Wei et al., 2022), etc. However, there are currently no widely recognized evaluation indicators and methods for clay slaking, so it is necessary to analyze the slaking characteristics of clay in depth to better evaluate its slaking properties.

The types of forces that affect the slaking of clay are diverse, including electrostatic repulsive forces, expansion or hydration repulsion, pore pressure, and mechanical breakdown(Große et al., 2015; Hu et al., 2018). These forces can disrupt the connections between particles and cause clay slaking. At the same time, moisture content is also an essential factor affecting the characteristics of clay slaking. Ze et al.(2019) pointed out that the slaking rate of Moscow covering loam decreases with increasing moisture content. There is a “critical moisture content” above which the soil does not entirely slake. Robinson and Dasari(2004) studied the slaking characteristics of kaolin clay and found that soil blocks with moisture content close to the liquid limit are the most difficult to slake. In shield tunneling projects, the tunnel is often located below the groundwater level, and the saturated soil is the main geological layer that shield tunneling passes through. Saturated soil usually does not have matric suction, and the void ratio is one of the main factors affecting the structure of saturated soil. Therefore, the variation of void ratio may be one of the main reasons for the differences in saturated clay slaking characteristics, and there is currently little research on the influence of void ratio on clay slaking characteristics. In addition, factors that affect clay slaking also include clay matrix properties and solution properties(Wang et al., 2017), but the role of solution properties in existing studies is often overlooked. In the shield tunneling process, the dispersant is commonly used to treat the shield clogging by soaking it in the chamber, causing the mud cake in the dispersant to slake and disperse, and detach from the surface of the metal cutterhead (Du et al., 2022; Wei et al., 2022). Investigating the influence of dispersants on clay slaking helps prevent and treat shield clogging and deepens the understanding of clay slaking.

To deeply investigate the characteristics of clay slaking and the influence of dispersants, this paper first studied the slaking characteristics of the mixed soil blocks of kaolin and montmorillonite over time

through slaking experiments. Then, based on the proposed equivalent slaking thickness, the slaking law of the mixed soil under the action of dispersants and pure water is explored under different porosity ratios.

2 EXPERIMENTAL RESEARCH

2.1 Testing materials

The mixed soil of kaolin and montmorillonite was used as a typical clay material. It comprises 10% montmorillonite and 90% kaolin, with a liquid limit of 54.43%, a plastic limit of 27.47%, and a plasticity index of 26.96. It belongs to high liquid limit clay, and its mineral composition is shown in Table 1. The commercial dispersant was used to study the effect of changes in solution properties on clay slaking, and their role in promoting clay slaking has been confirmed (Du et al., 2022; Liu et al., 2019). Chemical composition analysis showed that the main components of the dispersant are anionic surfactant sodium alkane sulfonate, combined with cationic surfactant Dodecyl trimethyl ammonium chloride, nonionic surfactant Polyethylene glycol (PEG500), and Lauryl Alkaline-8.

Table 1. Results of mineral composition analyzation.

Mineral name	Chemical formula	Mass percentage/%
Kaolinite	$Al_2(Si_2O_5)(OH)_4$	75.33
Muscovite	$KAl_{2.2}(Si_3Al)_{0.975}O_{10}((OH)_{1.72}O_{0.28})$	12.6
Na-montmorillonite	$Na_{0.3}(Al,Mg)_2Si_4O_{10}(OH)_2$	4.88
Soda feldspar	$NaAlSi_3O_8$	2.83
Quartz	SiO_2	2.32
Ca-montmorillonite	$Ca_{0.2}(Al,Mg)_2Si_4O_{10}(OH)_2$	1.41
Microcline	$(K_{0.95}Na_{0.05})(AlSi_3O_8)$	0.55
Calcite	$CaCO_3$	0.08

Table 2. Component analysis results of dispersants.

Component name	Characteristics	Mass percentage/%
Dodecyl trimethyl ammonium chloride	Cationic surfactant	1.5
Polyethylene glycol	Nonionic surfactant	1.5
Lauryl Alkaline-8	Nonionic surfactant	0.75
Sodium alkane sulfonate	Anionic surfactant	4.5
Water	Solvent	92.5

2.2 Testing approach

The slaking test is commonly used to evaluate the slaking characteristics of clay (Moriwaki et al., 1977; Qi et al., 2020), as it can intuitively observe the slaking features of clay blocks and obtain time-varying parameters for clay slaking. A new slaking apparatus (Figure 1) is used to study the law of clay block slaking. The slaking apparatus consists of an organic glass cylinder, a high-precision buoyancy scale (with an accuracy of 0.001g and a range of 500g), a mesh plate, etc. In the test, the clay block was placed on the mesh plate under the buoyancy scale, and the mesh plate and the clay block were immersed in the solution in the organic glass cylinder. The curve of clay slaking mass over time was obtained by collecting the readings of the buoyancy scale. The change in the reading of the buoyancy scale is mainly due to the slaked clay falling off the mesh plate and the decrease in buoyancy caused by the escape of pore bubbles in the clay block. When considering the correction of the buoyancy scale reading by the pore gas, it is usually assumed that the block mass and the pore gas are uniformly distributed (Zhang and Tang, 2013). Therefore, when the clay and pore gas of a certain buoyancy and volume detach from the block during slaking, their buoyancy accounts for a certain proportion of the total buoyancy of the clay and pore gas. In other words, the change in volume of the slaked clay block is proportional to the change in buoyancy (reading of the buoyancy scale). The slaking percentage of the sample can be obtained by applying Equation 1, and the slaking percentage represents the ratio of the slaked block's volume to the original block's (Tinebra et al., 2019).

$$A_t = \frac{R_0 - R_t}{R_0 - R_z} \times 100\% \quad (1)$$

where: A_t is the slaking percentage (%) of the clay block at moment t ; R_0 is the buoyancy scale reading at the beginning of the clay block slaking; R_t is the buoyancy scale reading at moment t of the soil block slaking; R_z is the buoyancy scale reading when the soil block is completely slaking.

Figure 1. The new slaking apparatus.

When the soil block is a polygon with corners, the corners disintegrate first, eventually leading the soil block to a more rounded shape (Moriwaki et al., 1977). To reduce the influence of shape changes during clay slaking, a cylindrical soil block with a radius (R) of 25mm and height (H) of 35mm was used for the slaking test. The mesh plate aperture is a key parameter determining whether the slaked unit falls off. The preliminary tests showed that surface slaking is the dominant mechanism for clay slaking, and the slaked unit was usually smaller than 5mm. In order to prevent the slaking unit from blocking the mesh plate aperture, the mesh plate aperture was set to 10mm according to relevant specifications (Yang and Wang, 1999). Furthermore, consistent with the Atterberg limit test (GB/T50123, 2019), the clay was fully compacted to remove air from the soil, and a fully saturated and uniform state was ensured for the soil blocks under different working conditions in the test. The specific test steps are as follows:

- (a) A predetermined mass of dry clay was mixed with water to achieve a specified water content, w . After thorough mixing, the mixture was sealed and left undisturbed in a cool environment for 24 hours, allowing for uniform water distribution within the soil sample and the complete hydration of clay minerals.
- (b) The compactor was placed on a rigid foundation. And the surface of the compaction meter hammer and base was covered with a layer of cling film to prevent clay adhesion.
- (c) The soil sample was divided into four equal portions, added to a compaction mold, and then leveled. After each addition, a compaction hammer with a mass of 482.5g was dropped from a height of 26.5cm to compact the clay. The clay was compacted ten times on both the front and back sides, with enough compaction cycles to fully release the gas in the soil sample and ensure its saturation. The adjacent interfaces between each layer were roughed, and finally, a fully saturated and uniform test specimen was obtained.
- (d) The soil block was pushed out of the compaction mold using a compaction hammer, and the volume and mass of the soil block were recorded. The soil sample's void ratio (e) and saturation (S) were measured using appropriate instruments or calculations.
- (e) The glass cylinder was filled with the specified solution level for slaking. The buoyancy scale was zeroed, and then the soil block was placed in the center of the mesh plate and hung from the buoyancy scale. The mesh plate was quickly immersed in the solution, ensuring the clay block was positioned approximately 3cm below the water level. Photographs of the soil block's slaking state were taken at intervals of one minute or smaller, and the readings from the buoyancy scale were recorded. Enough readings were obtained to plot a continuous and smooth curve.

(f) The experiment concludes when the soil block has completely passed through the mesh plate.

The slaking test conditions are shown in Table 3, with three tests conducted for each condition. The obtained saturation of the soil samples in all conditions is greater than 95%. Therefore, it can be assumed that all the soil samples were fully saturated. And the experiment aimed to investigate the influence of different void ratios on clay slaking.

Table 3. The slaking test conditions.

Soil Types	Water content (w)/%	Void ratio (e)	Saturation (S)
mixed soil composed of kaolin and montmorillonite	27.47	0.754	0.969
	30.84	0.829	0.989
	34.21	0.909	1.000
	37.58	0.999	1.000
	40.95	1.089	1.000
	44.32	1.178	1.000
	47.69	1.268	1.000

3 ANALYSIS OF THE TESTING RESULTS

3.1 Time-varying characteristics of clay slaking percentage

Figure 2 shows a schematic diagram of clay slaking. It is evident that among the four slaking modes described by Moriwaki and Mitchell, namely, swelling slaking, dispersion slaking, surface slaking, and body slaking(1977), the clay blocks in the experiment mainly undergo surface slaking, with a slight dispersion slaking observed (the solution is slightly turbid). During the slaking process, the clay debris on the clay block surface continuously peeled off,

gradually reducing volume. Figure 3 presents the variation curve of the slaking percentage of the clay blocks under different void ratios. Due to the abundance of recorded data, a continuous smooth curve is used to represent the clay slaking process. The slaking curve of the clay blocks generally follows an “S” shape. In the initial stage of slaking, there is no significant peeling of the clay debris. However, in some instances, such as when the void ratio of the clay block is 0.754 and the water content is relatively low, incomplete saturation of the block leads to a negative slaking percentage due to the release of air. As the soaking time of the clay block increases, the repulsive force between clay particles continues to develop, gradually offsetting the interparticle cohesive force, thus increasing the clay’s slaking rate. When the slaking rate reached its maximum, the volume of the clay block decreased continuously, and the slaking rate decreased due to the reduction in the interaction surface area between the solution and the clay block. It can be observed that the surface area of the clay block constrains the development of the slaking curve. When the surface area is large, the water-soil interaction area is also large, resulting in a higher slaking rate. During the slaking process of the specimen, the surface area continuously decreases, making it difficult to reflect the essential characteristics of clay slaking through the variation of slaking percentage or slaking mass over time.

3.2 Time-varying characteristics of the equivalent slaking thickness of clay

Considering the influence of the contact area between soil blocks and solution on the slaking percentage, Equation (2) defines the d_t value as the ratio of the soil block slaking volume to the soil block’s surface area at time t. Clearly, d_t represents the equivalent slaking thickness of the soil block during that period,

Figure 2. Schematic diagram of clay slaking.

Figure 3. The change in the slaking percentage of the clay blocks over time with different void ratios under the action of pure water.

indicating the soil block's size change. It eliminates the influence of surface area changes on the characteristics of the slaking curve and better reflects the slaking law of the soil block. As discussed in section 3.1, the clay block follows a surface slaking mode, where the shape of the block remains changed little during the slaking process. Therefore, as shown in Figure 4, starting with the change in the equivalent slaking thickness of the clay, we assume that the slaking rate is the same at any position of the soil block surface. By equal slaking rate, Equation (3) was established to convert the slaking percentage A_t into the equivalent slaking thickness d_t of the soil block, representing the cumulative reduction in the size of the soil block during slaking.

$$d_t = \frac{V_t}{S_t} \quad (2)$$

where: d_t is the equivalent slaking thickness of the soil block at time t ; V_t is the block volume slaked at time t ; S_t is the surface area of the soil block at time t .

$$\frac{(H - 2 \times d_t) \times (R - d_t)^2 \times \pi}{H \times R^2 \times \pi} = 1 - A_t \quad (3)$$

where: A_t is the slaking percentage at time t ; H is the original thickness of the soil block, with a value of 35mm in this study; R is the original radius of the soil block, with a value of 25mm in this study.

Figure 5 shows the changes in the equivalent slaking thickness of the mixed soil over time under the influence of pure water and dispersant. The change in the equivalent slaking thickness of the clay can generally be divided into two stages: the initial stable and the rapid development period. During the initial stable period, the solution infiltrates the clay pores, and the inter-particle connection force is gradually weakened under the action of the solution, causing the rate of change in the equivalent slaking thickness to increase gradually. After reaching the

Figure 4. Schematic diagram of the axial section.

maximum change rate of the equivalent disintegration thickness, it enters the rapid development period, after which the rate of change in the equivalent slaking thickness of the clay remains unchanged. Meanwhile, since the height of the soil block is 35mm, the soil block is completely slaking when the equivalent slaking thickness d equals 17.5mm. When the size of the soil block is smaller than that of the mesh plate aperture, the direct fall of the soil block from the mesh plate causes a sudden change at the final moment on the slaking curve. In Figure 5a, the mixed soil with a small void rate was more difficult to slake under pure water than with a large void rate. When the void rate is less than 0.829, the initial stable period exceeds 7 hours, and as the void rate increases, the total slaking time of the clay first decreases and then increases. In Figure 5b, the action of the dispersant significantly accelerates the soil slaking. When the void rate is 0.829, the slaking of the mixed soil is the fastest.

3.3 Analysis of slaking characteristics parameters

The previous section revealed that the equivalent slaking thickness of the soil exhibits two stages: the initial stable and rapid development periods. Clearly, the pore ratio and dispersant have different effects and mechanisms on the soil slaking in these two stages. Therefore, to analyze the characteristics of these two time-varying stages, the initial stable period duration (t_0) is selected to characterize the initial stability of the soil, and the slaking rate (v_t) during the rapid development period is selected to represent the speed of slaking in this stage. As shown in Figure 6, the initial stable period duration refers to the time the soil undergoes before entering the rapid development period, and the slaking rate during the rapid development period represents the change rate in the equivalent slaking thickness in this stage, as shown in Equation (4). Specifically, when the soil sample exhibits block-like "splitting", the slaking curve before the occurrence of "splitting" is used as the basis for obtaining t_0 and v_t .

(a) Time-varying curve of the equivalent slaking thickness of the mixed soil under the action of pure water

(b) Time-varying curve of the equivalent slaking thickness of the mixed soil under the action of dispersant

Figure 5. The change in the equivalent slaking thickness of mixed soil blocks slaking overtime under the different void ratios.

$$v_t = \frac{d_t - d_{t+\Delta t}}{\Delta t} \quad (4)$$

where: v_t is the change rate of equivalent slaking thickness at any given time t , d_t is the equivalent slaking thickness at time t (in mm), and $d_{t+\Delta t}$ is the equivalent slaking thickness at time $t+\Delta t$ (in mm).

Figure 7 shows the variation of the initial stable period duration and the rapid development period slaking rate of the mixed soil under the action of pure water and dispersant. Since the void ratio is less than 0.829, the clay does not slake within 7 hours under the action of pure water, so there are no corresponding data points in the figure. Under pure water, as the void ratio increases, the interparticle bonding strength between clay particles decreases, resulting in a shorter initial stable period of the mixed soil. However, due to the synchronous reduction of clay slaking mechanisms such as expansion repulsion, the slaking rate during the rapid development period first increases and then decreases. In

Figure 6. Schematic diagram for determining characteristic parameters of slaking.

(a) Changes in the initial stabilization period duration of the mixed soil

(b) Changes in the slaking rate during the rapid development period of the mixed soil

Figure 7. The change of the initial stable period and the slaking rate of the rapid development period of mixed soil over void ratio under different solutions.

addition, compared to pure water, the surfactant in the dispersant reduces the solution's surface tension, accelerates the liquid infiltration into the clay block, and promotes the dispersion and

slaking of the clay. Therefore, under the action of the dispersant, the initial stable period duration of the soil is significantly shortened, and it is less affected by the void ratio. The slaking rate during the rapid development period also shows a characteristic of increasing first and then decreasing with the increase of the void ratio.

4 CONCLUSIONS

This paper investigates the time-varying slaking characteristics of kaolin and montmorillonite mixed soil through slaking tests. Based on the proposed equivalent slaking thickness, the slaking patterns of the mixed soil with different void ratios under the influence of dispersants and pure water were explored. The main conclusions are as follows:

- (1) Among the four types of slaking modes, the primary mode of mixed soil slaking is surface slaking, with the solution becoming slightly turbid and clay debris continuously peeling off the clay block surface during the process;
- (2) Influenced by the extent of the water-soil interaction area, the slaking rate displays an “S” shaped curve over time. The equivalent slaking thickness of clay blocks can better evaluate clay slaking characteristics from the perspective of size change.
- (3) The equivalent slaking thickness increases gradually over time and then steadily increases at a certain speed, and it can be divided into the initial stable and rapid development periods. Under pure water, the slaking of the mixed soil becomes more difficult when the porosity is small. With the increase of porosity, the slaking duration first decreases and then increases, while the dispersant can significantly accelerate the soil slaking.
- (4) With the increased void ratio, the initial stable period of mixed soil gradually shortens, and the slaking rate in the rapid development period first increases and then decreases. Dispersants can significantly shorten the initial stable period of the mixed soil.

Revealing inherent mechanism affecting loess-metal interface adhesion properties: Insights from macro- and atomic-scale tests

Bin Wu, Wen-Chieh Cheng* & Xue-Dong Bai

School of Civil Engineering, Xi'an University of Architecture and Technology, Xi'an, China

Shaanxi Key Laboratory of Geotechnical and Underground Space Engineering (XAUAT), Xi'an, China

ABSTRACT: Although previous studies have greatly enhanced our understanding regarding adhesion, the interplay of the loess with cutting tools is still not clear raising the potential of unplanned downtimes. In this study, three laboratory tests were applied to explore the inherent mechanism affecting the loess-metal interface (termed interface hereafter) adhesion properties, in which the sand-loess, kaolinite-loess, and montmorillonite-loess mixtures were considered. The pull-out and sliding plate tests were introduced to measure the normal and tangential adhesion forces at the interface, while the mixing test was used to determine the adhesion ratio of the soil mixtures. In addition, the atomic force microscopy (AFM) test was applied to investigate the surface morphology and adhesion characteristics. Results showed that the normal adhesion force at the interface is governed by the intermolecular force and the capillary tension. The flatter the contact interface, the easier the water ring development. The sand addition of 75% significantly reduced both the normal and tangential adhesion forces. Further, the adhesion ratio applied to the sand-loess mixtures remained below 0.4, indicating that the sand acted as an addition against interface adhesion. Apart from that, both the normal and tangential adhesion forces generally increased with increasing kaolinite and montmorillonite fractions. The adhesion ratio applied to the loess-kaolinite mixtures remained above 0.4, whereas it applied to the montmorillonite-loess mixtures remained way higher than 0.4. These results indicated that the kaolinite and montmorillonite are featured with a high adhesion potential and a high clogging anomaly possibility (soil consistency prior to its peak). Practitioners, while shield tunnelling, should be aware of groundwater intrusion preventing the montmorillonite-loess mixtures from turning into critical sticky materials.

Keywords: Soil adhesion ratio, Soil consistency, Tangential adhesion force, Normal adhesion force

1 INTRODUCTION

While tunnelling in the loess strata, the shield cutterhead is often adhered with the soil, and then the “mud cake” will be formed on the cutterhead after extrusion, which causes the clogging of the soil inlet hole on cutterhead. The formation of mud cake will cause the problems such as increased torque of cutterhead, slower tunnelling speed and tool wear, delaying the construction schedule. Therefore, accurate evaluation of the loess adhesion properties is essential in the development and utilization of underground space so that appropriate preventive and disposal measures can be taken.

A series of researches targeting soil adhesion characteristic have been carried out till now. Thewes et al. (1999, 2004, 2012, 2013, 2016) proposed several basic mechanisms which cause

clogging of soil in shields, including adhesion, bridging, cohesion and insolubility, and concluded that adhesion is the main cause of clogging. The researches also related the adhesion risk to the consistency index of soil as well as plasticity index, and presented the empirical prediction plot for predicting the clogging risk, which provides a reference for subsequent researches. Fountaine et al. (1954), based on the study of the adhesion behaviour at soil-metal interface, concluded that interface adhesion occurs due to the cohesive force between soil particles being smaller than the soil-metal interface adhesion, and proposed two models of interface adhesion: the soil with low moisture content and large particles contacts the metal with the water rings, and the other is for soil with high moisture content and fine particles, in which the water rings between the soil particles and the metal

*Corresponding author: w-c.cheng@xauat.edu.cn

have linked to form a water film. As for laboratory tests, Zumsteg et al. (2013) put forward the mixing and plate shear test to quantify the adhesion and clogging behaviour of clay, and used these methods to further establish the relationship between adhesion and the soil physical properties, in particular the relationship between adhesion and soil strength. Then Oliveira et al. (2019a, 2019b) continued the research by proposing a simple laboratory test to characterize adhesion properties of cohesive soil, considering different soil components. Kang et al. (2019) evaluated the clogging potential with laboratory drilling test and semi-empirical plot, and found that bentonite samples have higher clogging potential than the pure kaolinite samples. In addition, Wang et al. (2020) carried out the plate shear test and investigated the variation rule of tangential adhesion strength of bentonite-kaolinite mixture with consistency index under different normal stresses. The test results showed that as the water content increased, the tangential adhesion strength first decreased significantly and then remained almost constant.

The normal adhesion force and the tangential adhesion force are usually not measured in a separate manner by the existing works, causing difficulty in exploring the role of intermolecular force and capillary tension in the change in normal adhesion force and tangential adhesion force. The above reveals several research gaps and shortcomings that remain to be addressed. The main objectives of this study are to (1) measure the normal adhesion force and the tangential adhesion force at the soil mixture-metal interface separately using the proposed pull-out and plate sliding tests respectively, and the adhesion ratio using the mixing tests; (2) explore the role of intermolecular force and capillary tension in affecting the interface adhesion properties; and (3) reveal further the adhesion reduction mechanism.

2 TESTING MATERIALS AND METHODS

2.1 Testing materials

Loess that contains mainly silt particles and is widespread in Northwest China at a depth range of 4-5 m was taken from Lantian County, Shaanxi Province. The physical property parameters of the loess were summarized in Table 1. Since the loess is featured with 5% sand, 85% silt, and 10% clay and possesses a plasticity index of 12.75%, it was classed as low plasticity clay (CL) according to the Unified Soil Classification System (USCS). In this study, three additions, namely sand, kaolinite, and montmorillonite, were added to the loess forming the soil mixtures. The soil mixtures were applied to the pull-out, sliding plate, and mixing tests. The Atterberg limits of the soil mixtures are tabulated in Table 2.

2.2 Methods

The laboratory tests were designed as the pull-out, plate sliding and mixing test to measure the tangential and normal soil-metal interface adhesion forces and the adhesion ratio. The equipment of plate sliding test is shown in Figure 1(a), specifically a metal plate controlled by the hand winch to uniformly stabilized tilt 0-90°. And the tangential adhesion forces are measured with following steps.

Table 2. Atterberg limits of the soil mixtures.

Soil mixture	Sand or kaolinite or montmorillonite fraction (%)	Plastic limit (%)	Liquid limit (%)	Plasticity index (%)	Classification symbol
Sand-loess	25	19.9	32.4	12.5	CL

	100	34.2	83.7	49.5	CH

- (1) Firstly, configure the soil mixture at the preset moisture content and mineral fraction, then fill it into ring-shaped container with a jackhammer at the certain level of compaction;
- (2) Subsequently, put the soil mixture on the metal plate and applied positive pressure for 60 s to ensure a certain degree of contact between the soil mixture and the metal plate;
- (3) Remove the positive pressure, and slowly lift one side of the metal plate to make it tilt with a uniform speed until it stops when the soil mixture begins to slide. Then, record the tilt angle θ of the metal plate, and calculate by Equation 1 to obtain the tangential adhesion strength at the soil-metal interface.

$$\alpha_{\tau} = 4mg \cdot \sin \theta / \pi D^2 = 4F_{\tau} / \pi D^2 \quad (1)$$

where, α_{τ} is the tangential adhesion strength at the soil-metal interface (Pa); m is the mass of the soil mixture and the container (kg); g is the acceleration of gravity (9.8 N/kg); θ is the inclination angle of the metal plate when the soil mixture starts sliding ($^{\circ}$); D is the contact diameter of the soil mixture (m); F_{τ} is the tangential adhesion force at the soil-metal interface (N).

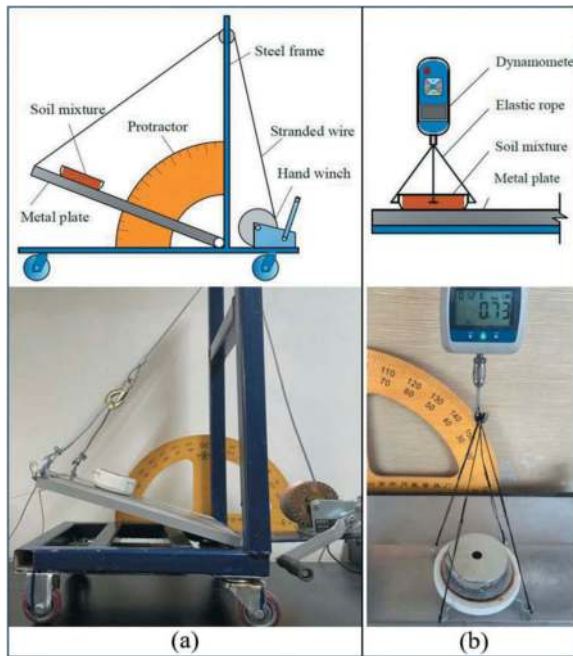

Figure 1. Proposed apparatus applied to the loess-metal interface adhesion tests: (a) plate sliding test and (b) pull-out test.

The operation of the pull-out test used to measure the normal adhesion force at the soil-metal interface is shown in Figure 1(b). The soil mixture was prepared in the same way as

described above and positive pressure was applied for 60 s. Subsequently, the elastic rope was driven by a dynamometer to lift the soil mixture at a constant slow speed until the sample was detached from the metal plate. Recording the maximum value measured by the tensiometer and the gravitational force of the soil mixture, the normal adhesion force at the soil-metal interface can be obtained by Equation 2. In addition, the friction coefficient $\tan \delta$ between the soil mixture and the metal can be calculated from the measured tangential and normal adhesion forces, as shown in Equation 3.

$$\alpha_n = 4(F_{\max} - mg) / \pi D^2 = 4F_n / \pi D^2 \quad (2)$$

$$\tan \delta = F_{\tau} / (mg \cdot \cos \theta + F_n) \quad (3)$$

Where, α_n is the normal adhesion strength at the soil-metal interface (Pa); F_{\max} is the maximum tensile force indicated by the dynamometer (N); F_n is the normal adhesion force at the soil-metal interface (N); $\tan \delta$ is the interfacial friction coefficient between the soil mixture and the metal plate.

An apparatus applied to the mixing tests is depicted in Figure 2. The mixing tests measured the masses of soil mixtures adhered to the agitator, which reflected the soil adhesion characteristics from a more macro perspective. The soil mixtures were stirred with the agitator at a constant rate and time. Then the agitator was dropped from the same height for seven times, weighing the adhered soil after each falling. The soil adhesion ratio can be calculated with Equation 4 and 5.

$$\lambda_x = G_{MTx} / G_{TOT} \quad (4)$$

$$\bar{\lambda} = (\lambda_0 + \lambda_1 + \lambda_2 + \lambda_3 + \lambda_7) / 5 \quad (5)$$

Where, G_{MTx} is the adhesion mass of soil after dropping x times (g); G_{TOT} is the total mass of soil (g); $\bar{\lambda}$ is the average adhesion ratio.

The microscopic atomic force microscopy (AFM) test was also carried out to characterize the three-dimensional morphology of the loess, kaolinite, and montmorillonite sample surfaces, and to measure the adhesion force between the metal probe and the soil particles, which was used to reveal the adhesion mechanism between the soil mixture and the metal.

The testing scheme is shown in Table 3. The adhesion tests applied to the soil mixtures of 200 cm³ take the effect of addition fraction and soil consistency into account at the normal pressure of 2 kPa. Each test is repeated three times, ensuring repeatability.

Figure 2. Apparatus applied to the mixing tests.

Table 3. Testing scheme applied to the adhesion tests.

Soil mixture	Sand or kaolinite or montmorillonite fraction (%)	Consistency index	Normal pressure (kPa)

Kaolinite-loess	10\30\50\70\100	0.6\0.4\0.2\0	
Montmorillonite-loess	10\30\50\70\100		

3 RESULTS AND DISCUSSION

3.1 Results of sand-loess mixture

When subjected to a sand fraction being 0%, the normal adhesion force first increases with increasing moisture content ($I_c = 0$ equal to the liquid limit and $I_c = 1$ equal to the plastic limit) and then decreases after reaching a peak (see Figure 3a). The maximum normal adhesion force is generally attained at $I_c = 0.4$. In case the moisture content of the loess cannot provide conditions favourable for developing water rings, the loess-metal interface contact falls into intergranular, meaning that intermolecular forces play major parts in developing the normal adhesion force. By contrast, when the moisture content is high enough, water rings are present with the interface frictional coefficient (e.g., 0.2-0.6) developing closed spaces between soil particles. Capillary tension accompanies the closed spaces' formation. When subjected to the pull-out effect, the capillary tension builds up, causing a substantial increase in the normal adhesion force. As the moisture content surpasses a threshold that corresponds to $I_c = 0.4$, the water rings transform to a water film. The higher the moisture content, the lower the capillary tension, and the lower the normal adhesion force. Despite that, the soil shear strength lower than the interface adhesion strength is deemed as the root cause leading to a decline in the normal adhesion force when subjected to $I_c < 0.4$. The maximum normal adhesion

force is shifted to the left to a place where I_c is about zero when subjected to a sand fraction equal to 50%. When subjected to a sand fraction of 75%, the normal adhesion force remains at approximately zero, irrespective of I_c , in which the interface frictional coefficient falls within a 0.6-0.7 range (see Figure 3c). On the whole, the normal adhesion force generally increases with increasing sand fraction, with the exception of a sand fraction equal to 75%. When subjected to a sand fraction of 75%, intermolecular forces play major parts in developing the normal adhesion force. The water rings accompany the interface frictional coefficient varying in a 0.2-0.6 range and help develop the capillary tension toward promoting the normal adhesion force development. By contrast, the water film prevents the capillary tension from developing impeding the normal adhesion force development.

Similarly, the tangential adhesion force first increases with increasing moisture content ($I_c = 0$ equal to the liquid limit and $I_c = 1$ equal to the plastic limit) and then decreases after reaching a peak (see Figure 3b). The maximum tangential adhesion force is generally attained at $I_c = 0.6$. The maximum normal adhesion force due to the interface frictional coefficient differs from the maximum tangential adhesion force. Despite that, the soil shear strength lower than the interface adhesion strength is considered to be the root cause that explains the formation of a reduction in the tangential adhesion force when subjected to $I_c < 0.6$. Apart from that, the adhesion ratio decreases with increasing sand fraction, and the lowest adhesion ratio is attained at a sand fraction of 75%. meaning that the higher the sand fraction applied, the lower the adhesion ratio, and the lower the potential of interface adhesion (see Figure 3d).

3.2 Results of kaolinite-loess mixture

The normal adhesion force first increases with increasing moisture content and then decreases after a peak is attained at $I_c = 0.4$. Water rings are not present at the interface when the moisture content of the loess remains at lower levels (corresponding to $I_c = 1$ to 1.2) (see Figure 4a). Under such a circumstance, intermolecular forces dominate the normal adhesion force development. The water rings accompany the moisture content high enough and help develop the capillary tension toward contributing to the normal adhesion force formation. It can also be seen from Figure 4c that a reduction in the interface frictional coefficient to 0.2 helps develop the capillary tension. As the moisture content of the loess is in excess of a threshold that corresponds to $I_c = 0.4$, the water film forms, thereby impeding the capillary tension and normal adhesion force developments. This also tallies with the formation of a decline in the normal adhesion force when subjected to $I_c < 0.4$. Apart from that, the normal adhesion force increases notably when the kaolinite fraction $> 10\%$. To summarize, the normal adhesion force in general increases with increasing kaolinite

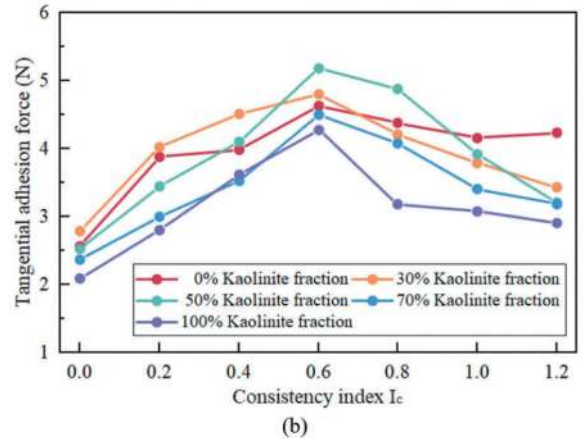

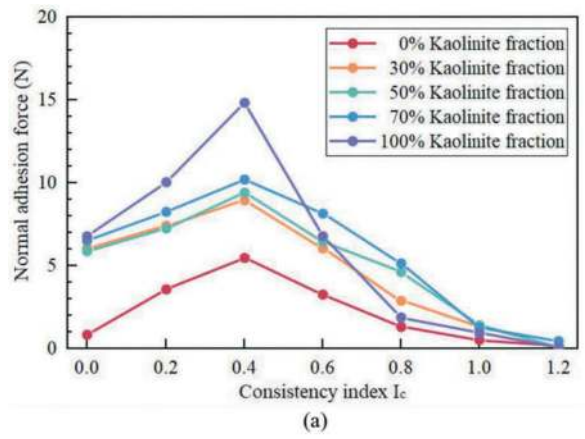

Figure 3. Results applied to the sand-loess mixture: (a) normal adhesion force, (b) tangential adhesion force, (c) AFM test, and (d) adhesion ratio.

Figure 4. Results applied to the kaolinite-loess mixture: (a) normal adhesion force, (b) tangential adhesion force, (c) AFM test, and (d) adhesion ratio.

fraction. The water rings accompany the interface frictional coefficient of approximately 0.2 promoting the normal adhesion force formation, whereas the water film prevents the capillary tension from developing impeding the normal adhesion force formation.

The tangential adhesion force increases in the first place with increasing moisture content and then decreases after a peak that corresponds to $I_c = 0.6$ is attained (see Figure 4b). The maximum normal adhesion force links to the maximum tangential adhesion force using the interface frictional coefficient. Notwithstanding that, the soil shear strength lower than the interface adhesion strength is considered the main contributor to a sharp decline in the tangential adhesion force when $I_c < 0.6$. Furthermore, a reduction in the tangential adhesion force is noted as well when the kaolinite fraction surpasses 50%. Moreover, the adhesion ratio of above 0.4 is measured, although the tangential adhesion force reduces when subjected to the kaolinite fraction $> 50\%$ (see Figure 4d). These results lead us to conclude that the adhesion ratio remains above 0.4 when the kaolinite addition intervenes in shield tunnel excavations. When subjected to $I_c < 0.6$, a sharp decline in the tangential adhesion force occurs. Although the water film prevents the capillary tension from developing, the soil shear strength lower than the interface adhesion strength is the main contributor to a substantial drop in the tangential adhesion force. As a result, the kaolinite addition raises not only the interface adhesion potential but also the clogging anomaly possibility. I_c prior to its peak aggravates further the clogging anomaly possibility.

3.3 Results of montmorillonite-loess mixture

Similarly, the normal adhesion force goes up initially with increasing moisture content and subsequently goes down after a peak that corresponds to $I_c = 0.2$ is attained (see Figure 5a). Water rings do not develop at the interface as the moisture content remains at lower levels (e.g., $I_c = 1$ to 1.2). In this case, intermolecular forces, in turn, play major parts in the normal adhesion force development. The water rings form along with the moisture content at high levels and help develop the capillary tension, contributing to the normal adhesion force formation. A reduction in the interface frictional coefficient to 0.2 provides testimony supporting the above claim (see Figure 5c). As the moisture content of the loess goes beyond a threshold (i.e., $I_c = 0.2$), the water film forms, preventing the capillary tension and normal adhesion force from developing. A slight decline in the normal adhesion force, when subjected to $I_c < 0.2$, shows good correspondence with the said phenomenon. On the other hand, the normal adhesion force increases dramatically when the montmorillonite fraction $> 50\%$. In short, the normal adhesion force increases with increasing montmorillonite fraction. The water rings form along with the interface frictional coefficient of approximately 0.2 encouraging the normal

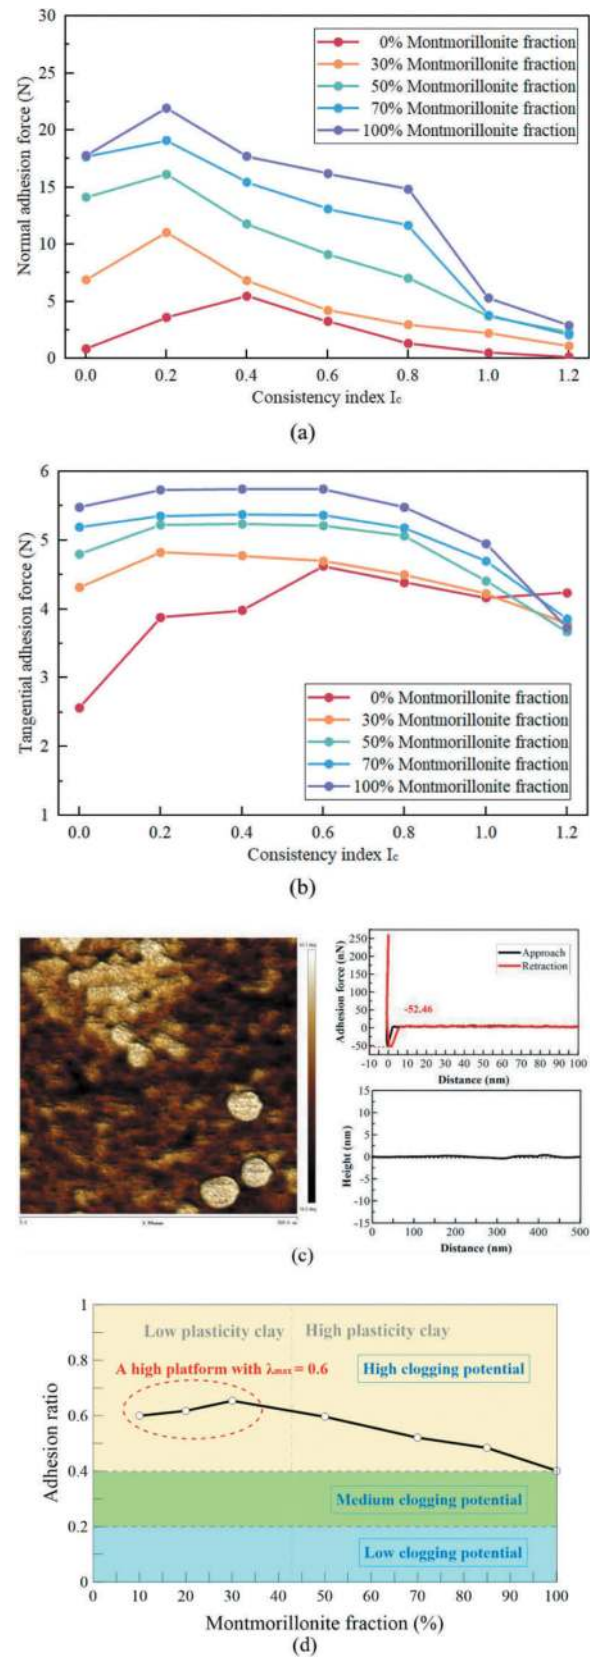

Figure 5. Results applied to the montmorillonite-loess mixture: (a) normal adhesion force, (b) tangential adhesion force, (c) AFM test, and (d) adhesion ratio.

adhesion force formation. While the water film prevents the capillary tension from developing causing difficulty in forming the normal adhesion force.

The tangential adhesion force increases in the first place with increasing moisture content and then decreases after a peak that corresponds to $I_c = 0.2$ is attained (see Figure 5b). The interface frictional coefficient explains the fact that the maximum normal adhesion force differs from the maximum tangential adhesion force. However, the soil shear strength lower than the interface adhesion strength is the main contributor of forming a decline in the tangential adhesion force when subjected to $I_c < 0.2$. Unlike the said two mixtures, the tangential adhesion force increases all the way with increasing montmorillonite fraction. Further, the adhesion ratio way above 0.4 is measured when the montmorillonite addition intervenes in tunnelling activities. Therefore, the montmorillonite addition more significantly lifts up the interface adhesion potential in comparison with the kaolinite addition and the clogging anomaly possibility. I_c prior to its peak further intensifies the clogging anomaly possibility.

4 CONCLUSIONS

According to the results of the pull-out, sliding plate, and mixing tests applied to the soil mixtures, some main conclusions can be drawn as follows:

- (1) The loess-metal interface normal adhesion force is affected by the intermolecular force and the capillary tension. While the tangential adhesion force at the loess-metal interface links to a combination of the normal adhesion force and the interface frictional coefficient. The moisture content of the soil mixtures high enough helps develop the water rings and capillary tension promoting the normal adhesion force formation. The interface frictional coefficient varying in a 0.2-0.6 range supports the above claim. The water film develops as the moisture content of the soil mixtures surpasses the threshold. It prevents the capillary tension from developing toward impeding the normal adhesion force formation.
- (2) The sand addition of 75% dramatically reduces both the normal and tangential adhesion forces. Furthermore, the adhesion ratio applied to the sand-loess mixtures remains below 0.4. These results show that the sand can act as an addition against interface adhesion. Apart from that, the normal adhesion force goes up with increasing kaolinite fraction, although the tangential adhesion force goes down with increasing kaolinite fraction in some circumstances. The adhesion ratio applied to the kaolinite-loess mixtures remains above 0.4, indicating that the kaolinite cannot act as an addition against interface

adhesion. I_c prior to its peak intensifies the clogging anomaly possibility as well.

- (3) Both the normal and tangential adhesion forces increase generally with increasing montmorillonite fraction. This is especially pronounced when the montmorillonite fraction is in excess of 50%. Further, the adhesion ratio remains way higher than 0.4, indicating that the montmorillonite cannot act as an addition against interface adhesion. Moreover, the montmorillonite-loess mixtures are featured with not only the highest adhesion potential but also the highest clogging anomaly possibility (when I_c prior to its peak). Therefore, practitioners should be aware of groundwater intrusion while tunnelling, preventing the montmorillonite-loess mixtures from turning into critical sticky materials.

Challenges and solution of super large diameter TBM tunnel construction in urban center

Xiaochun Xiao*, Lei Jiao & Yong Li
Shanghai Tunnel Engineering Co. Ltd, China

ABSTRACT: With the super large diameter TBM tunnel construction expanded from river-crossing passage to urban central expressway, new challenges would be inevitably encountered. Taking Shanghai Beiheng Expressway Package II which being opened now as an example, lots of technical difficulties and challenges including slurry TBM with diameter of 15.56m negotiating tight S curves, mining through all kinds of buildings and under-crossing live metro lines during the 6.4km tunnelling journey were introduced. To overcome the mentioned challenges, technical solutions such as TBM tailored design, lining special consideration, construction risk control measures etc. were adopted. The super large diameter TBM had negotiated 4 tight S curve sections with minimum plane radius of 500m merely, tunnelled through 89 buildings, and under-crossed 3 live metro lines successfully. The project results revealed that the quality of the tunnel was excellent, the max. ring ovality was 5cm and ring steps were less than 6mm, and disturbances to the environment, namely the ground subsidence, buildings tilt and live metro tunnels displacement were precisely controlled within the criteria, the max. rail displacement was 12.58mm which was less than specified criteria. The experience and data gained in this project could provide valuable references for similar projects in future.

Keywords: Slurry TBM, Super large diameter, Sensitive environment, Tight S curve, Tunnel through buildings, Under-cross metro tunnel

1 INTRODUCTION

In recent decades, more than 30 super large TBM tunnels whose diameter were bigger than 14m were constructed successfully in China, and the achievements gained in this field attracted worldwide attention. With the rapid development of TBM tunnel construction technologies and the growing needs of city development, extra-large TBM tunnel was gradually being expanded from river/sea crossing passage to urban centre expressway. TBM construction in urban centre indicated a more sensitive and limited construction environment, rules of ‘precise control, stable balance and slight disturbance’ must be followed, and new challenges would be inevitably encountered. Shanghai Beiheng Expressway Project (hereafter referred as BEP) was one of the above mentioned typical examples.

To make Shanghai move, a ‘3 Horizontal plus 3 Vertical lines’ expressway skeleton net was being planned and developed. As north horizontal line of it, BEP started from Beihong interchange of Middle ring in west and ended at the Neijiang road in east, refer to Figure 1. It run through 5 urban central

districts with total span of 19.1km, and 8 pairs of ramps were arranged along the route. The traffic flow of Middle ring and North-south elevated road was further reduced by interconnecting with BEP.

BEP was designed with combination of tunnels, elevated roads, flyovers and underpasses etc., and tunnel with length of 14.7km including 12km bored tunnels and 2.7km C&C was the main portion of the project. The single tube bored tunnel with outer and inner diameter of 15.0m and 13.7m respectively accommodated double decks, dual-way 6 lanes with design speed of 60km/h to serve motorcars, refer to Figure 2. The TBM tunnels were divided into 6 sections by 8 shafts and excavated with 3 slurry TBMs with 15.56m excavation diameter each.

BEP package II (hereafter referred as BEP II) was about 8km fully underground section constructed by Shanghai tunnel engineering Co.ltd, consisting of 2 tunnel drives in middle portion and 2 C&C sections at both ends, refer to Figure 1. The BEP II was completed successfully and opened to public on 18 June 2021.

Grand item of BEP II, the two tunnel drives namely section 1&2 in Figure 1 were constructed with one slurry TBM supplied by Herrenknecht. The TBM was

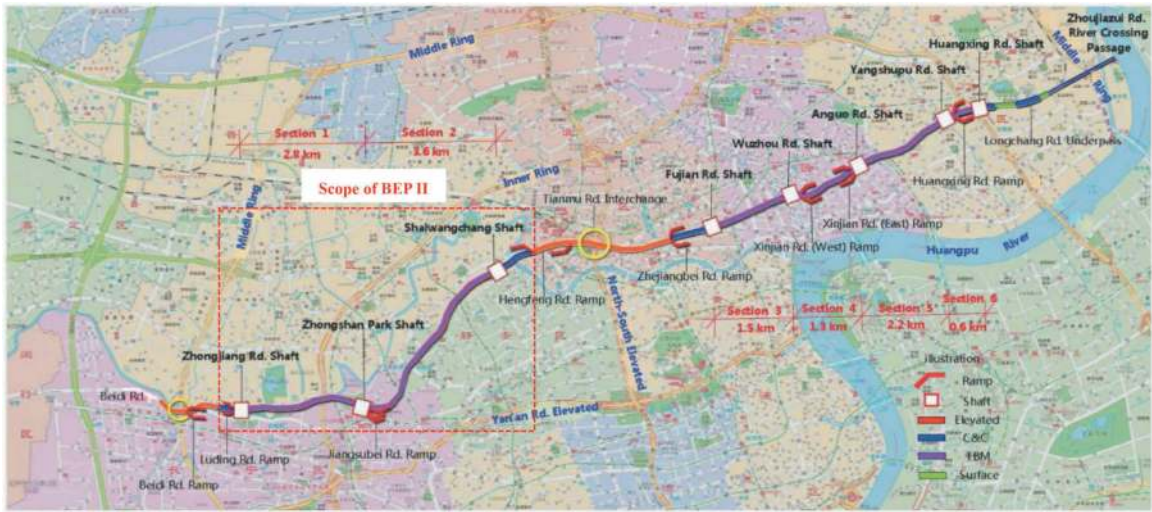

Figure 1. General layout of BEP in Shanghai part print map.

launched from Zhongjiang Rd. shaft on 26 December 2016, and received in Zhongshan park intermediate shaft on 23 December 2017, and completed the 1st drive after 2761m eastward excavation in one year. Then moved by 72m and launched again on 10 June 2018 in middle shaft. After 3665m eastward drive, the TBM finally entered into Shaiwangchang shaft on 28 October 2019 and completed the 2nd drive.

Figure 2. Bored tunnel cross section.

2 FEATURES AND CHALLENGES OF BEP II

Compared with other large diameter tunnel, one of notable features was that the BEP II tunnels run along densely residential and commercial corridor. The tunnel route passed through a large number of structures including buildings, flood retaining walls, subway system and utilities. During the crossing process, adverse factors such as tight S curves, low overburden, and unfavorable soil strata were also encountered. Such large-scale and high-risk crossings with mega TBM were unprecedented events worldwide. All these made the project known as “A cyclopedia of TBM underground boring through”.

The main features and challenges of BEP II were described as follows:

2.1 Tight S curves

Referring to the definition in Chinese code, the tunnel alignment could be defined as tight S curve if its radius was smaller than 300m for metro tunnel, while 40 times of tunnel diameter for large section tunnel. As for BEP, its excavation diameter was 15.56m, so the threshold for tight S curve alignment in this project was $R=602.24m$. Accordingly, the tight curve section accounted for 44.8% in the 1st drive and 57.9% in the 2nd drive. The distribution of the curve sections in the 2nd drive was shown in Figure 3.

Tight curve excavation would lead to severe problems such as big steps of segmental lining rings, tail skin wear by segments, failure of the tail seal due to uneven tail skin gap, and the scraping of the inner lining by the TBM backup gantries etc.

2.2 Tunnelling through buildings

As per defined effect zone along the tunnel route, 89 buildings fallen within it, including residential blocks, commercial offices and historical monuments etc., and 30 ones were above the tunnel crown and 59 ones were the case of tunnel passed within close proximity. To ensure buildings safety, the disturbance of the saturated soil strata caused by the tunnel construction must be strictly controlled within specified criteria. This was the most challenge issues faced by the construction teams.

2.3 Under-crossing live metro lines

The BEP II intersected with rail transit at 5 locations, namely line 15 (in planning), line 3(4), line 11, line 14 (in planning) and line 7 from west to east. For

Figure 3. Curve sections distribution in 2nd drive.

case of line 3 (4) which was an elevated viaduct, TBM passed by the pile foundation with horizontal clearance of 18m, the risk was therefore relatively low. On the other hand, while BEP under-crossed line 11 and 7, the vertical clearance was only 7m. It was the first time that a 15m diameter TBM crossed beneath a metro tunnel with such small clearance, and no references could be provided.

3 TIGHT S CURVES EXCAVATION

Aiming at the technical difficulties and challenges of such tight S curves excavation with super large TBM, researches focused on the TBM selection, segment special design and risk control measures were carried out.

3.1 TBM selection and design

To reserve certain safety margin, the TBM adaptability was designed based on alignment curve with minimum radius of 350m. Generally, for the curvature tunnel construction, the articulated shield TBM was preferred. Thus, 3 options of shield design including passive articulation, active articulation and fixed tail skin were proposed. The shield design was governed by the load case of 36m overburden plus additional 6-story building overload. Under this condition, the radial shield deformation at the articulation would be more than 10cm, and no strengthening measures could be taken because of the articulation. Leakage of the articulation seal would therefore be inevitable. Based on comprehensive analysis and in-depth review, STEC and Herrenknecht concluded that a shield with a fixed tail skin was the only solution for BEP II.

In order to increase the TBM's flexibility and decrease the friction between TBM skin and the ground soil, the large diameter TBM was designed to be conical. For the BEP II TBM, diameters of the front shield, middle shield and tail shield gradually decreased by 3cm respectively, and the overall conical volume was 90mm.

In addition, 4 nos. of copy cutters were equipped on the cutter edge. The extension was calculated based on curvature of the alignment. The maximum extension of the copy cutter was 50mm, corresponding to the curve with radius of R=300m.

After adopting the above measures, the selected TBM flexibility was significantly increased and met the requirements to negotiate specified tight curves. However, this caused severe disturbance on the soil strata. In this project, the TBM would tunnel through a large number of sensitive structures. In order to ensure low disturbance and safety of structures, the grouting system including synchronous grouting with 10 points, shield injection system and secondary grouting was also designed specially.

Figure 4. The TBM used in BEP II.

3.2 Segment lining design

For the extra-large diameter shield tunnel, universal segment lining and staggered assembly were always used. In case of tight curve simulation, segment taper and width were two important parameters to be considered. Generally, the segment taper was determined empirically based on factors of alignment curve radius, ring width, tail skin clearance and manufacturing etc. At the beginning of design stage, two types of universal segmental lining with segment width of 1.5m and 2.0m were comparatively studied, as shown in Table 1.

Referring to Table 1, comparison analysis showed that unique ring width had obvious advantages. Using 2m ring width would be beneficial to construction efficiency, tunnel quality and cost control. Instead, to fit the tight curve sections, the segment taper needed to be optimized based on 2m width. According to the statics data of previous large-diameter shield tunnels in Shanghai, most taper size

Table 1. Optimal analysis for different segment width.

No.	Items	Segment width (m)		
		1.5	1.5+2.0	2.0
1	Rings	4285	2339 (for 2.0m) 1460 (for 1.5m) 3799 in total	3214
2	Ring build efficiency	Low	Moderate	High
3	Joints	Maximum	Moderate	Minimum
4	Segment molds	①One type of mold. ②8 sets molds	①Two types of molds for various width. ②4 sets for 1.5m + 3 sets for 2m	①One or two type for various tapers. ②6 sets for 2m
5	TBM design	①Shortest shield tail, small tail skin clearance ②Erector: 1set	①Longer shield tail, more tail skin clearance required ②Erector:2 sets	①Longer shield tail, more tail skin clearance required ②Erector: 1 set

was 40mm, and the maximum was 80mm. Considering TBM tailskin clearance was 50mm, a variety of taper size (ranged from 40mm to 100mm) were used for DTA fitting analysis using 3-D numerical simulation model. When the fitting deviation was relatively small, two taper sizes of 40mm and 80mm (double-side tapered) were proposed. The 80mm taper size corresponded to the ring wedge slope of 1:375 (theoretical turning radius of 375m), which met the R=500m tight curve construction requirements. Based on above analysis and calculation, rules of segmental ring layout were determined as per Table 2.

Table 2. Rules of segmental ring layout.

Axis curve (m)	Ring width (m)	Arch radius R (m)	Taper (mm)
R<1000	2.0	375	80
R>1000	2.0	750	40

In addition, the gasket water resistance experiments had been carried out for tight curve cases. Important parameters were obtained to ensure the segment joints waterproof.

3.3 Tight curved section construction

In total, the length of the tight curved sections of BEP II was 2842m, which included the launching, receiving and normal drive sections. The construction records showed that, except for the launching and receiving sections, the average production rate reached 5.2r/d, and the peak value was 9r/d. All tight curved sections had been completed with high quality, ring joint openings was less than 5mm and maximum axis horizontal deviation was controlled within 9mm. Taking the first tight S curve as

example, it started at ring No.555 and ended at ring No.631 in 1st drive. There were 77 rings in total. The construction duration was 13 days, and construction rate was 5.9r/d, and the maximum construction rate reached 8 r/d.

Figure 5. Production rate of 1st tight curved section.

With the aid of efficient planning and rigorous construction management, the time of excavation and segment assembly accounted for 70%. Considering the factors such as interruption and transportation, the construction efficiency reached 80%.

(a) Turn left (b) Turn right

Figure 6. Tight curved tunnel photos.

4 TUNNELLING THROUGH BUILDINGS

4.1 Influence zone definition

Firstly the influence zone along the tunnel route need to be determined to confirm the affected structures and buildings because of tunnel excavation. In

Figure 7. Influence zone definition for different cases.

terms of extra-large TBM construction influence zone, no regulations were specified in China. To formulate the construction method statement, 3 different cases listed as follows were studied and reviewed,

- (1) case a, the 45°lines from both sides of the tunnel waist
- (2) case b, 1D offset from each side of the tunnel edges
- (3) case c, 1D offset from tunnel centre line at both sides

refer to Figure 7 for details.

According to above 3 cases, the numbers of buildings within influence zone were 173, 137 and 89 nos. respectively. Considering safety, society stability and construction cost issues, referring to previous experiences, case c was preferred as the influence zone. For BEP II, the TBM diameter was 15.56m, which meant that it had an influence zone with width of 31.12m along the tunnel route. Based on this criteria, BEP II affected 89 buildings, which the TBM under-crossed 30 buildings and side passed 59 buildings within the tunnelling influence zone in the 2nd drive.

4.2 Risk assessment

Extra-large TBM tunnelling through buildings was a typical multi-factor issue. With reference to previous engineering experience, the main parameters affecting the buildings' safety included TBM equipment, geology condition, building structure conditions, tunnel alignment, and level of the construction team etc.

For the same project, the equipment and construction team were fixed, so the risk of tunnelling through buildings was basically determined by the conditions of the soil stratum, building structures, and the tunnel alignment. Reference was made to similar projects, especially the experiences gained from the 1st drive, 6 factors were selected in the risk assessment model. Sorting by importance, they were overburden, foundation type, structure type, crossing pattern (under-crossing or passing by), structural status, tunnel alignment respectively. The risk of tunnelling through buildings could be calculated as function of the above 6 factors. The importance of

each factor was expressed by weight coefficient. Thus, the risk value for TBM tunnelling through one building could be expressed as:

$$F = \sum_{i=1}^7 \alpha_i \bullet F_i \quad (1)$$

Where, F was the gross risk value; F_i was the risk value of a certain factor; α_i was the weight coefficient of a certain factor, and the sum of all the 6 factors' weight coefficient should be 1.0.

Each factor was specifically categorized into three levels, i.e., high, moderate and low risk. In order to distinguish the risk level in number, risk estimates of each level were assigned as score of 10, 5 and 1 respectively, which denoted high risk, moderate risk and low risk respectively, as listed in Table 3.

As per formula (1), the risk of TBM tunnelling through 89 buildings within influence zone could be evaluated case by case. Based on the risk assessment results, risk management strategies and control measures for all cases were classified into 3 groups ranked grade I to III representing high risk, moderate risk and low risk respectively. Different prevention and risk control strategies were adopted for corresponding risk cases, refer to Table 4 for details.

4.3 Risk management for high risk cases

According to Table 4, 26 buildings involved with high risk (grade I) were the main focuses and challenges in BEP II. For these cases, to ensure the effectiveness of risk prevention measures, the risk resources for every high risk case were identified firstly, then composite measures targeting the major risk resources were tailored designed for the case. Some of the risk sources and corresponding methods for high risk cases were listed in Table 5. Taking case of TBM tunnelled through Zhaofeng villa F (3-6) as example, major risk resources were listed as shallow foundation, tight curve alignment, thin overburden, and risk control measures including automatic building monitor, early strength grouting, highest contingency response level were recommended.

Table 3. Risk scores for different factors.

Factor	Rate	Description	Score
Overburden (H)	Shallow	H < 1 5m	10
	Normal	15m < H < 25m	5
	Deep	H > 25m	1
Foundation	No foundation	Including independent column foundation	10
	Shallow foundation	Strips or raft foundation	5
	Deep foundation	Pile foundation	1
Structure type	Brick-concrete, masonry	Multi-layer buildings	10
	Concrete frame	Most high-rise buildings	5
	Core tube (shear wall) structure	High-rise and sky scrapes	1
TBM crossing pattern	Under-crossing	Distance < i	10
	By-pass	i < distance < 2i	5
	Beyond influence	Distance > 2i	1
Building conditions	High risk	Age > 30ys, inclination more than 10%, cracked	10
	Moderate risk	30ys > age > 10ys, inclination 5~10%, moderate cracked	5
	Low risk	Age < 10ys, small inclination less than 5%	1
Tunnel Alignment	Tight curve	R < 600m	10
	Normal curve	600m < R < 1000m	5
	Transition or straight line	R > 1000m	1

Table 4. Risk classification and risk management strategy.

Range	Risk grade	Buildings	Risk management strategy
6.5~10.0	I (High)	26 nos. (29.21%)	General measures for tunnelling through structures + special measures.
4.0~6.5	II (Moderate)	42 nos. (47.19%)	General measures for tunnelling through structures.
1.0~4.0	III (Low)	21 nos. (23.60%)	Treat as normal situation.

4.4 Construction results

In the 2nd drive, the TBM tunnelled through 89 buildings totally, and the section between ring 45 to ring 155 right after the initial drive was the worst case. In this 220m section, the tunnel alignment was

Table 5. Risk source identification and control measures for high risk buildings.

No.	Building	Risk sources	Recommended measures
1	Zhaofeng villa F(3-6)	Shallow foundation + Tight curve + Shallow overburden + Under crossing	Automatic monitor + Early strength grouting + Highest contingency response level
2	Shanghai public administration center (7)	Shallow foundation + Tight curve + Under-crossing	Automatic monitor + Shield grouting + Highest contingency response level
3	Rixu Business Center (18)	Shallow foundation + Tight curve + Under-crossing	Automatic monitor + TBM Shield grouting + Highest contingency response level
4	Galaxy Securities(22-1)	Shallow foundation + Under-crossing	Automatic monitor + Shield grouting + Highest contingency response level
5	No.234 Changning Rd (25)	Shallow foundation + Tight curve + Under-cross	Shield injection + Highest contingency response level
6	No.487 Yuyao Rd(50-1)	Shallow foundation + Tight curve + Under-crossing	Automatic monitoring + Shield grouting + Highest contingency response level
7	Yaoxi Community(50-3)	Shallow foundation + Tight curve + Under-crossing	Automatic monitoring + Shield grouting + Highest contingency response level

a R500 tight curve with 3.8% downward slope. The overburden was 10.2-23.5m which belongs to thin overburden. The TBM tunnelled through 10 buildings including Zhaofeng villa (7 buildings), Xunfa Apartment (2 buildings) and No.330 Huayang Rd. (1 building) etc, refer to Figure 8. All these buildings were shallow foundation, and Zhaofeng villa group was the historic preserved buildings with age of over 80 years. According to the risk assessment, they were cases of grade I, and measures of automatic monitoring, arly strength grouting, highest contingency level were adopted. The buildings displacement time history curves from TBM mined into the influence zone to 1 month after TBM left the building were depicted in Figure 9.

Learning from Figure 9, it could be known that due to the relatively shallow overburden, the house appears to heave between TBM cutter head entered the influential zoon and the shield tail left. In this stage, the maximum displacement was 12mm. After the tail left, the building started to sink down. The maximum absolute

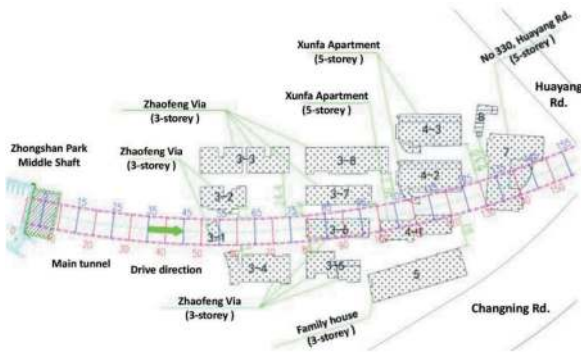

Figure 8. Plan of 2nd initial drive.

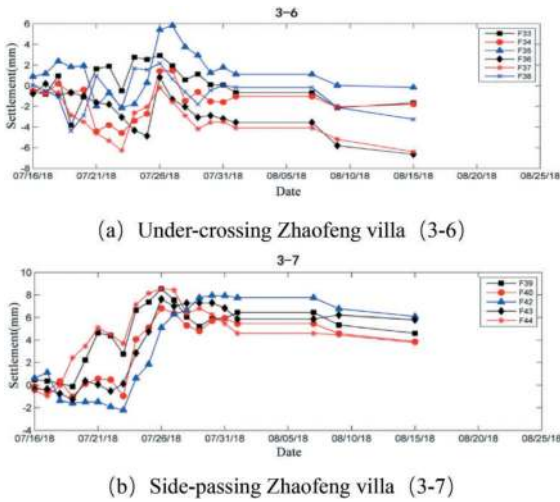

Figure 9. Settlement curve of Zhaofeng villa.

subsidence was -7mm (1 month after tail shield left). During the whole under-crossing process, the buildings were relatively stable. For both cases of under-crossing and by-passing, the max. differential settlement of the buildings was less than 10mm. Even if the old structures such as Zhaofeng villa were so fragile, there no unfavorable conditions such as structure cracks occurred.

To date, the TBM tunnelled through 89 buildings in 2nd drive successfully without any incidents reported. Instrumentation results revealed that all structures were well controlled within the allowable deformation and settlement criteria (-20mm~+10mm). During tunnelling through, the buildings were heaved slightly first, and then followed by gradually falling back after the shield had left, and the subsidence would converged 6 months later.

5 UNDER-CROSSING LIVE METRO LINES

5.1 General

Among the three cases of tunnelling through live metro lines, the TBM first crossed the viaduct of line 3 (4), and then under-crossed metro lines 11 and 7 both with about 7m clearance. The cases of passing

through metro line 11 and 7 were much more challenge and quite similar, so case of line 11 was introduced as an example in this paper.

Referring to design tunnel route, the TBM would under-cross metro line 11 between chainage K5+915 and K5+943 (ring 386 to 400 of 2nd drive) which was in the vicinity of Changning road and Jiangsu north road intersection. The intersection angle between two tunnels was 68 degree. The overburden of metro Line 11 and BEP II were 20.8m and 34.6m respectively with a clearance of 7.06m, the alignment of the BEP II was a R=500m tight curve in plane. Metro Line 11 located within ⑤₁(Grey silty clay) layer and covered with ① (Filled), ②₁(Brown yellow grayish yellow clay), ③(Grey muddy silty clay), ④(Grey mucky clay) soil layers above the tunnel crown and BEP II tunnel located within ⑦₂ (Straw grey silty fine sand) layer, ⑦₁ (Straw-grey silt) layer at the tunnel crown and ⑧₁₋₁ (Grey clay) layer at the invert. There was a 4m layer of ⑥(Dark green silty clay stiff clay) in between two layer tunnels. Details were illustrated in Figure 10, 11.

Figure 10. Plane of BEP tunnel and metro line 11 intersection.

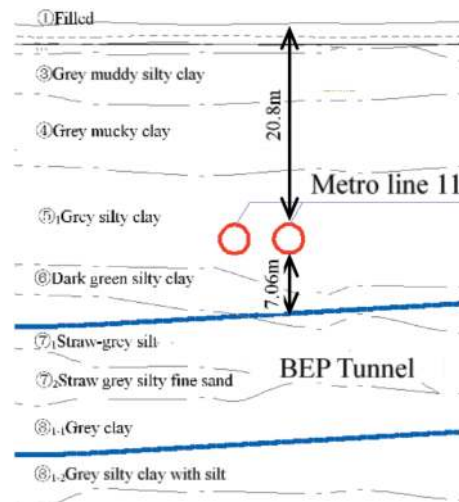

Figure 11. Cross section of the intersection.

Construction of under-crossing live metro lines faced lots of technical difficulties and challenges including: (1) no similar experiences could be provided; (2) the protection standards for the metro tunnel were not specified; (3) BEP II tunnel's alignment was R=500 tight curve; (4) it also under-crossed lots of buildings and utilities at this intersection.

5.2 Metro tunnel displacement control criteria

In view of the fact that displacement control criteria for the large-diameter TBM tunnelling through metro tunnel under such conditions were not defined. At the early stage of scheme design, previous cases were investigated and summarized in detail, including other under-crossing metro tunnel cases and the BEP II's TBM performance of tunnelling through buildings. Considering the geological and environment condition at the intersection, lots of special expert consultations were held. Criteria of the metro tunnel allowed displacement were agreed and defined as -20mm~+20mm for both cases of line 11 and 7.

5.3 Construction organization

To avoid accidents especially big impact to the rail traffic caused by TBM mining construction, some experts and government officials suggested shutting down the metro system during under-crossing construction. After in-depth evaluation, it was considered that the train outage would lead a great impact on the society, especially in the later stage, the situation of large TBM mining through live rail transit will occur frequently in other projects. Thus, in the process of scheme demonstration, two options were put forward on the premise that the train did not stop operation, i.e. intermittent drive and continuous drive. A detailed comparison was carried between the two options, and the option 2 was selected eventually. Considering the vibration influence on the excavation face stability caused by the train movement, Shentong group the metro system owner determined to limit trains' speed from normal 60km/h to 15km/h in this section based on field tests during the TBM tunnelling construction.

5.4 Under-crossing drive

Referring to the BEP's earlier experience on tunnelling through buildings, the process of under-crossing the live metro tunnels was divided into three phases which considered different parameter setting and optimization, they were phase I: before the cutter head arrived metro projection range, phase II: the TBM under the live metro, phase III: the tail shield left the projection range. On 16 November 2019, the cutter head began to enter into projection range. On 19 November shield tail left the projection range, and the shield left the influence zone on 23rd November. During the under-crossing construction, the maximum heaving recorded was 9.05mm for the north bound tunnel and 12.42mm for the South bound tunnel. After the shield tail passed line 11, the North bound tunnel shown settlement trend and the final reading recorded a heaving of 7mm. For the South Bound Tunnel, the tunnel continues to heave up to 12.5mm before dipping.

5.5 Metro tunnel displacement

In order to monitor the metro tunnel displacement and deformation, automatically instrumentation device such as EL beam was used to real time monitor the displacement of the metro tunnel. The monitoring zone was 86m each side from the BEP tunnel center line and cover a total length of 172m. A monitoring point was set every 2 rings (2.4m), which was consistent for the south bound and the north bound line. Laser diameter convergence survey was also applied, which install every 5 rings (6m) in the range of 120m. There were 42 laser diameter convergences in total were installed. All the monitoring data were read and send to control center every 5 minutes. The tunnel displacement monitoring results at two layer tunnels intersection points were shown in Figure 12 below.

Since the shield cutter head entered the influence zone of Metro Line 11, the tunnel closer to the crossing area showed a downward trend with a max. subsidence of -0.38mm. As the shield continued to advance, the tunnel of Line 11 began to be uplifted. With the driving continued, the south bound reached

Figure 12. Displacement time history curves of metro tunnel.

a maximum elevation of +9.6mm. While the shield left influence zone, the metro tunnels began to sink, with a subsidence of 3.02mm. In the whole process, displacement of the south bound tunnel reached +12.58mm which was less than specified criteria (-20mm~+20mm). As the shield machine moved away, the tunnels gradually sank.

During the under-crossing, the metro tunnel horizontal diameter increased firstly and then decreased. The maximum convergence deformation of the north bound tunnel was +4.8mm (“+” denoted transverse diameter increased). And the convergence value decreased to +0.7mm afterwards. The maximum convergence deformation of the south bound tunnel was +6.4mm, and the convergence value decreased to +1.1mm afterwards. This shown that the deformation of the metro tunnels was mainly recoverable elastic deformation.

After tail shield left the projection range of metro tunnel (after Ring No.412) on 24 November 2019, the tunnel’s uplift began to fall down. Before 9 July 2020, the maximum absolute settlement of the north bound tunnel reached -9.58mm, and the south bound tunnel was -7.29mm. In order to control the settlement, the post-perturbation grouting was applied inside the subway tunnel using the pre-set holes on 12 July 2020. From 12 July to 2 August 2020, 7 rounds of grouting had been carried out. By the end of 2 August the perturbation grouting finished and final settlement of the tunnel was successfully controlled within 5mm.

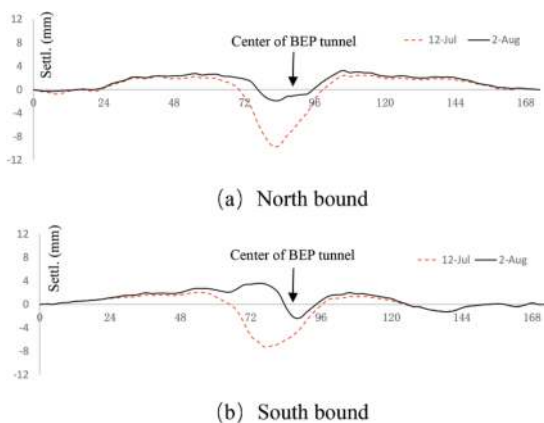

Figure 13. Metro tunnel settlement comparison before and after perturbation grouting.

6 CONCLUSIONS

In this paper the BEP II which was opened to public on 18 June 2021 was studied as an example. The extra-large slurry TBM with diameter of 15.56m had successfully tunnelled 6.42km, during which it faced many technical challenges such as continuous tight S curves excavation, tunnelling within close proximity to buildings and under-crossing live metro lines.

Focusing on each difficulty, technical solutions such as TBM selection, segmental lining design, construction risk control, etc. were adopted, and the project team successfully achieved the goals of ‘precise control, stable balance and slight disturbance’.

- (1) In order to negotiate the tight S-curve sections using slurry TBM with extra-large diameter of 15.56m, a comparative study was conducted to determine whether the shield skin should be articulated or fixed. Then, the conical shield, the copy cutter configuration and the overall design of the TBM machine were studied. Comparative studies were also performed on segmental rings, optimizing their width (2.0m/1.5m) and tapers (40mm/80mm). The TBM has tunnelled through 4 sections of tight S-curve, and the construction quality was excellent. Results shown that the overall tunnel axis deviation was less than 10mm. The average working efficiency reached 5.2r/d in normal condition.
- (2) Regarding TBM tunnelling through buildings, the influence zone along the tunnel route was defined firstly. A multi-factor and multi-level risk assessment model was formulated. Risks of TBM tunnelling through 89 buildings within influence zone in 2nd drive were estimated case by case. According to each building’s risk grade, corresponding construction methodologies were recommended. In case of high-risk situation, the source of risk must be considered, and each case would have its own construction scheme. The entire under-crossing process was successful, and the building tilt and settlement were controlled within specified criteria. During the under-crossing process, the buildings heaved at first, and it gradually fell back after the shield tail left, and the subsidence became stable and converged after 6 months.
- (3) There was no such precedent for a $\Phi 15.56\text{m}$ TBM to under-cross live metro tunnel with clearance of 7m before. The displacement criteria of the metro tunnel were discussed and determined as -20mm~20mm. A variety of schemes were optimized, and the overall methodology of ‘Reduce speed, Uniform speed and Continuous drive’ was adopted. Metro tunnel’s displacement and deformation were monitored automatically. The perturbation grouting was adopted in case of settlement, and the final displacement of the metro tunnel was successfully controlled within 5mm.

The success of BEP II had accumulated valuable experiences and data, formed a comprehensive technical system, and established a rich case library, which could provide references for similar constructions in the future, and further promote the development progress of entire TBM tunnel industry, and also find new solutions for urban center expressway construction.

ACKNOWLEDGMENTS

The authors appreciate all construction team members from Shanghai Chengtou Group Corporation, Shanghai Municipal Engineering Design Institute (Group) Co., Ltd., Herrenknecht AG, Shanghai Shengtong Group etc, and thanks also give to our STEC colleagues worked in BEP II.

Research on vertical dry tailings conveying technology and equipment of shaft boring machine

Chuge Yang*

China Railway Construction Heavy Industry Corporation Limited-CRCHI, Changsha Hunan, China

ABSTRACT: The vertical rock slag conveying technology has always been an important research direction in the field of shaft construction, and how to collect and lift the rock slag at the bottom layer of the shaft to the corresponding transfer height through continuous mucking equipment is the core technical problem. In this paper, by comparing and studying the application scenarios and technical characteristics of existing mature vertical conveying equipment, carrying out targeted research on mucking equipment in consideration of shaft construction conditions, and trial-manufacturing the prototype of vertical slag removing machine for relevant lifting tests and verifications, the effective vertical lifting operation of rock slag has been successfully realized, providing a reference breakthrough for solving the “bottleneck” mucking technical problems in the field of shaft construction.

Keywords: shaft boring machine, vertical slag removing

1 INTRODUCTION

Non-blasting rock breaking technology represented by mechanical rock breaking is an important orientation for the development of shaft sinking technology at present, and a feasible technical approach to solving the problems such as large number of underground operators, complex working procedures, serious occupational injuries and consequences and environmental pollution in existing drilling blasting shaft sinking [1]. Liu Zhiqiang [2] introduced the shaft sinking technology of mechanical rock-breaking shaft TBM using guide hole for slag discharge, and discussed the matters concerning tunneling equipment; Zheng Kangtai [3] formed a set of schemes and equipment specific to the adaptability of shaft boring machine slag discharge technology according to the research and test on key technologies of full-face shaft boring machine.

At present, the shaft construction methods both at home and abroad include drilling and blasting method, raise boring machine/undercut type shaft boring machine, cutting type shaft boring machine, full-face boring method, etc. The drilling and blasting method is in the slagging mode of rock grab loading → bucket mucking, with flexible device and equipment configuration and low cost; however, the construction efficiency is low, a large number of personnel are required for underground operation, the labor intensity of workers is high, and the construction safety risk is also high.

Figure 1. Main device and equipment configuration of drilling and blasting well construction system.

The deep shaft boring machine has equipment such as cutterhead scraper to scrape slag and bucket elevator to transfer slag from the cutterhead to the main engine. This mucking form distributes the slag

Figure 2. (a) Slag scraping by scraper conveyor (b) Slag conveying by bucket elevator.

*Corresponding author: yangchuge@crchi.com

scraping and transferring in two independent devices, and each needs to provide an independent power system, which has high requirements for equipment operation reliability, mucking speed and efficiency matching, and will be poorly adaptable to water-rich strata due to its low position of power unit.

The lower part of the main engine of the cutting type shaft boring machine is equipped with a telescopic cutting arm and a pick-type cutting head, which is flexible and can rotate up, down and around the vertical centerline of the main engine to cut and excavate the working face. The machine is suitable for construction in soft rock strata without water. During construction in hard rock, the pick could wear quickly, and the whole section cannot break rock at the same time, so the well completion speed would be slow. Typical products include Herrenknecht SBM and VSM models, with a maximum device excavation.

The mucking method of this type can also be divided into the two kinds of mucking: upper mucking or lower mucking, in which the upper mucking is mainly carried out by mud pump or vacuum suction, and the lower mucking also requires a bottom hole mucking channel.

Figure 3. Cutting type shaft boring machine.

The full-face shaft is excavated from top to bottom by the cutterhead, and the excavated rock slag is continuously lifted vertically and discharged to the ground. During construction, there is no need to excavate chute holes and underground mucking channels, which has high construction efficiency and low safety risks, and can implement working procedures synchronously such as shaft wall support and boring guidance. The slag discharge mode of the machine can be divided into mechanical slag discharge and fluid slag discharge, which can adapt to different geological conditions. For rocks and composite water-poor strata, the muck will be discharged by mechanical slag discharge; for water-rich strata, the muck can be discharged by fluid slag discharge.

According to the engineering characteristics of deep shaft construction by the boring machine, it is easy for the rock excavated in the shaft to sink after being crushed under dry tailings mucking mode, and it is very difficult to transfer and collect muck due to the large range of working face. If the slag is not

Figure 4. Full-face shaft boring machine.

scraped in time, it is easy to pile up slag and even cause cutterhead burial, resulting in excessive device torque load and affecting normal boring. When the muck is transferred to the slag receiving device, a certain height difference needs to be formed to meet the slag receiving requirements. However, it is difficult to form the height difference under the action of gravity when the muck rotates with the cutterhead, resulting in great difficulty in entering the slag receiving device. Therefore, how to realize automatic and fast muck transfer operation of tunnel face is one of the key factors that could affect mucking efficiency.

2 OVERALL DESIGN

According to the current technical characteristics of shaft mucking, the overall height and size of the main engine of the shaft shall be reduced as much as possible to reduce the excavation quantities of the launching shaft. It is considered to integrate the slag shoveling and slag-carrying lifting functions of the cutterhead tunnel face on the main engine mucking device, and in combination with the excavation characteristics of the cutterhead of the shaft boring machine, it is necessary to meet the slag carrying capacity under large particle size mucking and water-rich working conditions. The corresponding bucket opening shall be ≥ 2 times the limit size, and a screen plate shall be designed in the bucket body to realize the dual material lifting function of slag and water.

2.1 Technical principle

The vertical slag removing machine is driven by the upper double sprockets, and the traction chain and bucket rotate. During the action of the bucket, the slag is shoveled into the bucket from the bottom. After shoveling, it is vertically lifted with the traction chain, and runs to the arc top for unloading to complete the muck transfer under a single cycle. The

working principle and structure of the device and equipment are close to those of the existing removing machines. However, due to the differences in the types of conveyed materials and operating conditions, targeted design improvement is required for structures and materials, and the structural design of buckets needs to ensure smooth muck unloading.

2.2 Slag conveying capacity of vertical slag removing machine

The calculation formula is $Q = 3600 \frac{uc}{a} v$

Where: Q is the hourly slag transfer volume of vertical slag removing machine, m³/h; u is the bucket volume, m³; c is the bucket filling coefficient; a is the bucket spacing, m; v is the chain speed of vertical slag removing machine, m/s. Q shall meet \geq unit excavation volume Q1 of cutterhead to avoid large-area slag accumulation on the cutting face of the cutterhead.

2.3 Test schemes

To verify the feasibility of vertical slag removing technology, it is planned to carry out prototype slagging test verification, complete the prototype design of vertical slag removing machine and reserve support frame interface, design chute muck box to simulate the size of cutterhead excavation chamber and muck flow state. The vertical slag removing machine and muck box form a shoveling state. A spiral chute is set at the upper drive end to guide the discharge of removing machine back into the muck box for circulation. To ensure the normal operation of the vertical slag removing machine, a gap of 30~50 mm shall be reserved between the bucket and the arc bottom of the muck box, so that when the cutterhead hob cuts into the rock surface, there is still a certain safety margin between the lowest point of the bucket and the excavation face.

Figure 5. Test scheme of slag removing machine.

3 TEST VERIFICATION

After the trial production of test equipment and tooling is completed, assembly and commissioning shall

be carried out as per the test scheme. The vertical slag removing machine shall be started and stopped in no-load state to ensure that its functions such as stable start and stop and chain tensioning are normal, and the noise of drive device, deviation of drive chain, speed of drive chain and oil pressure of drive motor meet the design expectations;

Fill the muck box with composite muck and gravel, observe the shoveling, vertical lifting and unloading of the vertical slag removing machine for composite muck and gravel, and record the inspection results; add water to the composite muck and gravel in the silo to reach a surplus state, and observe and record the water-carrying lifting capacity of the vertical slag removing machine for water-rich slag;

Figure 9. (a) Muck and Gravel (b) Water-rich Muck and Gravel.

Table 1. Statistics of vertical slag removing machine operation.

S/N	Item	No-load standard value	No-load test value	Standard value with load	On-load test value
1	Chain speed	≈0.8m/s	0.8-1m/s	≈0.8m/s	0.8-1m/s
2	Drive motor oil pressure	≈2MPa	1~1.5MPa	≈5MPa	3~4MPa
3	Slag removing machine starts and stops smoothly	Normal	Normal	Normal	Normal
4	Slag shoveling, vertical slag lifting and unloading effect	/	/	Slag quantity of discharge hopper ≥0.5 efficiency coefficient	Slag shoveling, vertical slag lifting and unloading are normal, and the slag amount is close to 2/3
5	Water-carrying effect	/	/	Slag liquid volume in water-carrying chamber of slag bucket ≥0.5 efficiency coefficient	The water storage capacity of the water-carrying chamber is normal, and the amount of slag liquid is close to 1/2 of its volume

During the no-load operation of the vertical slag removing machine, the overall operation is relatively stable, the sprocket and chain are bonded smoothly, the driving oil pressure is within the range of 1~2 MPa (the lifting height of the prototype is smaller than that of the installed vertical slag removing machine, and the oil pressure is low), and the operating speed is 0.8~1 m/s. Due to the restriction of the working mode, there is certain noise interference. In the on-load operation test, the test muck is a mixture of shield soil and rock slag at the boring machine site. The driving oil pressure for on-load operation is within 3~4 MPa, and the test running speed is 0.8~1 m/s, which all meet the calculation requirements. The basic functions of bucket shoveling, vertical slag carrying and arc top slag unloading process have achieved their design effects, verifying that the principle of the vertical slag removing machine with integrated muck conveying function is feasible and can further promote its engineering application. The installed height and slag type of the device in this test deviate from the actual on-site loading conditions to some extent, so the engineering application will face a more severe actual test than this test.

4 CONCLUSION

- (1) Aiming at the difficult problem of vertical transportation of dry tailings in shaft boring machine construction, this paper puts forward a technical method of vertical slag extraction and removing integrating slag shovel and slag extraction, and expounds the working principle of vertical slag extraction and its matching relationship with excavation chamber.
- (2) By simulating the tunneling slag discharge test of vertical slag removing machine, it is proved that the performance of muck lifting system meets the design requirements, the particle size and slag discharge effect of rock slag meet the expected indicators, and the vertical muck extraction equipment runs well.
- (3) The vertical slag extraction equipment has been verified by the slag extraction and removing test, but there is a certain difference between the engineering test conditions and the actual boring and tunneling and mucking state. The performance of the vertical slag extraction and removing system needs to be technically verified in specific engineering applications.

ABSTRACT: Rockburst is a difficult problem in construction of deep-buried tunnels by full-face rock tunnel boring machine (TBM) due to its great impact on the safety and speed of TBM tunneling. This paper relies on the Yinhanjiwei (YHJW) Project, Xinjiang AiBiHu (ABH) Project, Jinping II Hydropower Station Project and Xinjiang EHe (EH) Project, and obtains the influence degree and temporal and spatial characteristics of rock burst on TBM construction speed through a large number of data analysis and research. The prevention and control objectives of TBM construction with four grades of slight, moderate, strong and extremely strong rockburst and four prevention and control criteria of TBM construction with speed control, risk control, space-time control and grading control are put forward. According to four grades of rockburst, the corresponding effective prevention and control technical schemes are given respectively. Furthermore, the theoretical and technical system of 4-4-4-4 graded rockburst prevention and control is constructed, which is controlled by monitoring, equipment, excavation and support. These results have been verified and applied in practical projects, and can provide a reference for the subsequent construction of ultra-deep tunnels.

Keywords: Rockburst grading, TBM, Graded prevention and control, Guideline, Technical methods

1 INTRODUCTION

The full-face rock boring machine (TBM) is a large underground engineering equipment with the characteristics of parallel process of excavation, support and slag discharge, so it has been widely used in various infrastructure construction fields. With the development of underground engineering construction towards “long, large and deep”, however, TBM construction is also facing new challenges. Especially for the super-deep tunnel, the ground stress is high and rockburst is easy to occur, which has a serious impact on the construction progress of TBM and the safety of construction personnel and equipment [Du, 2017].

From the practical experience of previous TBM projects, a large number of strong rockbursts or even extremely strong rockbursts occurred in the excavation process of Jinping II hydropower station project. As a result, the construction of two water diversion tunnels was stopped actively, and one drainage tunnel was destroyed and buried, causing casualties and huge economic losses [Yang et al., 2023, Yu et al., 2014]. Under construction, the Yinhanjiwei (YHJW) project also encountered a strong rockburst. The existing support was destroyed many times in early construction, and the TBM equipment was seriously damaged by rockburst impact. It has greatly affected the construction safety and progress [Xue, 2019].

*Corresponding author: dulj@stdu.edu.cn

Two TBM tunnels of Pakistan's N-J hydropower project suffered frequent rockbursts, causing casualties and serious equipment damage [Abdul, 2019]. Rock burst in TBM construction of Kobbelv HPS water conveyance tunnel in Norway also brought casualties [Øyvind, 2016].

At present, in order to better prevent and control rockburst, there are mainly three aspects of research work during construction. Namely, rock burst occurrence mechanism and theoretical method of rock burst prediction, microseismic monitoring and prediction of rock burst, and key technologies and methods of rock burst prevention and control. The theoretical research on rockburst prediction is earlier and there are many achievements. C.S.Ma et al. [2018] put forward a rockburst criterion based on the N-J hydropower project in Pakistan. The rockburst can be judged according to the ratio of the strength of rock mass to the horizontal stress perpendicular to the axis of the tunnel. In the aspect of rockburst microseismic monitoring, Zhao et al. [2017] relied on the monitoring data of rockburst microseisms and rockburst cases of Jinping II hydropower station project to analyze the temporal and spatial law of rockburst from the perspective of microseismic monitoring results. It shows that microseismic events have strong temporal and spatial correlation with rockburst. Yu et al. [2014] analyzed the changes of microseismic monitoring data before and after the rockburst of Jinpin II Hydropower Station project, and found that most rockbursts have microfracture precursors that can be monitored. It is preliminarily proved that the microseismic monitoring system is feasible for early warning of rockburst risk in TBM construction. Chen et al. [2011] analyzed the law of microseismic activity in the process of TBM excavation, and found that the faster the TBM excavation speed, the stronger the microseismic activity. The high incidence period of rockburst is 4 - 6h when the tunneling starts again after TBM maintenance. Wang [2019] made statistics on the monitoring results of rockburst microseisms and rockburst conditions in the upstream and downstream of No.3 and No.4 tunnels of Qinling Tunnel from the YHJW project, and found that the prediction accuracy rates were 95.89%, 90.00% and 88.46%. Ma et al. [2016] analyzed the rock bursts in the Jinping II hydropower station project and found that the accuracy of rock burst prediction in this project can reach 80.6 %. Du et al [2020] studied the accuracy and applicability of rockburst microseismic monitoring based on the big data analysis verified by comparison between rockburst microseismic monitoring and actual rockburst in the YHJW project and Xinjiang AiBiHu (ABH) project. It is concluded that the higher the rockburst grade, the higher the accuracy of microseismic monitoring, and the accuracy of strong rockburst risk grade prediction is close to 80%. In the key technology of rockburst prevention and control, slight rockburst and moderate rockburst have little influence on the safety and progress of TBM construction in terms of engineering practice. The main measures taken are steel mesh support, mechanical shell-expanding

prestressed grouting anchor, water-rising anchor, nano-steel fiber-like concrete and other comprehensive prevention measures [Chen et al., 2015]. For strong rockburst, TBM construction progress has a great influence. TBM equipment and personnel still face great security risks. It is difficult to get complete prevention and control. The main reason is that when the rockburst happens, firstly, the support is not done in time, and the personnel and equipment are at risk of being smashed. Second, the support was destroyed and the amount of slag removal was large. For example, after the TBM construction of the drainage tunnel of Jinping II Hydropower Station entered the strong rockburst area, the construction speed of TBM decreased a lot due to the destruction of the support and the huge workload of slag cleaning and support restoration, and only 600 m was excavated from July to November 2009 [Zhang et al., 2011]. In this project, in order to prevent the risk of strong rockburst ahead, the construction scheme of advanced pilot tunnel is put forward. That is, the pilot tunnel is excavated at the upper part of the tunnel face by drilling and blasting, and then the remaining section is excavated by TBM [Xiao et al., 2011]. In particular, it should be pointed out that this drilling and blasting pilot scheme is beneficial as an experimental research and exploration. However, it is difficult to be accepted by all parties as the construction technical scheme of TBM crossing the strong rockburst tunnel section. Because if so, it is better to excavate by full-face drilling and blasting.

To sum up, we can find that the accuracy of rockburst prediction needs to be improved. Higher than the actual prediction result of rockburst will increase the cost of prevention and control and affect the construction progress; The prediction result lower than the actual rockburst will bring greater safety risk and schedule risk. Moreover, even if the occurrence of rock burst is accurately predicted, it is ultimately necessary to rely on rock burst prevention and control measures to ensure the safe crossing of TBM.

2 PROJECT OVERVIEW

2.1 Project overview

The total length of the main tunnel of Xinjiang ABH project is about 41 km, of which 9 km is excavated by drilling and blasting, and 32 km is excavated by two open TBM. The tunnel is located in the strong uplift area of the northern Tianshan Mountains, with developed folds and faults, strong seismic activity and high ground stress. Hard and brittle rocks such as siltstone, metamorphic mudstone and granodiorite are distributed along the line, and the compressive strength of the rocks is 55.6-148.7 MPa, which has the geological conditions for rockburst.

The YHJW project is located in the Qinling Mountains in south-central Shaanxi Province, China. The total length of the project is 98.3 km, which is excavated by drilling and blasting method and two

8.0m diameter open-type TBMs. The elevation of the tunnel ranges from 1050-2420 m, the maximum buried depth is about 2012 m, and the ground stress is high. Hard rocks such as quartzite, granite and diorite are mainly distributed along the line. The compressive strength of rock is 107-317 MPa, and the average value is about 160-170 MPa, which has the conditions for strong rockburst.

2.2 Rockburst situation

The excavation pile number of the III section of ABH project studied in this paper is K9+600-K23+600. Up to August 2019, there were 151 rockbursts during the TBM excavation of this project, including 101 slight rockbursts, 18 slight to moderate rockbursts and 32 moderate rockbursts. There was no strong to extremely strong rockburst. The impact on the construction is not great.

The total length of the Lingnan section of the YHJW project studied in this paper is 18.28 km, and the pile numbers are K28+085-K46+360. Among them, the pile numbers K28+490-K37+011.5 are the first tunneling section of TBM, and the pile numbers K39+511-K46+360 are the second tunneling section of TBM. Up to November 2019, there were 795 rockbursts during TBM excavation, including 302 slight rockbursts, 84 slight to moderate rockbursts, 158 moderate rockbursts, 80 moderate to strong rockbursts and 171 strong rockbursts. It has a great impact on TBM construction.

3 IMPACT ANALYSIS OF ROCKBURST ON TBM CONSTRUCTION

3.1 Impact of rockburst on TBM construction safety

Once a rockburst occurs during TBM construction, it will not only slow down the construction speed, but also threaten the construction safety. Moreover, the impact of different grades of rockburst on TBM construction is generally different. The impact of rockburst on construction is shown in Figure 1.

Figure 1. Impact of rockburst on TBM construction.

3.2 Impact of rockburst on TBM construction efficiency

The construction speed of TBM, i.e. the feed rate, is mainly affected by both the pure digging speed and

the pure digging time of TBM. It is mainly affected by TBM pure advance speed and pure tunneling time. After classifying and summarizing the construction parameters of rock burst section, we can get the influence law of rock burst on TBM construction speed by comparing with the construction parameters of non-rock burst section. After the statistical analysis of types of surrounding rock with rockburst risk in two supporting projects, it is found that the Class IV surrounding rock with rockburst risk is only about 150m, and only 20 rockbursts have occurred. Due to the lack of rockburst data in Class IV surrounding rock, this paper only discusses the influence of rockburst on TBM construction speed under the conditions of Class I, Class II and Class III surrounding rock.

3.2.1 Influence of rockburst on TBM pure advance speed

The advance speed of TBM in rockburst section and non-rockburst construction tunnel section in two supporting projects is counted. The influence of rockburst on TBM advance speed is analyzed. The results are shown in Figure 2.

Figure 2. Comparison of advance speed under different surrounding rock classification and different rock burst grades.

It can be seen from Figure 2a that the advance speed of TBM is obviously reduced due to the existence of rockburst in ABH project. And in a certain range, the influence of rockburst on TBM advance speed is gradually strengthened with the improvement of rockburst grade. The main reason is that the compressive strength of rocks is low in ABH project, which is suitable for TBM excavation. If there is no rockburst, the pure advance speed of TBM is faster. Once rock burst happens, the advance speed will be obviously reduced. This is mainly due to the active control of TBM advance speed by rock burst tunnel section. However, it can be seen from Figure 2b that the influence of rock burst on TBM advance speed is not obvious in YHJW project. In some cases, the advance speed of rock burst section is even slightly higher than that of non-rock burst section. And only from the statistical results of this project, it can be found that the correlation between advance speed and rockburst grade is weak. The reason is that the rock compressive strength is extremely high in YHJW project. Even without rockburst, the pure advance speed of TBM is very low. After the rock burst happens in this extremely hard rock, the pure advance speed will not increase or decrease obviously, and it does not

need to be actively controlled. Therefore, the easier it is for surrounding rock to penetrate, the greater the proportion of rock burst will affect the construction speed of TBM. Moreover, the main factor affecting the construction speed of TBM is not the pure advance speed, but the pure advance time.

3.2.2 Influence of rockburst on TBM pure advance time

Rockburst will increase the workload of slag cleaning, support and equipment repair. It takes up pure advance time, which further affects the penetration speed of TBM construction. Generally speaking, under the same kind of surrounding rock, the higher the rockburst grade, the more the delay of pure advance time. The pure tunneling time of TBM in rock burst section and non-rock burst construction section of two supporting projects is counted. The influence of rockburst on TBM pure tunneling time is analyzed, as shown in Figure 3.

Figure 3. Comparison of pure advance time under different surrounding rock classification and different rock burst grades.

3.2.3 Influence of rockburst on TBM construction speed

The daily footage of TBM is counted in the rock burst section and the tunnel section without rock burst in two supporting projects. This paper analyzes the influence of rock burst at all levels on the construction speed of TBM under different surrounding rock classification. Taking the construction speed of the non-rockburst section as a reference, the construction speed is expressed as 100%. Then, under the influence of different grades of rockburst, the percentage of construction speed of rockburst section is non-rockburst section, as shown in Table 1.

The above construction speed takes into account the influence of rock burst prevention and control support

measures. From the statistical analysis in Table 1, it is found that: (1) In the same project with the same rockburst grade, the influence of rockburst on the construction speed of Class II surrounding rock is more obvious than that of Class III. Under the condition of similar surrounding rock of different projects, the influence of rock burst of different grades on the construction speed of ABH project is more obvious than that of the YHJW project. The reason is that the rock strength of ABH project is low and it is easy to penetrate. If there is no rockburst, the supporting capacity of Class II surrounding rock is very small. A very high advance speed can be obtained. Once there is the possibility of rockburst, it is necessary to take support measures similar to broken surrounding rock. This will increase the impact on the proportion of pure advance time. Therefore, rockburst has a great influence on the construction speed. (2) The active control of daily footage in Class I surrounding rock is not considered in the YHJW project. When moderate rockburst occurs in two projects, the construction speed is only about 1/2-3/4 of that without rockburst. This shows that rockburst has great influence on construction speed. (3) Within the scope of the tunnel studied in this paper, the strong rockburst occurred only under the condition of Class I surrounding rock in the YHJW project. The construction speed of strong rockburst tunnel section is less than 1/2 of that of non-rockburst tunnel section. It shows that rockburst has a great influence. If the same strong rockburst occurs in ABH project, because its rock strength is lower than that of the YHJW project, it is easy to penetrate and the pure tunneling speed is high. Moreover, there is a big gap between the pure tunneling time with strong rockburst and that without strong rockburst. Therefore, if a strong rock burst occurs in ABH project, the influence degree on the penetration speed of TBM construction is far more than half. In fact, especially the prevention and control of strong rockburst, preventive measures are generally taken in advance.

4 TEMPORAL AND SPATIAL CHARACTERISTICS OF ROCKBURST

It is very important to know the characteristics of rockburst in TBM construction for rockburst prevention and control. This paper will focus on the study and analysis of the “space-time effect” of rockburst.

Table 1. Comparison of construction speed between rock burst section and non-rock burst section.

Project	Class	Non-rockburst	Slight	Slight-Moderate	Moderate	Moderate-Strong	Strong
ABH	II	100%	67.8%	—	—	—	—
	III	100%	77.2%	49.5%	48.4%	—	—
YHJW	I	100%	95.8%	87.3%	74.6%	54.9%	45.1%
	II	100%	76.7%	73.6%	45.0%	—	—
	III	100%	78.9%	82.9%	51.3%	—	—

That is to say, the characteristic law of rockburst is analyzed from three aspects: the occurrence time (tunneling lag time), the occurrence position (the distance to the heading face) and the influence range. Due to the low rockburst grade of ABH project, there is no rockburst with medium or above grade. There are few rockburst data, so the accuracy of the conclusion may be biased. This will make the research less meaningful. Therefore, the following only summarizes the temporal and spatial characteristics of rockburst in the YHJW project.

For the convenience of statistics, T is used to represent the lag time of rockburst (that is, the time from the excavation of a certain pile number to the occurrence of rockburst). According to the construction time of the project, T is grouped with 12 h, 24 h, 48 h and 72 h as nodes. S is used to represent the distance from the position of rockburst to the working face. According to the structural characteristics of TBM, 5 m, 15 m and 60 m are used as nodes for grouping. D is used to represent the influence range of rockburst (including the length of rockburst section and the circumferential position of rockburst). Among them, the length of the rockburst section is the distance from the starting pile number to the ending pile number of the rockburst location. The location of rockburst refers to the location of rockburst on the circumference of tunnel section. The upper 120 range is divided into top arch, the lower 120 range is bottom arch, and the left and right sides are side walls.

4.1 Statistical analysis of rock burst characteristics

Because some rockburst data are incomplete, 788 groups of relatively complete rockburst data are selected for analysis in YHJW project, including 301 minor rockbursts, 83 minor-moderate rockbursts, 157 moderate rockbursts, 80 moderate-strong rockbursts and 167 strong rockbursts. The temporal and spatial characteristics of rockburst are obtained by statistical analysis of T, D and S in these data. The relatively complete rockburst data recorded in the YHJW project are classified according to the rockburst grade. T, D and S of rockburst at all levels are statistically analyzed, and the statistical results are shown in Figure 4.

As can be seen from the statistical analysis results in Figure 4, the rockburst occurred has the following characteristics in the YHJW project. (1) More than 90% of rockbursts occur within 24 h, and the frequency of rockbursts is the highest within 10 - 24 h after excavation, and about 9% of strong rockbursts occur within 24 - 48 h.. Therefore, the key prevention and control time of rockburst should be within 24 h after excavation. (2) The distance from the rockburst position to the tunnel face is mostly 5-15m. With the increase of rockburst grade, the distance from rockburst to heading face decreases. The proportion of strong rockburst before the shield is 31.1%. According to the characteristics of open

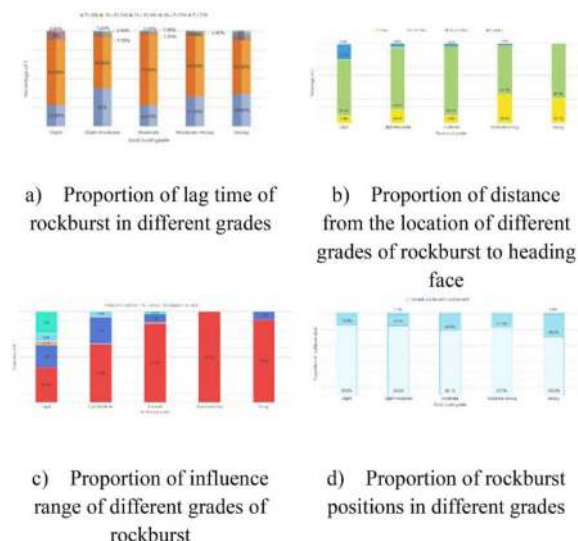

Figure 4. Temporal and spatial characteristics of rockburst.

TBM, the main girder is usually located within the range of 5 - 15 m from the tunnel face. The personnel and equipment here are relatively concentrated, so the prevention and control of rockburst must be done well. (3) The length of single rock burst section is mostly within 5 m. 100% moderate to strong rockburst and 98.2% strong rockburst are in the range of 5m. Rockburst mostly occurs within 120 of the top arch, and 98.1%, 97.5% and 100% of moderate rockburst, moderate-strong rockburst and strong rockburst occur in the top arch respectively. There are 15.9% - 38.9% rockbursts on both side walls. There are cases where the top arch and the side wall rock burst simultaneously. Rock burst at the bottom arch accounts for very little. Therefore, the key prevention and control positions can be determined according to the influence range of rockburst at all levels. At the same time, the support of rock burst section should be mainly within 120 of the top arch.

4.2 Characteristic of strong rockburst controlling TBM daily footage

The influence of strong rockburst is reduced by actively controlling the daily footage of TBM excavation in the YHJW project. In order to clarify its prevention and control effect, the moderate ~ strong and strong rockburst in this project is verified in groups with the daily footage of 3 m as the node. In the selected data of this project, there are 80 moderate to strong rockbursts, and 13 times with daily footage below 3 m. There were 167 strong rockbursts, and 46 times the daily footage was below 3 m. Data with daily footage above 3 m can be represented by medium-strong A and strong rockburst A, and data with daily footage below 3 m can be represented by medium-strong B and strong rockburst B. The statistical results are shown in Figure 5.

It can be seen from Figure 5 that after the daily footage is reduced, more than 90% of rockburst still

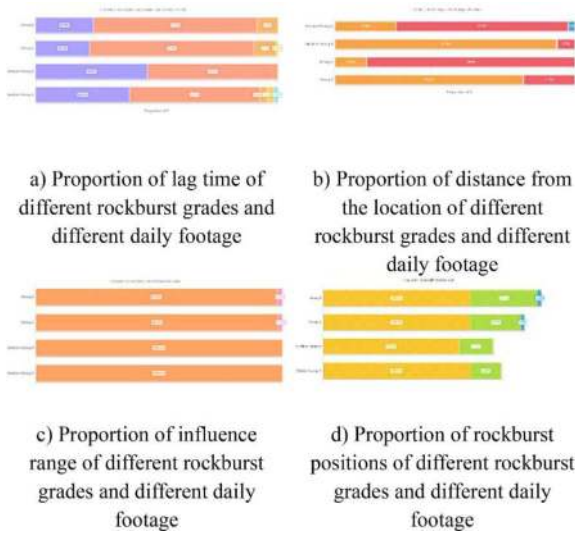

Figure 5. Characteristic of strong rockburst controlling TBM daily footage.

occurs within 24 hours, and there is no obvious change in T and D, but S is significantly reduced. The proportion of moderate-strong and strong rockburst occurring within 5m (i.e. from shield to tunnel face) increased obviously, reaching 92.3% and 78.3%. This is of great significance to the prevention and control of rock burst in TBM construction.

5 PREVENTION AND CONTROL OF ROCKBURST

The concept and technology of rock burst prevention and control in TBM construction are put forward based on the understanding of the above characteristics and laws of rock burst, combined with the structural characteristics and construction methods of TBM.

5.1 Criteria of rock burst prevention and control in TBM construction

Engineering practice shows that even if there is good rock burst prevention and control technology, it is difficult to achieve good prevention and control effect if the technical scheme cannot be selected and implemented according to certain theoretical criteria. For example, the support can not be completed at the right time, or the technical scheme can not be selected according to the rock burst grade. Therefore, the prevention and control of rockburst must first consider the characteristics of TBM construction and the law of rockburst occurrence, and follow the correct concept and theoretical criteria of rockburst prevention and control. Four theoretical principles of rock burst prevention and control are put forward based on the characteristics of TBM construction, the characteristics and laws of rock burst occurrence and the practical experience of rock burst prevention and control in engineering.

- (1) Construction speed control criterion. The construction speed control here refers to controlling the footage every day or within a certain period of time.
- (2) Risk control criteria. The concept of risk here refers to the risk brought by rock burst, that is, the safety risk of rock burst to TBM construction personnel and equipment, and the risk of the impact of TBM construction speed, construction period and trapped. The corresponding prevention and control technical measures shall be taken according to the magnitude of risk hazards and the probability of occurrence.
- (3) Temporal and spatial control criterion. Engineering practice shows that rockburst may occur instantly or in a short time after excavation, which is called instant rockburst. This kind of rockburst mainly occurs in the tunnel face and TBM cutter head or shield area. Rockburst may also occur after a period of delay after excavation. As mentioned above, the probability of such rockburst occurring within 24 hours is very high. Individual occurrence in a longer period of time. The location is mainly concentrated in the TBM host area.
- (4) Graded control criterion. Different surrounding rock conditions have different rock burst grades. Rockburst is generally divided into no rockburst, slight rockburst, moderate rockburst, strong rockburst or even extremely strong rockburst. Different rockburst grades have different hazards. Different prevention and control technical measures have different prevention and control effects. The influence on the construction footage speed and the construction cost are different. The technical measures for prevention and control of minor and moderate rockburst may not solve the fundamental problem for strong rockburst and extremely strong rockburst.

5.2 Prevention and control technology of rock burst in TBM construction

The technical system of classified prevention and control of rock burst in TBM construction based on coordinated control of equipment-excavation-support is put forward according to the influence law, space-time effect, equipment structure and construction method characteristics, as well as the prevention and control objectives and guidelines of rock burst. Compared with open TBM, the shield-type TBM is generally easier to prevent and control rockburst, and the control is relatively simple, because the main engine area is protected by shield and the back supporting part is supported by prefabricated segments. Therefore, the following mainly discusses the technical scheme of rock burst prevention and control with the open TBM.

5.2.1 Rockburst prevention and control technology of different grades

For slight rockburst, the conventional open TBM is equipped with anchor drilling machine at the tail of

shield, which is convenient for anchor operation. Moreover, the combined support of bolt and mesh can resist slight rockburst. The operation speed of bolt and mesh support is also relatively fast. Basically, it can keep up with the TBM excavation, even if it can't keep up with the excavation for a while, it will generally not bring the safety threat of equipment and personnel, and even can remedy the support. Therefore, it is not necessary to actively control the pure tunneling speed of TBM, but it is necessary to ensure that the support follows the tunneling. Rock burst prevention and control support may actually cause some delay to TBM construction speed, i.e. footage speed. And if the rockburst occurs in front of the shield tail and is a large-scale continuous rockburst. In this case, the use of anchor rod and steel mesh is invalid, because it will cause a lot of slag to be cleaned up. The technical scheme of the combination of arch frame and steel bar row with large spacing should be adopted. It not only ensures safety, reduces slag falling, but also greatly improves the construction speed. According to the above analysis, the prevention and control technical scheme of minor rockburst is a combination of conventional TBM design and bolt mesh or large-spacing arch reinforcement row support and support following excavation without actively controlling footage speed. For moderate rockburst, ordinary bolt and mesh support are difficult to resist the impact of rockburst. The support by spraying concrete at the main engine of TBM will pollute the main engine and the strength will increase slowly. It is not a good choice, unless the concrete with low price, no rebound and high speed can be developed. Therefore, it is proposed that the continuous closed support method combining steel arch frame and steel bar row is adopted for moderate rockburst. In this case, the TBM construction speed does not need to be actively controlled. Because the support may not keep up with the excavation, the construction speed will be passively controlled. In addition, in order to enable the TBM shield to store steel bars and achieve uninterrupted closed support, it needs to be designed as a shield with storage interlayer. Thus, the medium rockburst prevention and control technical scheme is constructed, which includes the design of storage bunker shield, the support of arch reinforcement row with regular spacing and the passive control of excavation. For strong rockburst, the past engineering practice shows that the conventional steel arch support is difficult to resist the impact of strong rockburst. Support is often damaged. And a lot of slag cleaning work will be brought. It will threaten the safety of equipment and personnel and seriously affect the construction progress. Nevertheless, according to the analysis results of the characteristics and laws of rockburst, the active control of the daily footage in the case of strong rockburst has a significant impact on the location of rockburst. So most strong rockburst can occur in the face and shield area by actively controlling the daily footage. In this way, not only the equipment and personnel behind the shield

are protected. It is more important that the problem of rock burst protection with huge impact energy can be transformed into the problem of landslide and broken zone support. Namely, the rockburst and its falling rocks fall in the area from the tail of shield to the front face, and the cutter head and shield play a role in resisting the impact of rockburst. Small-spacing steel arches and steel bars can be combined at the tail of the shield to support rockburst and rockfall. On this basis, a strong rock burst prevention and control technical scheme is put forward, which combines the design of robust cutter head shield, active control of footage speed and steel bar row support of small spacing steel arch frame. Generally, the distance from the tunnel face to the shield tail is about 6m, and more than 90% of the strong rockburst occurs within 24h. According to this law, the daily footage of TBM excavation can be actively controlled below 3 ~ 5 m. With the excavation process, the combined support of steel arch frame and steel bar row at the tail of shield follows closely. After the footage control index is completed, the machine can stop and wait. The spacing between steel arch frames is reduced to enable TBM support shoes to cross. If the smaller spacing cannot be crossed, concrete pouring can be used to smooth it. For extremely strong rockburst, there are actually local extremely strong rockbursts in the strong rockburst tunnel section of the Han-Ji-Wei Water Diversion Project. The concept and technology of rock burst prevention and control can be controlled with reference to strong rock burst. The specific footage speed index, arch spacing and model can be adjusted appropriately. At the same time, the water hammer drilling rig equipped with TBM can be used to carry out advanced drilling to degrade the extremely strong rockburst energy. Then, the tunneling support method mentioned above is adopted for crossing. In addition, double-type support TBM can also be selected. On the basis of the traditional open TBM, it adds a steel sheet installer and an auxiliary propulsion system, which is closely behind the shield to support the steel sheet. This further improves the safety and construction speed of TBM crossing strong rockburst. But its disadvantage is high cost.

The technical schemes of rock burst prevention and control with different grades are shown in Figure 6.

5.2.2 *Engineering application effect of graded rockburst prevention and control technology*

The technical scheme of prevention and control of minor rockburst has been fully applied in Xinjiang ABH project and Xinjiang EHe (EH) project. The ABH project in Xinjiang had 101 slight rockbursts by August 2019. The rock burst can be completely controlled by the support, and no equipment damage and casualties have occurred. Because of the compressive strength and integrity of surrounding rock of ABH project, it is easy to tunnel. The construction speed under slight rockburst is about 70 - 90% of that without rockburst. In Xinjiang EH project, a large area of continuous minor rockburst to moderate rockburst occurred in

Figure 6. Different grades of rock burst prevention and control technical schemes.

front of the shield tail, and the slight rockburst adopted the technical scheme of combining long-distance arch frames and steel bars. The field application of tunneling for several kilometers, the effect is obvious, the safety is controlled, and the monthly footage can reach about 400m

In the ABH project and the YHJW project, the monitoring and prediction of rockburst microseisms include moderate rockburst, slight-moderate rockburst or moderate-strong rockburst, all of which adopt the above-mentioned rockburst prevention and control technical scheme. From the start of TBM excavation in ABH project to August 2019, there were 18 slight-moderate rockbursts and 32 moderate rockbursts. From the excavation to November 2019, there were 84 slight-moderate rockbursts, 158 moderate rockbursts and 80 moderate-strong rockbursts in the YHJW project. By adopting the above prevention and control technical scheme, the support resisted the impact of rockburst, no casualties occurred and the equipment was not greatly damaged. Moreover, it has reached a relatively fast TBM construction speed, which is about 50% - 70% of the construction speed without rockburst. The daily footage is about 10m when steel arch frame and steel bar row are used for support in ABH project.

The application of double-type support TBM in the construction of plateau railway provides another technical means for TBM to cross the extremely strong rock burst. There is no engineering case list of steel pipe segments in dealing with extremely strong rockburst, but the steel pipe segments in dealing with large deformation of soft rock in Xinjiang EH project have been verified by engineering, and the effect is very good.

The actual effect of engineering application of graded rockburst prevention and control technology is shown in Figure 7.

6 CONCLUSIONS

The paper takes the YHJW project and Xinjiang ABH project as the main cases to study the characteristics and prevention technology of rock burst in TBM construction of deep-buried tunnel. The results are compared with Jinping II hydropower station

Figure 7. Engineering application effect.

project. This study covers all three TBM construction projects in China with a buried depth of more than 2000m and strong rockburst. The technical scheme of TBM construction prevention and control of classified rockburst is put forward through engineering practice exploration, data statistics and theoretical analysis. It is verified in engineering and draws the following main conclusions.

- (1) Different grades of rockburst have different effects on the construction speed, equipment and personnel safety of TBM. In particular, strong rockburst poses a great threat to the safety. However, the safety risk of rock burst in TBM construction can be basically controlled by adopting appropriate prevention and control concepts and technologies. By comparing and analyzing the construction speed with and without rockburst, the construction speed of TBM is reduced to about 70 - 90% of that without rockburst when the rockburst is slight. It decreases to about 50% - 70% in moderate rockburst and to about 25% - 50% in strong rockburst. Hence, the influence of rockburst should be fully considered in the surrounding rock classification, construction period and cost prediction of TBM construction.
- (2) The occurrence time of rockburst shows that about 20% - 40% of rockburst occurs within 10h after excavation. The frequency of rockburst is the highest within 10 h - 24 h after excavation. More than 90% rockburst occurred within 24 h after excavation. About 9% of the strong rockburst has a lag time of 24 h - 48 h. From the location of rockburst, more than 30% moderate and strong rockburst occurred in the area from shield to tunnel face. Above 90% moderate and strong rockburst occurred within 15m behind the tunnel face. The scheme of actively controlling the penetration speed of TBM can make about 80% - 90% of strong rockburst occur in the area from TBM shield to heading face. This provides favorable conditions for TBM rockburst prevention and control. The penetration speed of TBM actively controlled by strong rockburst is generally about 3 m - 5 m per day, which can be determined according to different engineering conditions.

(3) On the basis of the influence of rockburst on TBM construction and its temporal and spatial characteristics. The structure, construction characteristics, safety and speed of TBM are comprehensively considered. For four levels of rockburst, namely, slight, moderate, strong and extremely strong, this paper puts forward the corresponding rockburst prevention and control objectives, rockburst prevention and control criteria (i.e., construction speed control, risk control, time and space control, hierarchical control) and rockburst prevention and control technical scheme. Thereby, a 4-4-4 theoretical and technical system of rock burst prevention and control based on monitoring, equipment, excavation and support is constructed.

To sum up, using the prevention and control technical scheme proposed in this paper, one of the TBM in Xinjiang ABH project has safely and efficiently passed through all the medium rock burst tunnels, and completed the 14km excavation of the bid section. TBM in Lingnan section of the YHJW project passes through the 18km rockburst tunnel section. During the construction of the second tunneling section of TBM, it has passed through the 5km continuous strong rockburst tunnel section, and the average monthly footage of the strong rock burst tunnel section has reached 110m. The proposed concept and technology of rock burst prevention and control have achieved good prevention and control effect in practical engineering application, which can provide important reference for subsequent ultra-deep tunnel construction.

ABSTRACT: The penetration rate (PR) of tunnel boring machine (TBM) is often used to evaluate the tunneling performance and predict the construction period cost. But most prediction models of penetration rate are based on a single specific project, which leads to poor universality of the models. Besides, the selection of cutter head speed in the prediction of construction period in the survey and planning stage depends on manual experience and lacks theoretical guidance. Therefore, based on several TBM engineering data of different surrounding rocks and different diameters, this paper statistically analyzes the distribution law of cutter head speed (N) and the relationship between field penetration index (FPI) and geological parameters (uniaxial compressive strength (UCS) and rock mass integrity coefficient (Kv)) and penetration (P). The results show that FPI is significantly related to geological parameters and P is significantly related to FPI. Geological parameters and tunneling parameters are the main factors affecting the penetration rate. Based on this, the FPI prediction model, P prediction model and the calculation model of cutter head speed are established, and then the prediction model of penetration rate is obtained. The accuracy and reliability of this model have been verified and analyzed by the ErHe (EH) project in Xinjiang, and the average prediction error is 15.15%, which has a good effect and can provide theoretical support for the cost prediction of the construction period in the survey and planning stage.

Keywords: TBM, penetration rate, Geological parameters, Different projects, Prediction model

1 INTRODUCTION

The tunnel boring machine (TBM) has been widely used in many tunnel construction projects such as railway, highway, water conveyance and hydropower development because of its many advantages in construction efficiency, tunneling safety and ecological protection. Recently, the analysis and prediction of tunneling performance has become a hot issue in TBM industry (Shang et al., 2007). The penetration rate (PR) is one of the main indexes to evaluate the tunneling performance of TBM. The research on the prediction of PR can provide theoretical support for TBM tunneling performance evaluation and construction period prediction. Nowadays, the research on TBM PR prediction mainly focuses on two aspects:

on the one hand, it is based on theoretical analysis of indoor tests or numerical simulation; On the other hand, it is the analysis of engineering data based on tunneling parameters. In theoretical analysis, Boyd (1986) made full use of numerical simulation to make dimensional analysis of tunneling performance, and puts forward the concept of specific energy. By calculating the driving power required by the cutter head, the PR can be obtained. But the specific energy can't be calculated and analyzed at present, so the prediction model has little practical application. The CSM model (Luo, et al., 2018; Wu, et al., 2020) mainly calculated the hob penetration of TBM based on the force balance method through many linear cutting tests. Nevertheless, the data obtained from the indoor cutting test ignores the actual rock characteristics,

*Corresponding author: dulj@stdu.edu.cn

which leads to the relatively conservative prediction results of the model. The NTNU model (Jing, 2022) was based on a large number of geological parameters and many laboratory tests, and considers many factors that affect the tunneling parameters, and uses various mechanical variables to predict the PR. But the model relies heavily on the previous engineering data, so it is necessary to re-introduce the revised data for the new tunnel project. Thus, the model has great limitations. In the aspect of engineering data analysis, Alber (2000) put forward the concept of specific penetration based on field excavation data, and established the relationship model between specific penetration and UCS. But the model only considers the UCS and ignores the influence of other factors, so the prediction accuracy of the model is low. Du et al. (2015) studied the field data of a super-long tunnel in Northeast China, and selected factors such as UCS and integrity coefficient (Kv) to establish a field penetration index (FPI) prediction model by multivariate nonlinear fitting method. Zhou et al. (2021) used data mining clustering method to select geological and excavation parameters to build a prediction model of excavation speed. Gholaimi (2012) selects UCS, structural plane conditions and other influencing factors, and establishes a prediction model of PR by using neural network. Mahdevari et al. (2014) selects UCS, Brazilian tensile strength (BTS) and brittleness index (BI), etc., and establishes the prediction model of PR through support vector machine. Yagiz (2011) and Armaghani et al. (2017) used particle swarm optimization algorithm to predict the PR. Luo et al. (2018) analyzed the relationship between penetration and cutterhead thrust and torque, and established the prediction model of PR with UCS, Kv and cutterhead thrust as inputs. Wu et al. (2020) analyzed the engineering data of several tunnels, and established the prediction formula of FPI based on factors such as UCS, Kv and tunnel diameter (D). Xu et al. (2021) established penetration prediction formulas by curve fitting and multiple linear regression respectively according to the analysis of several engineering data. Feng et al. (2021) predicted the cutterhead thrust, rotating speed and FPI of TBM based on the data of Jilinyinsong project, and the results showed that the prediction effect was good. To sum up, it can be found that most of the PR prediction models are based on the actual tunneling data of TBM in a single specific project. The model has poor universality. Some real-time prediction models of PR are based on the data after excavation and cannot be used in the planning stage of construction period.

2 FACTORS AFFECTING TBM PR

Based on the previous related research literature and a large number of engineering practices, it is shown that UCS, Kv, F and N are the main factors affecting the PR of TBM. Kv can be obtained by testing rock mass and rock wave velocity during exploration or construction. It can also be calculated by the number of joints of surrounding rock exposed after excavation, so as to verify the measured Kv. Code for Geological Exploration of Water Resources and Hydropower Engineering (GB 50487-2008) states that the integrity of rock mass is closely related to the degree and stability of rock mass fragmentation, and the degree of correlation is shown in Table 1. With the increase of Kv, the surrounding rock is more complete and the stability of rock mass is better.

The size of P is determined by F and surrounding rock condition. The N is mainly regulated by TBM drivers according to geological conditions and combined with subjective experience. Under the condition of poor surrounding rock, TBM driver actively controls the thrust and speed of cutter head, and then limits the penetration. Therefore, this paper introduces the field penetration index FPI to establish the relationship between tunneling parameters and geological parameters. The FPI can comprehensively reflect the difficulty of TBM tunneling in rock mass. The calculation formula is shown in formula (1).

$$FPI = \frac{F}{nP} \quad (1)$$

Where n represents the number of disc cutters.

3 PREDICTION MODEL OF FPI BASED ON GEOLOGICAL PARAMETERS

3.1 Correlation analysis between FPI and geological parameters

With the data in the range of 82+606-77+548 in Dahuofang Project (DHF), the influence of UCS and Kv on the distribution of FPI is analyzed, and the three-dimensional scatter and color map of the data is drawn. The result is shown in Figure 1.

It can be seen from Figure 1 that the distribution law of FPI based on UCS and Kv is obvious. In the case that both UCS and Kv are small or UCS is small but Kv is large, FPI is at a low level, which indicates that TBM is easy to penetrate. However, in the range where UCS and Kv are both large, the distribution of FPI is also obvious. When UCS is in the range of 60-70 MPa and Kv is in the range of 0.6-0.7, FPI is in

Table 1. The relationship between Kv and rock integrity degree.

Kv	>0.75	0.75~0.55	0.55~0.35	0.35~0.15	<0.15
Integrity degree	complete	Relatively complete	Relatively broken	Broken	Extremely broken

Figure 1. Three-dimensional scatter and map of FPI, UCS and Kv.

the range of 38-44 kN·r·mm⁻¹. The distribution of FPI is annular when UCS is 60-80 MPa and Kv is 0.5-0.7. Above all, FPI has a significant correlation with UCS and Kv, and its distribution law is obvious.

3.2 Prediction model of FPI

The engineering data of Zhuxishuiku (ZXSK) Project, DHF Project and ErHe (EH) Project (including TBM7 and TBM8) are selected, and the pile numbers are 21+891-17+731, 82+620-77+546, 172+578-169+816 and 173+863-177+410, respectively. The correlation between FPI and UCS and Kv is analyzed. The scatter plot of FPI, UCS and Kv is drawn, and its fitting analysis is carried out. The result is shown in Figure 2.

Figure 2. The correlation between FPI and UCS and Kv.

As can be seen from Figure 2, the FPI of the four TBM is highly correlated with UCS and Kv. The correlation coefficient R² is close to 0.9, showing an obvious exponential relationship and a significant positive correlation. With the increase of UCS and Kv, FPI also increases. As the rock becomes harder and more complete, it is more difficult for TBM to penetrate for tunneling, which is consistent with the actual working conditions.

Based on the analysis, it is found that FPI has obvious correlation with UCS and Kv. However, the correlation between other geological parameters and FPI is not significant, or there is collinear superposition effect with UCS and Kv, and its data is not easy to obtain in the exploration stage. Therefore, UCS and Kv are taken as independent variables, and FPI is taken as dependent variables for prediction and analysis. Furthermore, FPI has a nonlinear relationship with UCS and Kv. Both of them show

exponential distribution. So the FPI, UCS and Kv were regressed by multiple nonlinear regression.

Select 400 groups of data from 4 TBMs of ZXSK Project, EH Project (including TBM7 and TBM8) and DHF Project for multivariate nonlinear regression fitting, and initially set the optimal mathematical expression as shown in Formula (2).

$$FPI = a \times \exp(b \cdot UCS + c \cdot Kv + d) + e \quad (2)$$

Where: a, b, c, d and E are all mathematical regression parameters; The initial set values are a=0.328, b=0.017, c=2, d=1 and e = 0.15; Set constraints a≥0, b≥0 and c≥0.

After 19 iterations, the sum of squares of residuals has remained unchanged and the value is too small. By fitting, the estimated values of the optimal regression parameters are a=0.497, b=0.014, c=0.683, d=2.190, and e=0.836. At this time, the correlation coefficient R² of the fitting formula is 0.801. To sum up, the empirical formula of multivariate nonlinear regression of FPI is shown in Formula (3).

$$FPI = 0.497 \exp(0.014 UCS + 0.683 Kv + 2.19) + 0.836 \quad (3)$$

The formula has a high overall fitting degree, and the corresponding FPI value can be obtained according to the geological data in the preliminary investigation stage of the project.

4 PREDICTION MODEL OF P BASED ON FPI

The previous literature research [Du et al.] shows that P has a significant correlation with FPI. However, previous studies are based on a single engineering data fitting, and the prediction model lacks universality. Therefore, this paper brings TBM cluster data into the relationship model between P and FPI.

The pile number ranges of DHF project, EH project (including TBM1, TBM2 and TBM3), Shenzhen Metro Line 6 (SZM-6) project and Gaoligongshan (GLGS) project are 82+620-77+546, 14+133-17+922, 57+797.40-54+415.19 62+973-67+570, 0+242-2+757 and 226+126-225+784 respectively. Based on these tunneling data, the fitting relationship between P and FPI is established by fitting regression method, as shown in Figure 3.

Figure 3. The correlation between P and FPI in different projects.

It can be seen from Figure 3 that there is a strong correlation between P and FPI, and the correlation coefficient R^2 is close to or greater than 0.9. The decrease of P with the increase of FPI indicates that the drivability of rocks is getting worse. When the FPI is small, the dispersion degree of P is large. With the increase of FPI, the fluctuation degree of P is smaller. This is mainly because when the FPI is small, the rock can be excavated better, and the main driver can cause a large fluctuation of P by adjusting F slightly. However, when the FPI is large, the rock mass is difficult to tunnel, and the change of P will be small if the main driver increases the thrust. Furthermore, it can be seen that the fitting curves of the seven projects are very close. It can effectively avoid the problem of poor universality of the prediction model caused by a single project to some extent if a unified fitting formula of P and FPI is established through the TBM data of multiple projects. Based on this, 800 groups of excavation data of the above seven projects are fitted and regressed as a whole, and a P prediction model suitable for multiple projects is established, as shown in Figure 4.

Figure 4. The fitting relationship between P and FPI based on multi-engineering.

By fitting and regressing the data of the above seven projects as a whole, it can be seen from Figure 4 that the relationship between P and FPI is exponential and has a strong correlation, and the correlation coefficient R^2 reaches 0.883. The data in Figure 4 shows the same trend as that in Figure 3. The prediction model of P is shown in Formula (4).

$$P = 15.202\exp(-0.023FPI) \quad (4)$$

5 THE THEORETICAL CALCULATION METHOD OF CUTTER HEAD SPEED UNDER DIFFERENT SURROUNDING ROCKS AND DIFFERENT DIAMETERS

The cutter head speed is related to surrounding rock and cutter head diameter. But in the stage of survey and design or construction period planning, there is no theoretical calculation method for selecting cutter head speed under different surrounding rocks and different diameters, and the selection is always based on experience. Thus, based on the engineering data of TBM with different diameters, this paper puts forward the theoretical calculation formula of cutter head speed by using mathematical statistics method.

5.1 The theoretical calculation formula of cutter head speed

When designing a TBM, it is considered that if the cutterhead speed is too high, it will generate high temperatures, which will affect the performance and life of the bearings and some seals. At the same time, the side cutters will be quickly damaged. Therefore, the allowable peripheral linear speed (v) of the cutterhead is generally 2.5m/s. Based on this principle, the cutterhead speed can be determined by the formula (5).

$$N = v/\pi D = 2.5 \times 60/\pi D = 47.7/D \quad (5)$$

Furthermore, the relationship between the speed of the cutterhead and its diameter can be written in the form of formula (6).

$$N = x/D \quad (6)$$

Where x is the cutter head speed factor, generally taken as 45-50, and the corresponding circumferential linear speed of the cutterhead is 2.4-2.6m/s.

In addition, considering that the rotation of the cutter head during TBM tunneling will cause a certain amount of centrifugal force on the rock slag. The slag tapping effect of TBM will be affected if the centrifugal force is too large. Hence, in the design of the rotational speed, the centrifugal acceleration generated by the rock debris should be smaller than its own gravitational acceleration g . That is, the requirement of formula (7) should be met.

$$v^2/r \leq g \quad (7)$$

Where r is the radius of the cutter head.

The formula (8) can be further derived from the formulas (5) and (7).

$$v = N\pi D/60 \leq \sqrt{gD/2} \quad (8)$$

Then, the allowable cutterhead speed meeting the design requirements is obtained, as shown in formula (9).

$$N \leq 42.6D^{-0.5} \quad (9)$$

It can be seen from formula (8) that the cutter head speed is often calculated according to the maximum cutter head speed in TBM design. However, in practical engineering, the TBM operator will adjust the cutter head speed according to his personal experience and the change of surrounding rock conditions, so it will be quite different from the maximum cutter head speed.

In order to obtain a reasonable formula for calculating cutter head speed, firstly, the cutter head diameter and rated speed of some representative TBM projects in China, such as ZXSK project, Nabang (NB) project, Chongqing Metro (CQM) project (including Line 5 and Line 6), Xinjiang EH project

(including VII and IV sections), Jilinyinsong (JLYS) project, DHF project, Shaanxi Yinhanjiwei (YHJW) project, Gaoligongshan (GLGS) project and Jinping (JP) II hydropower station project, are statistically analyzed. The distribution law of rotating speed of TBM cutter heads with different diameters is studied, and the results are shown in Table 2.

Table 2. Statistics of cutter head diameter and rotation speed of some representative TBM projects in China.

Proejct	TBM type	Diameter/(m)	Cutter head speed/(r/min)
ZXSK	open-type	4.03	0-12
NB	open-type	4.53	0-12
CQM-6	open-type	6.36	0-10.53
ABH	open-type	6.53	0-9.8
CQM-5	Single shield	6.83	0-0.54-11.9
EH-VII	open-type	7	0-10.9
EH-IV	open-type	7	0-10.9
JLYS	open-type	7.93	0-6.7
DHF	open-type	8.03	0-4.63-6.93
YHJW	open-type	8.05	0-6.87
GLGS	open-type	9.03	0-3.4-6.5
JP	open-type	12.4	0-4.5

From Table 2, it can be seen that with the increase of cutter head diameter, the rated speed of cutter head also decreases. It shows that the diameter has a certain influence on the speed of TBM cutter head. Moreover, the influence of surrounding rock conditions on the speed of TBM can be obtained through the speed distribution law of different surrounding rock types in different projects. The regular distribution statistics are shown in Figure 5.

Figure 5 shows that the cutter head speed decreases with the increase of cutter head diameter under the same surrounding rock conditions. The overall trend of cutter head speed in different surrounding rock types is that it also decreases with the deterioration of surrounding rock. The same diameter TBM, under the same surrounding rock grade, the cutter head rotation speed is similar, showing only a small change, such as EH-TBM1, EH-TBM2, EH-TBM10 and EH-TBM5. The average rotation speed of cutter head varies in the range of 0~1.4 r/min under the same surrounding rock grade. But the rotating speed distribution of TBM cutterheads with different diameters is quite different under the same surrounding rock grade. Take NB project and EH project for example, the average rotating speed of TBM cutter head changes by 41.15% under class II surrounding rock. It is further explained that diameter and surrounding rock are the main influencing factors of cutter head speed. The average and peak values of the rotating speed of eight TBM cutterheads under various surrounding rock grades are statistically analyzed, as shown in Table 3.

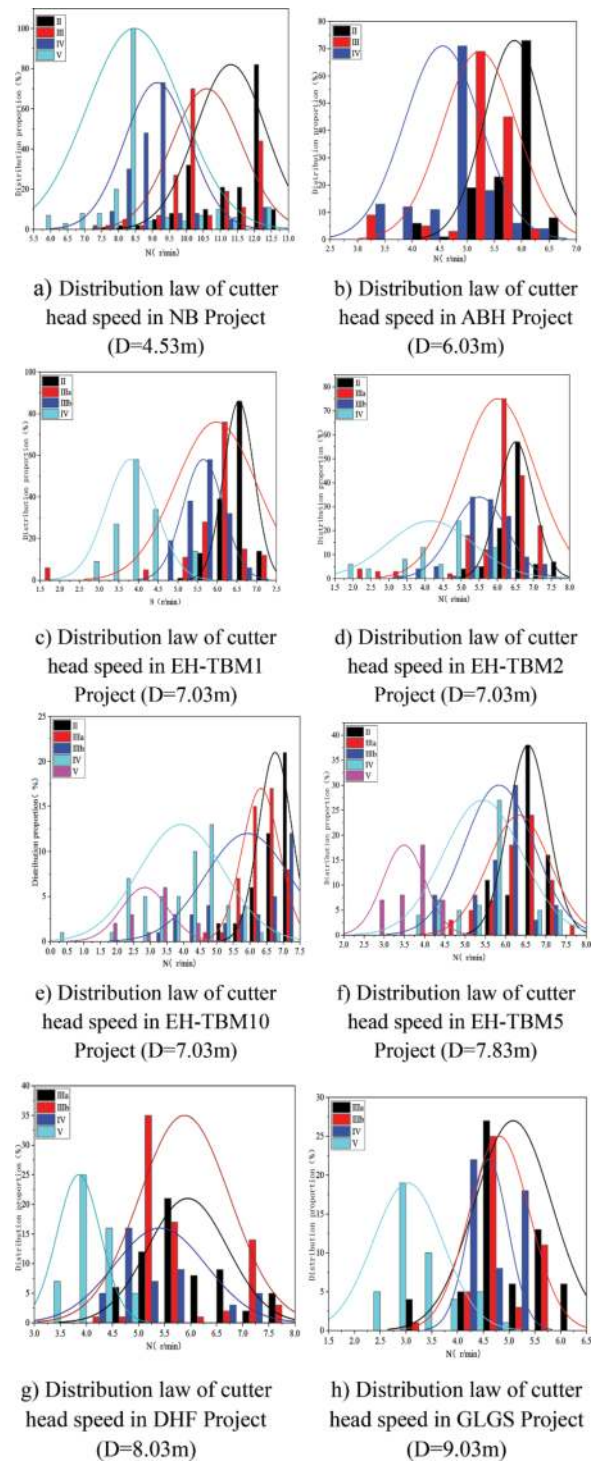

Figure 5. Speed distribution law of TBM cutter head with different diameters in different projects.

To sum up, it is further explained that the diameter and surrounding rock are the main influencing factors of cutter head speed. So the factors of surrounding rock and diameter are included in the calculation of cutter head speed, which are reflected in the form of correction coefficient respectively. The diameter factor is represented by k_1 , and the surrounding rock factor is represented by k_2 . In this

Table 3. Distribution statistics of rotating speed of eight TBM cutterheads under different surrounding rock types.

Project Class	II		IIIa		IIIb		IV		V	
	Mean	Max	Mean	Max	Mean	Max	Mean	Max	Mean	Max
NB	11.3	11.2	10.6	10.6	10.5	10.5	9.1	9.1	8.5	8.6
ABH	5.9	5.7	5.2	5.2	5.2	5.2	4.6	4.5	—	—
EH-TBM1	6.5	6.6	6.0	6.0	5.6	5.6	3.8	3.7	—	—
EH-TBM2	6.5	6.5	6.0	6.0	5.5	5.5	4.1	4.0	—	—
EH-TBM10	7.0	6.8	6.3	6.4	5.9	5.7	3.9	4	2.8	2.7
EH-TBM5	6.6	6.6	6.3	6.2	5.8	5.7	5.4	5.2	3.5	3.5
DHF	—	—	5.9	6.0	5.9	6.1	5.4	5.4	3.9	3.7
GLGS	—	—	5.1	5.2	4.8	4.7	4.6	4.5	3.0	3.0

paper, TBM with D=7.03 m is taken as reference diameter. So the calculation formula of cutter head speed is as shown in Formula (10).

$$N = k_1 k_2 N_0 \tag{10}$$

Where: N - cutter head speed, r/min. k_1 - diameter coefficient. K_2 - surrounding rock coefficient. N_0 -cutter head speed under reference diameter, r/min.

5.2 Determination of cutter head diameter correction coefficient

According to the research of [Du Yanliang et al. [2]], the influence of TBM diameter on cutter head speed is mainly related to the linear speed of edge cutter. The relationship between cutter head speed and TBM diameter in TBM design is shown in Formula (11).

$$N = \frac{X}{D} \tag{11}$$

Where: X - velocity coefficient, generally 45 or 50; D - cutter head diameter.

While the calculation formula of reference speed N_0 is formula (12).

$$N_0 = \frac{X}{D_0} \tag{12}$$

The influence of diameter on TBM cutter head speed can be measured by calculating the ratio of cutter head speed N to reference cutter head speed N_0 , that is, the diameter coefficient k_1 . The formula for calculating the diameter coefficient k_1 is as shown in Formula (13) with reference to the ratio of the diameter D_0 to the design diameter D .

$$k_1 = \frac{N}{N_0} = \frac{D_0}{D} \tag{13}$$

5.3 Selection of correction coefficient of surrounding rock

To obtain the cutter head rotation speed of TBM reference diameter, the average rotation speed of six 7.03m diameter TBM cutter heads in Xinjiang EH

Project was statistically compared and analyzed, and the results are shown in Figure 6.

Figure 6. Statistical analysis of cutter head speed under TBM reference diameter (D=7.03m) in EH project. Note: The horizontal axis number in the figure is the code name of TBM in EH project.

From the comparative analysis of the average cutter head speed in Figure 6, it can be seen that the distribution of TBM cutter head speed is in a small range under the same surrounding rock grade. The maximum and minimum values of cutter head speed are only 0.5 r/min under Class-II and Class-IIIb, 0.6 r/min under Class-IIIa, 1.6 r/min under Class-IV and 1r/min under Class-V, and the overall fluctuation range is small. It can be seen that different surrounding rocks have different effects on the cutter head speed. The reference rotational speed N_0 of the reference diameter $D_0(7.03m)$ under different surrounding rock grades can be obtained by averaging the rotational speeds of six sets of 7.03 m diameter TBM under the same surrounding rock grade. The results are shown in Table 4.

Table 4. Reference cutterhead speed N_0 under different surrounding rock grades.

$D_0(m)$	$N_0(r/min)$				
	II	IIIa	IIIb	IV	V
7.03	6.6	6.0	5.5	4.5	3.0

It is necessary to study and analyze the law of cutter head speed under the same TBM diameter in different

projects considering the influence of surrounding rock factors. Therefore, the tunneling data of TBM in NB Project (D=4.53m) and Beijiangyinshui (BJYS) Project (D=4.53m) are selected respectively, and the cutter head speed is statistically compared and analyzed. The results are shown in Figure 7.

Figure 7. Statistical analysis of cutter head speed under the same TBM diameter in different projects.

As can be seen from Figure 7, the diameter of TBM in BJYS project and NB project is the same, but the cutter head speed is obviously different under the same surrounding rock grade. The main reason is the influence of surrounding rock factors. The physical and mechanical properties of the two projects are different from the surrounding rock lithology under the same surrounding rock grade. The UCS of BJYS project is 60.15-203 MPa, the content of quartz is 20%-45%, and the lithology is medium-coarse grained biotite granite. The UCS of Nabang project is 100-220 MPa, the content of quartz is 25%-35%, and the lithology is mixed gneiss. Without the influence of the diameter factor, the TBM cutter head rotation speed of BJYS project under Class-II surrounding rock is about 0.68 of that of NB project, and it is about 0.67 under Class-III surrounding rock. The k_2 can be obtained from Formula (10) without the influence of the diameter factor, as shown in Formula (14). The TBM cutter head rotation speed of BJYS project under class II surrounding rock is about 0.68 of NB project, and it is about 0.67 under class III surrounding rock. That is, the correction coefficient k_2 of surrounding rock is 0.67 and 0.68 respectively.

$$k_2 = \frac{N}{k_1 N_0} \quad (14)$$

In order to cover more specifications of TBM, the cutter head speeds of TBM in ABH project (D=6.53m), DHF project (D=8.03m) and GLGS project (D=9.03m) are statistically analyzed, which can be obtained from Table 2. First, k_1 is calculated according to Formula (7), and then the distribution range of surrounding rock correction coefficient k_2 is obtained according to actual cutter head speed n and cutter head speed N_0 under reference diameter, as shown in Table 5.

In summary, according to Formula (10) and Formula (13), and referring to Table 4 and Table 5, the

Table 5. The range of the correction coefficient k_2 of surrounding rock.

Class	k_2
II	0.65~0.75
IIIa	0.75~0.85
IIIb	0.85~0.95
IV	0.95~1.05
V	1.05~1.15

rotating speed of TBM cutter head with different diameters and different surrounding rock grades can be calculated.

6 PREDICTION MODEL OF PR

The PR represents the tunneling distance of TBM per unit time, which can be expressed by N and P and is the product of them, as shown in Formula (15).

$$PR = N \cdot P \quad (15)$$

Based on the above prediction model, the prediction model of PR can be obtained as shown in Formula (16).

$$PR = 15.202k_1k_2N_0 \cdot e^{-0.023FPI} \quad (16)$$

The application flow of the PR prediction model is shown in Figure 8.

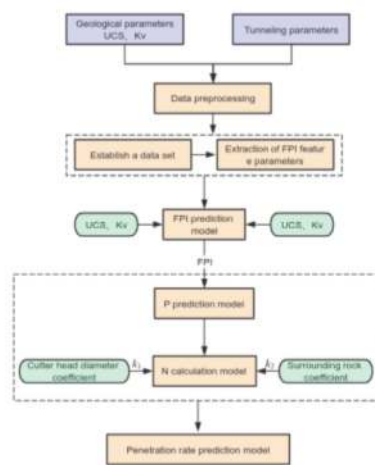

Figure 8. The application flow of the PR prediction model.

Based on the geological parameters (UCS and Kv, etc.) obtained in the geological exploration stage or construction stage, firstly, the data is cleaned to eliminate abnormal data, and then the FPI value is obtained by inputting the FPI model. Thirdly, the FPI is substituted into the P model to get the value of P. Fourthly, considering the influence of TBM diameter and surrounding rock, the diameter correction coefficient k_1 and surrounding rock correction

coefficient k_2 are selected and substituted into the theoretical calculation formula of N, and the value of n is obtained. Finally, based on the above model, the prediction model of tunneling speed is obtained.

7 VERIFICATION AND ANALYSIS OF THE MODEL

7.1 Project verification of FPI prediction model

Based on the geological data in the investigation stage, the FPI prediction model can get the corresponding FPI value. The prediction results of FPI were compared and tested by selecting 30 sets of data from DHF project, EH-TBM7 project and EH-TBM8 project. The comparison between FPI prediction and actual value is shown in Figure 9.

Figure 9. Comparison between predicted value and actual value of FPI.

It can be seen from Figure 9 that the predicted value of FPI is generally close to the actual value, with the maximum prediction error of 23.5% and the average prediction error of 7.84%. The verification of project site data shows that the prediction accuracy of this model is good.

7.2 Project verification of penetration prediction model

Select 30 groups of data from EH-TBM7 and EH-TBM8 projects to verify the prediction effect of P model. The comparison between the predicted value and the actual value of p is shown in Figure 10.

As can be seen from Figure 10, the actual value of p is close to the predicted value, with the maximum prediction error of 25.5% and the average prediction error of 11.91%. The prediction errors of some data points in Figure 10 are relatively large, one is that FPI itself has certain prediction errors, and the other is that it may be caused by the artificial regulation of TBM drivers. But on the whole, the prediction effect of P is good, which can better reflect the relationship between P and FPI, and can lay a foundation for the subsequent prediction of PR.

Figure 10. Comparison between predicted value and actual value of P.

7.3 Project verification of PR prediction model

The universality and accuracy of the PR prediction method are verified by selecting 40 groups of data from EH-TBM7 and EH-TBM8 projects in Xinjiang. Some prediction results are shown in Table 6.

Table 6. The statistics of PR prediction.

UCS	Kv	Predicted				Actual	RE (%)
		FPI	P	N	PR	PR	
66	0.6	25.22	8.5	5.8	49.4	50	1.28
76	0.69	28.98	7.8	6.8	53.1	49	8.32
80	0.63	29.30	7.7	7.1	55.0	44	25.1
69	0.63	26.31	8.3	6.6	54.8	47	16.6
...
81	0.7	30.63	7.5	6.9	51.9	50	3.71
65	0.56	24.54	8.6	5.2	45.0	48	6.34
82	0.73	31.41	7.4	6.8	50.2	47	6.79
76	0.59	27.62	8.1	6.5	52.3	48	9.06

The data in Table 6 are plotted as a point chart to clearly show the comparison effect between the predicted value and the actual value of PR, and the result is shown in Figure 11.

Figure 11. Comparison between predicted value and actual value of PR.

It can be seen from Figure 11 and Table 6 that the predicted value of PR is consistent with the actual value, but the predicted value is slightly larger than the actual value on the whole. The main reason is that in the actual tunneling process of TBM, the main driver will take the initiative to reduce the cutterhead speed or thrust due to the influence of geological conditions and tools. The predicted value is based on the previous high tunneling parameters, which leads to the predicted value slightly larger than the actual value. However, through validation analysis, the average prediction error is 15.15%, the maximum prediction error is 28.7%, and the minimum prediction error is only 0.14%. Overall, this indicates that the PR prediction effect is good. At the same time, since the validation analysis data is randomly selected and indicates that the prediction model is applicable, it can provide reference for the prediction of other engineering PR.

8 CONCLUSIONS

This paper, based on the data of several engineering sites, analyzes the main influencing factors of excavation speed from how to accurately estimate the construction period cost in the engineering investigation stage. The FPI prediction model and P prediction model are established. The theoretical calculation method of cutter head speed with different diameters and different surrounding rock grades is put forward. Furthermore, the relationship model between geological parameters and PR is established. The following research results are obtained: (1) The cutter head speed is mainly related to the diameter of TBM and surrounding rock. With the increase of TBM diameter or the deterioration of surrounding rock, the rotation speed also decreases. Therefore, the diameter correction coefficient and surrounding rock correction coefficient are put forward, and the value method of correction coefficient is determined. The theoretical calculation method of cutter head speed suitable for different diameters and different surrounding rock grades is established. (2) The fitting relationship between FPI, UCS and Kv is established, and both of them are exponentially distributed. Through multivariate nonlinear regression fitting, the empirical model of FPI is obtained and verified in project. The average prediction error is 7.84%. The P and FPI data of seven projects are analyzed by regression, and a more universal P prediction model is established. The average prediction error is 11.91% verified by field data. (3) The prediction method of PR is put forward, and the prediction model of PR is established based on geological parameters. Through engineering verification and analysis, the maximum prediction error is 28.7%, the minimum prediction error is only 0.14%, and the average prediction error of PR is 15.15%.

A more universal PR prediction model is established in this paper, based on the field data of several projects and considering the influence of geology and TBM diameter on PR. It can not only meet the cost prediction of the construction period in the early stage of TBM project, but also provide theoretical

guidance for tool consumption prediction and tunneling performance evaluation.

Research on prefabricated metro station structure and key assembly technologies

Xiuren Yang* & Fang Lin*

Beijing Urban Construction Design and Development Group co., Ltd, Beijing, China

National Engineering Research Center for Green & Safe Construction Technology in Urban Rail Transit, Beijing, China

ABSTRACT: The prefabrication and assembly construction technology for metro stations provides a new industrial construction mode for urban rail transit underground stations. It not only solves the winter construction problems in severe cold areas, but also demonstrates irreplaceable advantages in terms of quality, efficiency, safety, and environmental protection. This paper is based on the research and application of this technology by the research team in Changchun, Qingdao, and Shenzhen, China since 2012. It is a brief introduction to the prefabricated metro station structure system as well as the key technical achievements in the research and application of prefabricated assembly construction technology for metro station structures in the past 10 years, mainly including joint connection technology, key technology for the design of closed-cavity thin-walled components, structural mechanical behavior and calculation method of fabricated station, structure assembly design method and key technology, joint waterproof technology, etc. It has been proved by engineering practice that the prefabrication and assembly construction technology for metro stations significantly improves engineering quality and reduces operating and maintenance costs; Greatly improve construction efficiency, save labor, and shorten construction period; Green environmental protection, emission reduction and noise reduction, sustainable development; With wide applicability, it has significant technical, economic, and social benefits.

Keywords: metro station, prefabricated, grouted mortise-tenon joint, closed-cavity thin-walled components, prefabricated structure waterproof

1 INTRODUCTION

Promoting the industrialization of construction and the development of prefabricated building technology is an important measure to realize the optimization and upgrading of China's construction industry, practice the concept of green development and promote the realization of the dual carbon goals. In recent years, the country has constantly introduced policies to promote the development of prefabricated building technology and applications, and has made remarkable achievements. The proportion of prefabricated building in new construction projects around the country keeps rising, and the development of prefabricated building presents a prosperous situation.

Compared with the booming field of prefabricated buildings, the research and application of prefabricated technology in the field of underground engineering in China started late and the development was relatively lagging behind, especially in the application of prefabricated construction technology for large and complex underground structures. Ten years ago, in 2012, it was still in a blank state. The main application of

prefabricated assembly technology for underground structures was basically limited to tunnel lining, municipal pipeline and utility tunnel structure constructed by shield tunneling method. Its application characteristics are relatively simple in structure type (circular or simple rectangular), small in structural section size, and simple in structure assembly method (such as using prefabricated assembly of whole ring pipe sections).

For the purposes of solving the problem of cast-in-place concrete construction in severe cold winter, the former Soviet Union carried out research and application of prefabricated assembly construction technology for the first time in metro stations and interval tunnel engineering in the 1980s (Frarov, 1994). The same problem existed in the construction of rail transit in the severe cold areas of Northeast China, where winter break lasted as long as 5 months a year, imposing huge pressure on the construction period.

In 2012, the author's research team carried out the research and application of the prefabricated structure construction technology for cut-and-cover metro stations based on the Changchun Metro Line 2

*Corresponding author: yangxr@bjucd.com; felyo@foxmail.com

Project. Up to now, a total of 21 prefabricated stations have been successfully built. It has been proved by practical engineering applications that prefabricated construction technology can not only solve winter construction challenges in severe cold areas, but also demonstrate irreplaceable advantages in terms of high quality, high efficiency, safety, environmental protection, etc. (Lawson, 2011; Baghchesaraei et al., 2016; Jiang et al., 2018; Yang et al., 2019, 2021 & 2022; Lin et al., 2023). This technology is also applicable to other non-severe cold areas. In the present age that the concept of engineering construction in China is gradually changing from the traditional economic applicability and aesthetics to the energy conservation, environmental protection and sustainable development, the successful construction of the first prefabricated station of Changchun Metro is a significant milestone, arousing the widespread concern of industry and society. This innovation is of great significance to promote the deep integration of rail transit engineering construction with industrialization and informatization, as well as the transformation of the construction industry from the traditional labor-intensive industry to the high-end industry.

Based on the prefabricated stations of Changchun Metro, this paper briefly discusses the research achievements and applications of the research team in the construction technology of fully prefabricated structures in the past 10 years (Yang 2020) for reference in the industry.

2 STRUCTURE SYSTEM OF PREFABRICATED STATION

Take the prefabricated stations of Changchun Metro as an example. All prefabricated stations of Changchun Metro are 2-storey underground standard stations with 11m island platforms, and the largest prefabricated station structure is 246m long. Except for the air ducts at both ends of the station and the shield working shafts in the section, which are of cast-in-place concrete structure, the standard sections in the middle are all of prefabricated structure. Figure 1 shows the schematic diagram of the prefabricated station structure system.

Figure 1. Schematic diagram of prefabricated station structure system.

2.1 Prefabricated metro station structure

The metro station is of large size. In addition to longitudinal splitting into several standard structural rings, the horizontal structural links shall also be split into several standard components. The standard rings used in the prefabricated station structure of Changchun Metro consist of 7 large prefabricated components with a ring width of 2m, as shown in Figure 2. In prefabricated structures, except for the longitudinal joint between the top arch components D and E, which is assembled in a staggered joint manner, the rest are assembled in a straight joint manner.

Figure 2. Schematic diagram of single-arch long-span structure type of prefabricated station.

After the lining structure is assembled as a whole, a stable tunnel-type bearing structure will be formed under the restraint of the hard backfill in the lateral extra trench for the foundation pit. The internal structures such as the mid-floor slabs, columns, and beams can be of prefabricated structure according to the engineering conditions and be assembled with the lining structure, or be cast in place or superposed as a whole after the assembly of lining structure.

2.2 Prefabricated closed-cavity thin-walled components

Each prefabricated component is a new-type light-weight “closed-cavity thin-walled component”, which can effectively reduce the weight of the component and facilitate transportation and construction assembly under the condition of meeting the structural stress, and reduce the hydration heat of large prefabricated concrete components while reducing the amount of concrete used for the components.

See Figure 3 (a) for the schematic diagram of the section of closed-cavity thin-walled components, and Figure 3 (b) for the perspective view of single-ring fully prefabricated structure. The single-ring fully prefabricated structure has a weight of 292.5t and a total volume of 144m³. The volume of the cavity is 27m³, and the cavity rate is 18.75%.

2.3 Grouted mortise-tenon joint

The grouted mortise-tenon joint is composed of mortise, tenon, and later joint grouting. One of the two

(a)Sectional view (b) Perspective view of single-ring prefabricated structure

Figure 3. Closed-cavity thin-walled components.

opposite ends of the prefabricated components is a tenon, and the other end is a mortice, see Figure 4. After the assembly of the components is completed, grout is injected into the gap between the mortise and the tenon through the reserved grouting hole to effectively fill the gap between the mortise and tenon, so as to effectively transmit the internal force of the section and limit the interface dislocation between the mortise and tenon.

Figure 4. Closed-cavity thin-walled components.

2.4 Joint waterproofness

The waterproof mode of prefabricated station shall be structure waterproof + joint waterproof, without an outer waterproof layer required. For structure waterproof, the scheme of “two gaskets + one injection + one caulking” is adopted, as shown in Figure 5, that is, two composite expansive rubber gaskets are arranged at the joint, modified epoxy resin is injected into the joint, and waterproof caulking is carried out for the reserved grooves of the joint inside the tunnel.

(a) Waterproof measures for joints (b) Waterproof measures of embedded joint

Figure 5. Waterproof measures for joints.

2.5 Structure assembly

In each lining ring, the floor component joints are tensioned and compressed by prestress, while the joints of the upper components are mainly compressed by

their own weight, and are connected by auxiliary bolts. Relay-type prestressed reinforcement is used to tension and compress the ring-ring joints ring by ring, as shown in Figure 6 (a). To ensure the assembly accuracy of prefabricated components and prevent collisions between components during assembly, a guide positioning pin rod is specially provided at the joint, as shown in Figure 6 (b), to guide the assembly movement direction of the components and limit unexpected assembly dislocation of joints.

(a) Schematic diagram of longitudinal prestressed tension connection

(b) Schematic diagram of guide positioning pin rod

Figure 6. Auxiliary devices for structure assembly.

2.6 Assembly steps

The assembly of prefabricated station structures starts from the fixed end of the first ring in the longitudinal direction and advances in one direction. In the process of circumferential assembly of prefabricated station structures, the “bottom-up” sequence is adopted, that is, starting from the lower floor structure and continuing the assembly upward in a block by block and layer by layer manner, similar to the way of “building blocks”. In the case that a horizontal structure such as floor, floor slab, or roof is assembled from multiple components, it is recommended to place the middle components in place first, and then assemble the components on both sides. Figure 7 (a) is a schematic diagram showing the assembly steps of fabricated station structures, while Figure 7 (b) is a schematic diagram showing the main assembly steps of the fabricated station structure of Changchun Metro Line 2 under the pile-anchor support system.

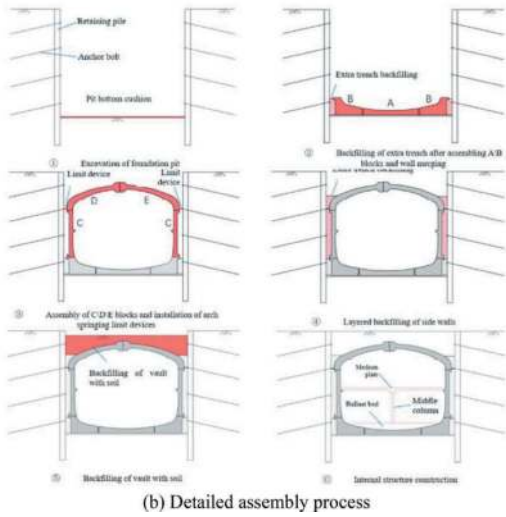

3 KEY TECHNOLOGY RESEARCH

3.1 Joint connection technology

“Grouted mortise-tenon joints” are a new type of connection joints specifically developed for prefabricated underground structures. The research team has conducted a comprehensive and in-depth discussion on the mechanical properties and design methods of grouted mortise-tenon joints from the perspectives of joint type, mechanical behavior, failure mode, bearing

(a) Schematic diagram of assembly steps for prefabricated station structure

(b) Detailed assembly process

Figure 7. Schematic diagram of assembly steps for prefabricated station structure of Changchun Metro.

capacity, and key design technologies, etc. by means of 1:1 prototype test and theoretical analysis. It mainly involves experimental research on the basic mechanical properties of joints, research on bending resistance characteristics, research on bending stiffness characteristics, research on bending and shear bearing capacity and failure modes, research on the design and calculation methods of compression bending bearing capacity, research on the design and calculation methods of shear bearing capacity, and research on key technologies for constructional design of joints.

Regarding different joint types, grouting materials, grouting ranges, and bending combinations, a self-developed joint prototype bearing performance and destructive loading test system was used to conduct a series of 1:1 full-scale prototype mechanical property tests (Figure 8).

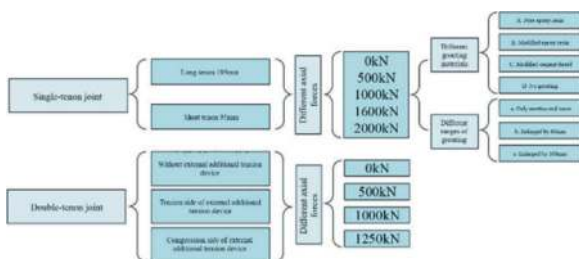

Figure 8. Schematic diagram of assembly steps for prefabricated station structure of Changchun Metro.

Main conclusions from the test:

- The test revealed the bending resistance characteristics of grouted mortise-tenon joints under axial force, and proposed the concept of

“resistance moment”. As an important basic index of joint bearing capacity, “resistance moment” is a strong support for subsequent research on joint mechanical behavior.

- It revealed the “variable stiffness” characteristic of the stiffness of grouted mortise-tenon joints changing with axial force and bending moment, formed an empirical formula for the bending stiffness of the joints by deriving the fitted $M-\theta$ curve, and proposed the main factors affecting the bending stiffness of the joints.
- The bearing characteristic curve of various joints and the proportion of bearing capacity at different bearing stages were revealed.
- Based on the impact of the above indexes on the bearing capability, fabrication, and construction convenience of joints, a set of joint constructional design steps (see Figure 9) and requirements are proposed.

Figure 9. Steps for joint constructional design.

3.2 Key technologies for the design of closed-cavity thin-walled prefabricated components

The use of closed-cavity thin-walled components is an important means for the lightweight design of large prefabricated components in underground structures. Cities such as Changchun, Qingdao, and Shenzhen have taken the lead in adopting closed-cavity thin-walled components in the lining structure of prefabricated metro stations. Given the fact that the structure types, stress environments, and mechanical behaviors of closed-cavity thin-walled components in underground structures are relatively complex, and there are no applicable norms and standards available for reference, a discussion will be made in this section on the key points of lightweight design for large fabricated underground structural components and the key technologies for closed-cavity thin-walled component design in conjunction with theoretical research and practical engineering applications, mainly involving lightweight methods for commonly used structural components, research on mechanical properties of closed-cavity thin-walled components, and key points of structural design and calculation analysis of closed-cavity thin-walled components. Research has shown that closed-cavity thin-walled components have significant lightweight effects, excellent mechanical properties, and similar characteristics to ribbed components with T-shaped, I-shaped and box-shaped sections in terms of shear lag effect and shear stress distribution law. The internal cavity ratio,

flange plates, longitudinal rib plates, diaphragm plates, and end plates of the components have a certain impact on the mechanical properties of the components. In practical engineering applications, it is necessary to, based on the specific situation of the project, grasp the mechanical behavior characteristics of components through numerical analysis or experimental research, determine the section type and constructional measures of closed-cavity thin-walled components in a reasonable manner, effectively control the influence of shear lag effect on the section, and ensure that the whole process of prefabricated components from production, lifting, transportation, assembly to use meets the design requirements of bearing capacity limit state and normal use limit state.

3.3 Structural mechanics behavior and calculation method of prefabricated stations

Grouted mortise-tenon joints have typical variable stiffness characteristics. The existence of joints makes the mechanical behavior of fabricated station structures significantly different from that of traditional cast-in-place one-piece structures. In this section, numerical simulations of multiple models, multiple construction stages, multiple load conditions, and multiple structure types are conducted, and field tests are made for comparative analysis to study the mechanical behavior of fabricated station structures. The research focuses include the research on the calculation and analysis method of overall action effect of prefabricated structures based on variable stiffness joint connection, the research on the influence of joint stiffness on mechanical behavior of prefabricated structures, the research on the structural mechanical behavior characteristics in assembly construction process and the main influencing factors, and the comparative research on in-situ testing of fabricated station structures, etc.

Based on the structural characteristics of prefabricated metro stations, and by means of dynamic time-history analysis and response displacement methods, and numerical model analysis, the seismic performance of prefabricated station structures is studied by comparing the seismic response laws of prefabricated station structures and the same type of cast-in-

place structures. The research focuses include the research on seismic response laws of prefabricated metro station structures, the influence of joints on the behavior characteristics of prefabricated structures under earthquake action, the research on the follow-up characteristics of prefabricated station structures and strata, and the influence of formation hardness on the seismic response of prefabricated station structures.

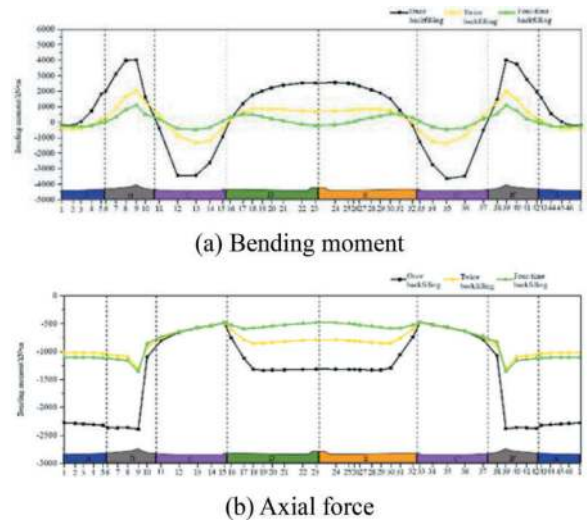

Figure 11. Structural internal forces in different backfill schemes when concrete materials are used for extra trench backfilling.

3.4 Key technology of joint waterproof

Regarding the characteristics of the structure construction, component manufacturing and construction technology of prefabricated stations, the main influencing factors and control indexes of two key parameters, “joint opening” and “gasket dislocation”, which are highly related to the waterproof performance of joints, are analyzed in this section. Based on the experimental research on gasket waterproof performance and the monitoring results of practical engineering applications, the key technology of “two gaskets + one injection + one caulking” multiple defense lines for joints has been proposed and fully demonstrated. In the double-gasket mode, the EPDM elastic gasket serves as the main waterproof, and the composite water-swallowable rubber as the reinforced waterproof, forming a composite sponge and multi-groove gaskets. The gaskets are the main line of defense for joint waterproof, while grouting and caulking are auxiliary lines of defense. According to the existing and under-construction projects, both the measured maximum opening and surface dislocation of the station structure joints meet the requirements of the joint waterproof performance control standards. In places where no enclosed waterproof layer is set, there is no water leakage at the joints.

4 APPLICATION EFFECT

The above technologies have been promoted and applied in many cities such as Changchun, Qingdao and Shenzhen, and the first batch of prefabricated stations in China have been built. As of now, the number of existing and under-construction prefabricated stations has reached 44, becoming the largest cluster of prefabricated stations in China and even the world. No safety accidents occurred during the construction period, and the stations are safe and reliable after operation, without structural water leakage. The technical, economic, and social benefits are significant. Figure 12 (a) is a schematic diagram of different prefabricated station structures in different cities, Figure 12 (b) shows photos of the assembly sites for prefabricated stations, Figure 12 (c) shows photos of the fabrication and assembly sites for prefabricated components, and Figure 12 (d) shows photos of the first batch of prefabricated metro stations in China opened to traffic. Among them, Xinglongpu Station is rated as one of the top ten most beautiful stations in China.

Moreover, this technology has also achieved extended application in other engineering fields such as highway tunnels and deep and large vertical shafts. Figure 13 (a) shows the schematic diagram and on-site construction photo of the highway tunnel (under construction) structure on Xinsen Avenue in Jinfeng Park, Chongqing. Figure 13 (b) shows the cross section of the fabricated vertical shaft structure of Terminal 3 (T3) of Chongqing Rail Transit Line 15 Phase I Project (under construction).

5 MAIN TECHNICAL ECONOMIC AND SOCIAL BENEFIT ANALYSIS

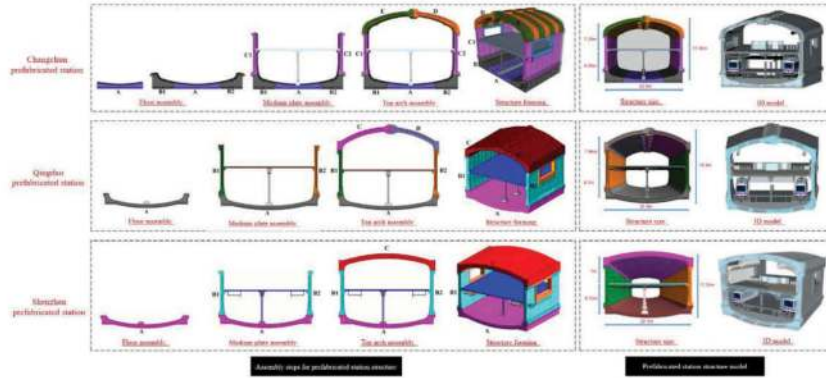

With the prefabricated stations of Changchun Metro as the measurement basis, compared with the cast-in-place concrete structure, the main advantages of the prefabricated structure for standard cut-and-cover station of the same scale are as follows:

- a. In the assembly link, more than 70% of the construction time can be saved, and the duration of each station can be shortened by 4-6 months, equivalent to the duration shortened by 25%-30%.
- b. In the assembly link, the construction personnel on the construction site are reduced by 85-90%; the operators during peak hours are reduced from 150-180 per shift to about 20.
- c. About 800t steel bars can be saved for each station.
- d. About 800m³ of timber used temporarily for construction can be saved.
- e. Construction wastes generated in construction are reduced by more than 50%.
- f. The land for construction can be reduced by about 1,000m².
- g. The comprehensive carbon emission can be reduced by about 19%.

Rail transit is the traffic artery of modern cities, which plays an important role in urban development and residents' life. The metro stations are usually built in the center of densely populated and busy commercial areas, located at the main traffic routes and are highly sensitive to construction.

Completely different from the cut-and-cover cast-in-place concrete structure, precast concrete components are used for prefabricated structure construction technology to enable quick mechanical assembly on site without wet concrete placing operation, so as to minimize the construction activities on site, give full play to the greatest advantage of prefabricated assembly. This construction technology with industrialization mode as the core has played an important role in social development, mainly in the following aspects:

- a. Project quality and construction safety have been greatly improved.
The industrialized and mechanical automation construction mode makes the prefabricated structure have higher production accuracy, better quality assurance and durability. The on-site high-risk operation links are reduced, and manpower is greatly reduced, which is convenient for project management and risk reduction in personal injury.
- b. Comprehensive benefits improved
The operation time on the assembly construction site is reduced by 70%, and the labor is saved by 85%. By reducing the duration and man-day, the comprehensive duration of a prefabricated station can be shortened by 4~6 months. Considering the above two advantages, the indirect economic benefits generated can reach RMB 10 million. Meanwhile, improving construction efficiency and speeding up construction are conducive to reducing the impacts of construction on urban land, transportation, commerce and the environment, alleviating labor shortages, and greatly improving the comprehensive benefits of urban rail transit construction.
- c. Employee-oriented principle
The industrialized construction mode will greatly change the low-end situations of the traditional construction industry, provide a clean work environment, reduce labor intensity, save labor, improve construction safety, and improve the happiness of employees as a whole.
- d. Green and environmental protection
No operations such as formwork erection on site, steel rebar binding and concrete placing & vibration on site during assembly can effectively reduce the pollution of construction noise and dust to the surrounding environment, and thus the satisfaction of residents is greatly improved. Wood consumption can be reduced by 800m³, construction waste can be reduced by more than 50%, and carbon emissions can be effectively controlled, which is conducive to reducing the impacts on the global environment.

Figure 13. Technical expansion.

- e. Promoting the development of construction industrialization and industry science and technology progress

The transformation from traditional labor-intensive mode to industrialization mode is of great significance to promote the optimization, upgrading and sustainable development of the construction industry. The R&D and successful application of fabricated station technology have led the development direction of green construction technology and strongly promoted the scientific and technological progress of the industry.

6 CONCLUSIONS AND RECOMMENDATIONS

For prefabricated structure construction technology of metro stations, a series of core achievements in industrialized construction covering engineering design, component production, construction technology and equipment, etc. have been achieved, forming a technical system supporting the whole process of construction, e.g. standardized design methods, high-accuracy fabrication methods for large precast components, intelligent testing devices, automatic mechanical assembly processes and technical standards, and providing a new construction mode for underground rail transit stations. This technology is an industrialized construction method developed for metro stations developed to solve the problem of construction impossibility in the severe cold winter in

Changchun, China, and is also applicable to the metro construction in other cities under various environmental conditions. This technology has been currently applied in Changchun, Qingdao and Shenzhen Metros.

The prefabricated construction technology developed for metro station structures is also applicable to other cut-and-cover underground structures such as metro section structures, entrance and exit passageways, air duct structures, and underground pipe racks. The structure type can be a single-arch long-span tunnel structure or a rectangular frame structure. The cut-and-cover foundation pit support system can be applied for slope setting, soil nail wall, shotcrete and rockbolt support, pile (wall) + anchor cable, and pile (wall) + interior support, etc. This innovative technology has broad applicability.

Although the outstanding achievements have been made for this technology after more than 10 years of development, there are still many problems to be solved and the technology shall be further improved and upgraded, e.g. improving the prefabrication ratio of the structure, reducing engineering investment, improving the concept of assembly, and strengthening innovation, deepening the integration of industrialization, increase the further development of informatization and intellectualization, and strengthening the promotion and application. This requires the joint efforts of the industry and continuous exploration to make this advantageous technology play a greater role and create more value.

ABSTRACT: Understanding the distribution of excess pore water pressure induced by the TBM is of importance when assessing the stability of the tunnel face. The presence of high excess pore water pressure is not favourable in this regard. Previous studies have extensively investigated the excess pore water pressure generated by TBM tunnelling in saturated aquifers using field measurements and numerical simulations. However, there is a lack of investigation into the excess pore water pressure in the front of the TBM when excavating in unsaturated soils. To address this knowledge gap, a CFD (Computational Fluid Dynamics) model is introduced in this paper to simulate the water flow in front of the tunnel excavation face under both saturated and unsaturated soils. Results show that in the case of saturated soil, the distribution of excess pore water pressure obtained from the model calculation exhibited excellent agreement with the measurements taken during the excavation of the second Heine-noord Tunnel in the Netherlands. Excess pore water pressure in unsaturated soil exhibited a much shorter influence zone compared to saturated soil conditions. Moreover, the influence zone of excess pore water pressure in unsaturated soil expands as a function of infiltration time and saturation degree.

Keywords: Excess pore water pressure, TBM, CFD, Saturated, Unsaturated

1 INTRODUCTION

During the drilling process of a slurry TBM, the infiltration of bentonite triggers the generation of excess pore water pressure within the soil in front of the tunnel face. This phenomenon may pose challenges for tunnel face stability, as the excess pore pressure will reduce the effective tunnel face pressure (Bezuijen et al., 2001, Broere, 2002).

Extensive research has been conducted on the excess pore water pressure induced by slurry TBM in saturated soil conditions. Through analysis of the field measurements during the construction of the Second Heine-noord Tunnel, the Netherlands, Bezuijen et al. (2016) concluded that excess pore water pressures can be expected when drilling in saturated sand, and the formula developed can be used to calculate the pore water pressure distribution at a certain distance from the tunnel face, assuming unconfined flow

in the aquifer where the tunnel is constructed. This formula was subsequently validated using 3D simulations (Zizka et al., 2017). Furthermore, Xu and Bezuijen (2018) compared this model with the transition model for estimating the excess pore pressure in a semi-confined aquifer, proposed by (Broere and van Tol, 2001). It was found that these two models gave comparable results, and both can be fitted to the field measurements. In the case of the Second Heine-noord Tunnel, the maximum influence distance of excess pore water pressure was found to be up to 30 m. Mori et al. (1995) reported a similar value of 30 m in sandy soil based on laboratory tests, numerical modelling, and field observations.

Compared to the well-studied saturated conditions, there is a notable lack of research examining excess pore pressure in the unsaturated soil influenced by the slurry TBM. Some investigations explored the stability of the tunnel face in unsaturated soil through centrifuge tests and numerical

*Corresponding author: Chenghao.Zhang@Ugent.be

analysis. Soranzo et al. (2015) found that suction played a favourable role in enhancing the effectiveness of tunnel face. Dziuban et al. (2018) observed that with the increase of the saturation degree of the soil, the failure zone decreases, while the settlement of the ground surface increases. To bridge the knowledge gap, this study deals with the excess pore water pressure distribution in the unsaturated sandy soil just in front of the tunnel. The results were compared with the saturated condition.

2 NUMERICAL MODELLING

COMSOL Multiphysics computer software was used to perform the finite element analysis, incorporating the porous media and subsurface flow models. The 2D finite element model built has a length of 150 m, a width of 100 m, and a 50 m × 10 m opening, while the dimension of 3D model is 150 m × 100 m × 100 m, with a cylindrical tunnel opening (diameter in 10 m and length in 50 m). It is important to highlight that achieving convergence in 3D models can be notably challenging when simulating unsaturated conditions. As a result, 3D modelling is only reserved for saturated conditions in this study. A free triangular mesh for 2D model or a free tetrahedral mesh for 3D model was generated across the entire domain, with a refined mesh strategically applied around the tunnel face to enhance the precision of calculation results.

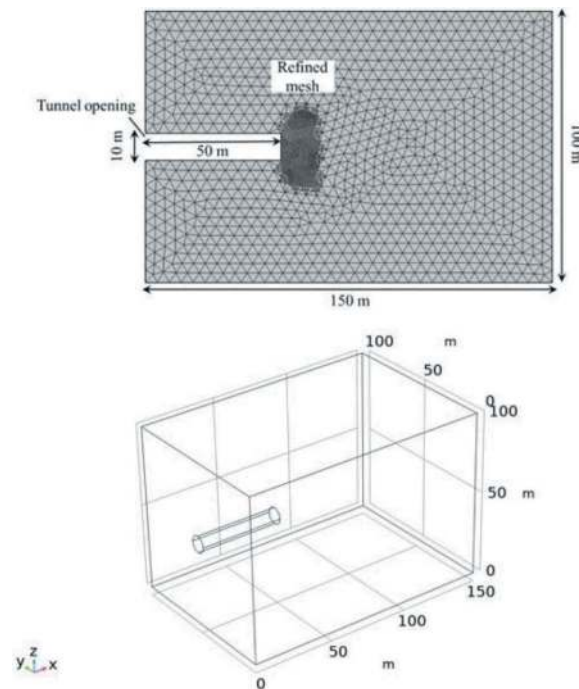

Figure 1. Geometry of the tunnel models, 2D model (top), and 3D model (bottom).

2.1 Governing equations for the water flow

In the case of saturated soil, the governing equation comprises a combination of Darcy's law and the continuous model:

$$\frac{\partial \varepsilon_p \rho}{\partial t} + \nabla \cdot \rho \mathbf{u} = 0 \quad (1)$$

$$\mathbf{u} = -\frac{K}{\mu} (\nabla p - \rho \mathbf{g}) \quad (2)$$

With ε_p the porosity, ρ (kg/m³) the fluid density, t (s) the time, \mathbf{u} (m/s) the Darcy's velocity or specific discharge vector, K the intrinsic permeability of the porous medium (m²), μ (Pa·s) the fluid dynamic viscosity, p (Pa) the pore water pressure, and \mathbf{g} (m/s²) the acceleration of gravity.

To describe water flow in unsaturated soil, Richards' equation, as depicted in Equation (3), was chosen as the governing equation.

$$\rho(C_p + Se \cdot S) \frac{\partial p}{\partial t} + \nabla \cdot \rho \left[-\frac{K \cdot k_r}{\mu} (\nabla p + \rho \mathbf{g} \nabla D) \right] = 0$$

With ρ (kg/m³) the fluid density, C_p (m⁻¹) the specific moisture capacity, Se (-) the effective saturation, S (m⁻¹) the storage coefficient, p (Pa) the pore water pressure, K (m²) the intrinsic permeability of the porous medium; k_r the relative permeability (a function of saturation for a given fluid), μ (Pa·s) the fluid dynamic viscosity, \mathbf{g} (m/s²) the acceleration of gravity, and D (m) the coordinate (for example, x, y, or z) of vertical elevation.

The specific moisture capacity C_p depends on changes in the effective saturation with respect to the capillary pressure as

$$C_p = (\theta_r - \theta_s) \frac{\partial Se}{\partial p_c} \quad (4)$$

where θ_s is the total porosity or saturated volume fraction; θ_r is the residual volume fraction; so the difference $\theta_s - \theta_r$ is the available pore space for phases to move.

The capillary pressure p_c is commonly defined as the difference between the pressure of the nonwetting (p_{nw}) and wetting phases (p_w).

$$p_c = p_{nw} - p_w \quad (5)$$

It is assumed in Richards' equation that the air in the soil is supposed to be at atmospheric pressure, suggesting $p_{nw} = 0$ and then $p_c = -p_w$.

The storage coefficient S represents the ratio of the change in the volume of groundwater that can be extracted from or released into an aquifer to the change in the hydraulic head (water level) within that aquifer.

$$S = \rho g(\chi_p + \theta\chi_f) \quad (6)$$

Here, ρ is the fluid density, (kg/m^3), g is the acceleration of gravity, (m/s^2), while χ_p and χ_f are the compressibility constants of the solid particles and fluid, respectively, ($\text{m}\cdot\text{s}^2/\text{kg}$).

The solution to the governing equation, Equation (3), can be obtained if the simultaneous variations of θ , C , Se , k_r , and p_c are addressed. These relationships are defined by specific equations, such as the Van Genuchten-Mualem formulas (Van Genuchten, 1980), see Equation (7).

$$\theta = \begin{cases} \theta_r + Se(\theta_s - \theta_r) & H_c > 0 \\ \theta_s & H_c \leq 0 \end{cases}$$

$$Se = \begin{cases} \frac{1}{[1 + \alpha H_c^n]^m} & H_c > 0 \\ 1 & H_c \leq 0 \end{cases}$$

$$C_m = \begin{cases} \frac{\alpha m}{1-m} (\theta_s - \theta_r) Se^{\frac{1}{m}} (1 - Se^{\frac{1}{m}})^m & H_c > 0 \\ 0 & H_c \leq 0 \end{cases}$$

$$k_r = \begin{cases} Se^L \left[1 - \left(1 - Se^{\frac{1}{m}} \right)^m \right]^2 & H_c > 0 \\ 1 & H_c \leq 0 \end{cases} \quad (7)$$

where S_e is the effective saturation; θ_s is the total porosity or saturated volume fraction; θ_r is the residual volume fraction; H_c is the capillary pressure head, $= P_c/\rho g$; C_m is the specific capacity, $= C_p \cdot \rho g$; α , n , and m are the parameters in the Van Genuchten model; and L is a lumped parameter that incorporates both pore tortuosity and pore connectivity.

The excess pore water pressure reported in the subsequent sections originates from determining parameter p in Eq. (1) under saturated conditions or in Eq. (3) under unsaturated conditions.

2.2 Boundary conditions and input parameters

The boundary conditions for both saturated conditions and unsaturated conditions are demonstrated in Figure 2. In both scenarios, a pressure head of 5 m (consistent with the pressure head used in the Second Heinenoord Tunnel) was imposed at the tunnel face. The roof and bottom of the tunnel were modelled as impermeable, no flow. For the remaining domain and boundaries, an initial pressure head of 0 m was applied in the case of saturated condition, while in unsaturated conditions, an initial pressure head which is related to the initial degree of saturation was employed (for example, -0.05 m, for initial saturation

of 0.8). Additionally, a pressure head of 0 m was specified at the bottom boundary of the unsaturated soil model, suggesting this is a saturated boundary.

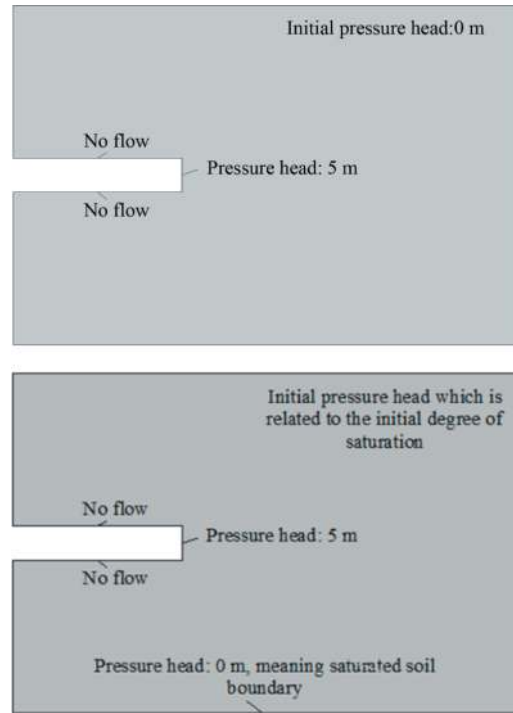

Figure 2. Boundary conditions for saturated soil model (top) and for unsaturated soil model (bottom).

The values for the input parameters are listed in Table 1.

Table 1. Summary of the input parameters.

Variable	Description	Unit	Value*
ρ	Fluid density	kg/m^3	1000
μ	Fluid dynamic viscosity	$\text{Pa}\cdot\text{s}$	$1\cdot 10^{-3}$
K	Intrinsic permeability of the porous medium	m^2	$4\cdot 10^{-11}$
θ_s	Saturated volume fraction	-	0.4
θ_r	Residual volume fraction	-	0.021
α	α parameter	m^{-1}	14.5
n	n parameter	-	2.68
m	m parameter	-	$1-1/n$
L	Lumped parameter	-	0.5
χ_p	Compressibility of the solid particles	$\text{m}\cdot\text{s}^2/\text{kg}$	0
χ_f	Compressibility of fluid	$\text{m}\cdot\text{s}^2/\text{kg}$	$4.4\cdot 10^{-10}$

* The parameters in the Van Genuchten model (α , n and m) were set to typical values for sandy soils. (Brunner et al., 2010). The value for L is an optimal value for a data set of 45 samples (Mualem, 1976).

3 SIMULATION RESULTS

3.1 Saturated conditions, 2- and 3-D modelling

The excess pore pressure in the saturated sandy soil just in front of the tunnel face was demonstrated in Figure 3.

Figure 3. Excess pore water pressure distribution, surface (top), and central axis (bottom). Arc length means the distance from the tunnel face.

Based on the observations from Figure 3, it becomes evident that excess pore pressure is immediately present up to 50 m in front of the tunnel face. There is some difference with the field measurement data recorded during the construction of the Second Heinenoord Tunnel, suggesting that the 2D model may not accurately depict the actual geological layers. Additional 2- and 3-D numerical calculations were conducted using models of varying sizes to gain a more comprehensive understanding of how the excess pore pressure varies with distance from the tunnel face. The resulting data was then subjected to fitting using a model proposed by Bezuijen et al. (2001) for an unconfined aquifer, see Equation (8). The outcomes and the quality of the fit can be examined from Figure 4.

$$\phi = \phi_0 (\sqrt{1 + (x/R)^2} - x/R) \quad (8)$$

With ϕ_0 the pressure head at the tunnel face in front of the infiltrated zone, ϕ the pressure head at a distance x in front of the tunnel face, and R the radius of the tunnel, assuming a pressure head of zero far from the tunnel in the pore water.

Figure 4. Excess pore water pressure distribution of 2D and 3D modelling (central axis). 2D big model (150m*100m), 3D big model (150m*100m*100m), 2D small model (70m*70m), and 3D small model (70m*70m*70m).

From Figure 4, it can be concluded that both the 2D and 3D models proposed exhibited a satisfactory fit with Equation (8). The 3D model proved to be more accurate, closely mirroring the excess pore water distribution observed in the actual field measurements, and values ϕ_0 and R used in the project and as input in the numerical model. It is worth noting that the model size substantially affects the outcomes of the 2D simulation, whereas its impact on the 3D simulation is relatively modest. Only the 3D model results in a value for R which is comparable to the radius of the tunnel (5 m).

3.2 Unsaturated conditions

The distribution of excess pore water pressure within the unsaturated soil at 80 % saturation is demonstrated in Figure 5. Additionally, Figure 6 displays the corresponding variations in the degree of saturation.

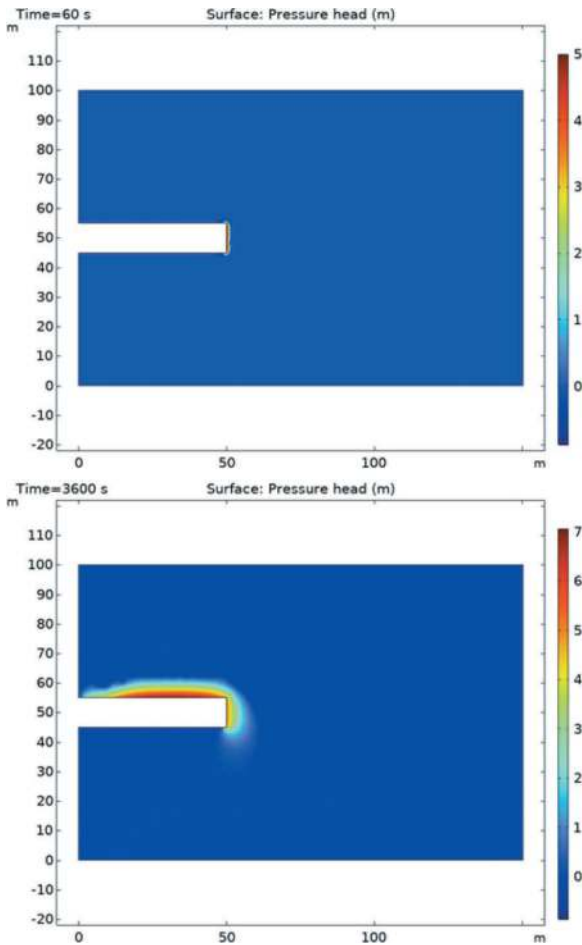

Figure 5. Pressure head changes with time (t=60 s, top and 3600 s, bottom), 80 % saturation.

Based on Figure 5, it can be observed that the pressure head increased as the fluid arrived. The remaining aspects remained unaltered, signifying the initial pressure. The initial pressure assumed a negative value due to the unsaturated nature of the soil.

In a manner similar to the pressure head variation, the degree of saturation increased upon the arrival of the fluid, as depicted in Figure 6. The remaining components were constant, representing the initial saturation. At 3600 s, alterations in saturation occurring at the upper boundary of the tunnel are primarily attributable to gravitational effects, whereas changes at the lower boundary of the entire model stem from capillary pressure.

Moreover, it is interesting to see an emergence of a saturated flume at 3600s, flowing from the upper section downward at the tunnel face, which will influence the excess pore water pressure in front of the tunnel face to some extent, as discussed in more detail in the following section.

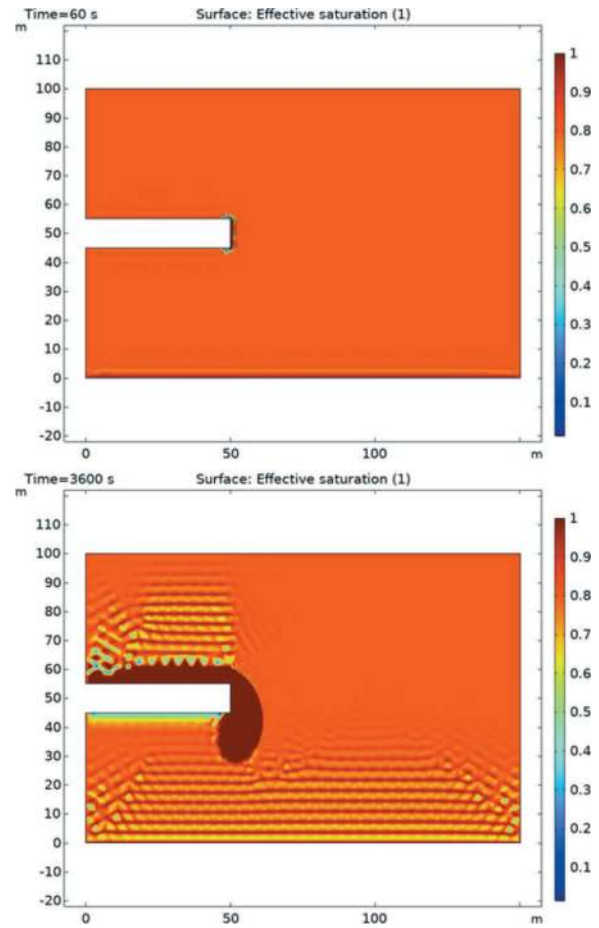

Figure 6. Degree of saturation changes with time (t=60 s, top and 3600 s, bottom), 80 % saturation.

From a practical perspective, it is important to highlight that the unsaturated condition with a constant degree of saturation in sand over 100 m does not align with reality. In real-world scenarios, saturation typically increases at the bottom and decreases at the top. Therefore, the overall calculated pressure distribution is not correct. However, this calculation can still be valuable when assessing the excess pore water pressure distribution in front of the TBM since the laminar flow conditions are applied.

Figure 7 illustrates the distribution of excess pore water pressure along the central axis of the tunnel, accompanied by the corresponding variations in effective saturation.

Figure 7 reveals that excess pore pressure is evident within a limited zone in front of the tunnel face, even with 80 % saturation, which is considerably less than that seen in saturated conditions. In real TBM projects, penetration times typically range from 20 to 60 seconds or even longer (Zizka et al., 2019), derived by calculating the timespan between subsequent cutting

a) initial degree of saturation: 0.2, pressure head (top), effective saturation (bottom).

c) initial degree of saturation: 0.6, pressure head (top), effective saturation (bottom).

b) initial degree of saturation: 0.4, pressure head (top), effective saturation (bottom).

d) initial degree of saturation: 0.8, pressure head (top), effective saturation (bottom).

Figure 7. Pressure head and saturation variations along the central axis over time.

tool passing. Consequently, the influence zone typically spans less than 1 m. In saturated soil scenarios, however, the influence zone can be 50 m.

Given the presence of a saturated front entering the previously unsaturated soil, as evident in Figure 7, an analytical calculation can be made to determine the penetration distance x :

$$q = k \frac{\phi_0}{x} \quad (9)$$

With q (m/s) the Darcy's velocity, k (m/s) the permeability of the soil, and ϕ_0 (m) the difference in piezometric head.

Regarding pore velocity, Equation (9) transforms into:

$$n(1 - Se) \frac{dx}{dt} = k \frac{\phi_0}{x} \quad (10)$$

With n (-) the porosity, and Se (-) the degree of saturation.

Integration of Equation (10) with $t=0$, $x=0$, leads to:

$$x = \sqrt{2 \frac{k}{n(1 - Se)} \phi_0 t} \quad (11)$$

By utilizing the same parameters employed in the numerical simulation, namely a water permeability of 4×10^{-4} m/s (k) and a porosity of 0.4 (n), the penetration distance of water in the unsaturated soil at 60% saturation was calculated using the analytical model Equation (11). The calculated results are depicted in Figure 8, alongside the results derived from the numerical analysis.

It follows from Figure 8 that the analytical model Equation (11) provided a comparable prediction of the excess pore pressure when compared to the numerical simulation (without considering the gravity influence). As previously

Figure 8. Distribution of excess pore water pressure in front of the tunnel face, both from numerical simulation and analytical calculation.

stated, it is clearly seen from Figure 8 that gravity induced a downward saturated flow, which reduced the excess pore pressure in front of the tunnel face. This downward flow only happened after a prolonged penetration time, around 3600 s in this case study. However, this long penetration time is impossible in the real slurry TBM project due to the cutting of TBM tools and the potential formation of a filter cake.

4 DISCUSSION

The simulations conducted in this study highlight a significant difference in the behaviour of excess pore water pressure in saturated versus unsaturated soils. When drilling in saturated sandy soil, the excess pore water pressure can extend as far as 50 m ahead of the tunnel face. In contrast, the impact of excess pore water pressure is confined to around 1 m, see next sections, when dealing with unsaturated sandy soil. Based on the experiences with slurry-filled trenches (Kilchert and Karstedt, 1984), it is advisable to consider that only the pressure drop within the wedge width, roughly equivalent to half of the tunnel diameter (Broere, 2002), may be reckoned in the effective support force. The excess pore water pressure beyond the wedge can lead to an upward force and a force on diagonal of triangle of the wedge, diminishing the effective support pressure. For a tunnel with a diameter of 10 m, the estimated critical failure wedge width may be around 5 m. This suggests that excess pore water pressure can exert a detrimental influence on tunnel face stability when excavating saturated soil. However, its impact is significantly less pronounced when the soil is unsaturated. These findings for unsaturated soils need field verification, especially when the saturated degree is high. This is because the simulation, which solved Richards' equation, does not account for the air pressure. In soils with lower degrees of saturation, air can be interconnected, implying that the pressure is close to the atmospheric pressure. However, in soils with higher degrees of saturation, air might become entrapped in the water, leading to a pressure that deviates from atmospheric conditions. In this latter scenario, it becomes imperative to carefully monitor and assess the air influence during the drilling of slurry TBM.

It is worth noting that this paper does not explore the influence of bentonite slurry infiltration. If considering the infiltration of bentonite into saturated soil, certain insights may emerge. Specifically, if the drilling velocity of the TBM is lower than the infiltration rate, there will be some slurry infiltration zone in front of the tunnel face and a certain percentage of the pressure drop will happen in this infiltrated zone, causing a reduction in excess pore water pressure

(Kaalberg et al., 2014). Consequently, the diminished pore water pressure aligns with a reduced risk of tunnel face instability. On the other hand, when the drilling velocity of TBM exceeds the infiltration rate, the distribution of excess pore water pressure remains comparable to the findings presented in this paper (Bezuijen et al., 2016).

In the case of unsaturated soil, the distribution of excess pore water pressure in a real slurry TBM drilling in the same soil, as studied in this paper, would be shorter than the simulated results. Assuming the permeability of sand for bentonite slurry is 4×10^{-5} m/s, ten times smaller than the water permeability, the excess pore pressure would extend up to 0.39 m at 60 s and 3 m at 3600s when the soil is at 60% saturation, as determined by Equation (11). These values are significantly smaller than the corresponding values (1.22 m at 60 s and 9.49 m at 3600 s) when considering only water penetration, as demonstrated in Figure 8. This indicates the excess pore water distribution is limited during the drilling of TBM in fine and medium-coarse sand. Only for coarse sand and gravel can the penetration depth be large enough to influence the stability of the front face.

Furthermore, our ongoing experimental tests reveal that the penetration of the bentonite slurry in unsaturated soil is notably faster than that in saturated soil, and there probably will be a filter cake formation before the subsequent TBM cutting tool passing. This suggests the main pressure drop will happen within the slurry infiltrated zone or almost entirely over the thin filter cake, which is favourable for enhancing the stability of the tunnel face.

In our future work, the influence of bentonite slurry penetration on the excess pore pressure is planned to be incorporated into the modelling. Field assessments should be conducted to monitor the influence of air, and the collected data will be valuable for back analysis. Additionally, for unsaturated soil, our current simulations for unsaturated soil has solely centred on 2D models. The future work will shift its focus towards the implementation of 3D models to investigate potential disparities when compared to the 2D models.

5 CONCLUSION

The numerical simulation presented, and the results discussed in this paper allow the following conclusions to be drawn.

- 1) In the case of saturated sandy soil, the excess pore pressure was observed at a significant distance from the tunnel face, which closely aligns with field measurements. Notably, the 3D model exhibits better fit compared to the 2D model.
- 2) When dealing with unsaturated sandy soil, the zone of excess pore water pressure expanded with increasing saturation levels; however, it

remains significantly smaller than what is observed in saturated conditions, even at 80% saturation. This finding needs field verification because the simulation relies on the assumption of atmospheric air pressure, which may not be valid, particularly in unsaturated soils with high saturation degrees. Since there is a saturated front entering the unsaturated soil, an analytical calculation can be made to determine the penetration distance.

- 3) The limited extent of the excess pore water pressure zone in unsaturated soil implies that it has a minimal impact on tunnel face stability. In contrast, the longer excess pore pressure distribution zone in saturated sandy soil exerts a noticeable unfavourable influence on tunnel face stability.

ABSTRACT: In order to solve the problems of shallow overburden, large slope of launching section, mixed face ground condition (upper sand layer, middle and lower whole, strong and medium-weathered pelitic siltstone), curve radius launching with umbilical system, etc., combined with the implementation conditions and the geological condition of the launching area of the project. Measures such as breaking the launching eye wall in stratified sections, two-time sealing the launching gate, enhancing the water dispersion resistance of synchronous grouting and in time secondly grouting, strictly controlling the excavation speed, slurry density, strengthening CW central flushing, washing exaction chamber invert while ring building, replacing alloy-inserted cutting tools, strengthening settlement monitoring interval and timely feedback of monitoring results, etc, ensuring the successfully launch of the shield machine in Guangzhou Haizhu Bay Tunnel. The paper summarized the key technology of shield machine launching with shallow overburden in Haizhu Bay Tunnel, to provide reference for similar projects.

Keywords: Super large diameter slurry shield, Shallow overburden launching, Mixed face ground condition, Risks of launching

1 INTRODUCTION

As a key link of shield construction, initial test driving is also an important and difficult point in shield construction^[1,2], which has been studied by relevant scholars. Such as: You Yongfeng et al^[3] developed a set of construction techniques for ultra-shallow soil cover of Chunfeng tunnel, aiming at the problems that the tunnel door seal is prone to soil erosion, and the driving attitude and section attitude are difficult to control. Zhang Boyang^[4] summarized the key technologies of shield tunnel initiation based on a river crossing project in Nanjing. Du Chuangdong et al^[5] gave a detailed introduction to each process of underground assembly and start-up construction of mud shield in the Shiziyang Tunnel of the new Guangzhou-Shenzhen-Hong Kong Passenger Special Line, and summarized the construction experience of shield assembly and start-up; Fang Xinsheng et al^[6] summarized the experience of shield tunneling in Qinghuayan Tunnel, studied its driving parameters and the layout of engineering components such as reaction frame, and used finite element software to analyze and calculate the static strength of the reaction frame. In addition, some scholars have studied the

initiation of steel sleeves^[7], the sealing technology of tunnel doors^[8], the emergence of segment floating^[9] and the formation of mud with shield cutters^[10,11] during the initial test driving.

Taking Haizhuwan Tunnel in Guangzhou as an example, this paper analyzed and studied the construction risks and problems in the preparation and test driving stage, and summarized the key technologies of Haizhuwan Tunnel.

2 PROJECT OVERVIEW

2.1 Project introduction

The length of the western line of Haizhuwan Tunnel is 2093.13m, and the length of the eastern line is 2102m. The length of the initial test driving section of the double-line shield tunneling is 100 rings (200m), and two slurry shield tunneling machines with excavation diameter of 15.07m are used for construction. Among them, the western shield is a normal pressure cutter head, and the eastern shield is a pressure cutter head. The minimum flat surface radius of the line is 1000m, and the maximum slope is 4%.

2.2 Hydrogeological conditions and surrounding environment

2.2.1 Hydrogeological condition

The covering thickness at the beginning of the shield is 8.87~24.95m. The strata from top to bottom are mainly: mixed fill soil, silt, fine sand, medium coarse sand, whole, strong and medium-weathered argillaceous siltstone, and the excavated section is mainly located in the sand layer and whole, strong and medium-weathered argillaceous siltstone. The clay mineral content of the argillaceous siltstone is about 30%, and the maximum uniaxial compressive strength of the rock is about 50MPa.

The surface water and groundwater at the beginning of the shield are as follows:

- (1) Surface water: The project runs through the Lijiao River and Sanzhixiang River, which are major rivers of the Pearl River System. At the same time, there are also four inland river surges along the route, which are important flood drainage channels for Haizhu District, Luoxi Island and Nanpu Island to communicate with the Pearl River.
- (2) Ground water:
 - ① Type: There are mainly water retention in the upper layer, pore diving in the quaternary sand layer and confined water in the pore fissure of bedrock.
 - ② Groundwater level and dynamic changes: The groundwater level of the site is generally shallow. According to the observation 24 hours after the final hole of the drilling, the buried depth of the mixed stable water level of the site is generally 0.10 ~ 3.30m, and the elevation is generally 3.09 ~ 6.04m. Every year from May to July is the rainy season, the atmospheric rainfall is abundant, the water level will rise slightly, and in winter due to the decrease of precipitation, the groundwater level will drop slightly. The variation range of the water table is about 1.0m.

2.2.2 Surrounding environment

The surface environment is mainly self-owned roads and river surges. The surface environment is shown in Figure 1.

Figure 1. Surface environment plan of the starting section.

3 ACTUAL CONSTRUCTION SITUATION

The Haizhuwan Tunnel started smoothly with a super large diameter slurry shield tunnel, however, there were still problems such as crack removal at the entrance of the tunnel, leakage of slurry from the sealing of the initial warehouse entrance, surface monitoring and warning, pipe leakage, deterioration of excavation parameters (mud accumulation at the cutterhead opening), and severe tool wear. The specific problems were analyzed and summarized below, and suggestions were provided for the subsequent excavation construction under similar conditions.

3.1 Cracks appear in the tunnel door and slurry leakage from the initial construction tunnel door seal

3.1.1 The tunnel door cracks

- (1) Briefing
On February 9, 2023, the shield machine of the western line began to break the concrete of the tunnel door. On February 12, 2023, transverse cracks were found in the tunnel door and stopped breaking.
- (2) Causes analysis
 - 1) The 1.2m range of the tunnel door is reinforced with fiberglass bars (without hooks on the inner and outer layers) and a washing tank joint, and there is no rigid connection between the ground and wall.
 - 2) During the hoisting of large components such as the cutterhead and main drive of the shield tunneling machine on the western line, a single track of an 800 ton crawler crane was pressed above the ground connecting wall of the tunnel portal, while the other track was in the end reinforcement area. Although the monitoring data of the ground and the side walls of the main structure were normal, cracks have appeared inside the connecting walls.
- (3) Targeted measures
 - 1) Disposal measures: A 300mm I-beam support was set up at 1.5m below the crack position of the ground link wall (Figure 2), and the two ends were welded with the tunnel door steel ring. In the middle, three I-beams were arranged evenly to the cutters of the shield tunneling machine, and the bottom I-beam supports were arranged according to the monitoring situation of the tunnel door. The I-steel support was close to the palm surface of the ground connecting wall, and the gap position was filled with wood wedges to ensure that the I-steel fits the ground connecting wall; The reinforced area at the end of the west line shall be enclosed, and large equipment shall not be allowed to walk.

Table 1. Statistical table of internal monitoring control value of tunnel door at the end of Nanpu working well.

Number	measuring items	Methods and tools	Measurement frequency	
			Allowable value /mm	Average rate control value mm/d
1	Site inspection	Photography observation	/	/
2	Horizontal displacement	Total station	30	3
3	Vertical displacement	Total station	30	3

2) Monitoring measures: In order to ensure the safety state of the internal structure of the tunnel door ring, 6 small L-shaped prisms were evenly arranged at the ground connecting wall inside the tunnel door ring to monitor the internal structure, and the monitoring frequency is 3 times /d. By comparing and analyzing the monitoring data in real time, the changing trend of the horizontal displacement and vertical displacement of the palm surface can be grasped, and timely warning can be made to ensure the construction safety. Specific control values and change rates of monitoring items were listed in Table 1.

Figure 2. Layout diagram of I-beam support.

3.1.2 Initial warehouse door seal leakage

(1) Briefing

During the construction of the west line shield, leakage occurred at the bottom and middle of the tunnel door sealing device.

(2) Causes analysis

- 1) Under the influence of the anti-planting cushion in the outer door ring, the folding plate and curtain rubber plate interfered with the outer edge hob, which caused the bottom folding plate and curtain rubber plate to crack during the shield advancing process, resulting in large leakage at the bottom of the door ring.
- 2) The internal filling of the sealing device at the cave door was not timely, resulting in a small amount of mud leaking from the middle of the sealing device at the cave door.

(3) Targeted measures

At the bottom of the external tunnel door ring, a secondary sealing seal was applied in advance to seal the bottom leakage. At the same time, before the departure of the eastern line, the position of the anti planting head cushion layer, curtain rubber plate, and folding pressure plate inside the tunnel door ring should be confirmed to ensure that the curtain rubber plate and folding pressure plate were intact and undamaged. By taking the above measures, the sealing condition of the door of the shield tunnel starting from the east line was good and there was no leakage.

3.2 Surface monitoring and early warning

(1) Briefing

Surface monitoring and early warning of the western Shield: On April 9, 2023, the accumulated change of the settlement value of the surface monitoring points exceeded the red warning value.

(2) Cause analysis

- ① The settlement area was mainly in the area of Dongxiangcun River, and the buried depth of the tunnel vault was about 12m. When the shield tunneling was driven in the upper soft and lower hard stratum, the upper stratum was easily disturbed when the cutter cut the soil layer, resulting in the instability of the undisturbed soil and the ground settlement.
- ② The shield body of the shield machine was a conical structure, with a maximum gap of 110mm between the excavation diameter of the cutterhead and the diameter of the shield tail, and a gap of 570mm between the protruding pipe segment and the shield tail. Improper grouting filling in this area can easily lead to ground settlement;
- ③ There was F237 fault zone near the River, with a width of about 20m. The rock mass was broken to relatively broken, and the sidewall stability was poor. When the shield tunneling in this stratum, the instability of the palm surface may also affect the surface settlement.

(3) Targeted measures

① Considering the surrounding environment of the project and expert advice, the monitoring level of the 150m starting excavation section of the project was considered as three levels. The

cumulative monitoring control value of surface settlement was 45mm, and the change rate was used as a reference value.

② Through the radial grouting hole of the shield tunneling machine, the effect of mud removal was injected into the shield shell to effectively fill the gap between the shield shell and the excavation profile and prevent the natural settlement of the formation.

③ Timely secondary grouting and increase the incision pressure to achieve “head and tail protection”.

3.3 Analysis and countermeasures of quality problems in segment forming

(1) Briefing

When the shield segment was assembled into a ring, the overall quality was good, but it is easy to produce misalignment, cracking and leakage after the shield tail is removed. The maximum misalignment was 15mm between the rings, with 13 damaged pipe segments and 37 water leaks.

(2) Cause analysis

1) When assembling the inner segments of the shield tail into a ring, they were constrained by the shield tail brush and had no buoyancy effect, resulting in better forming quality of the segments. However, due to the effect that the hole passes through the upper stratum of medium coarse sand and fine sand, it was difficult to solidified after simultaneous grouting slurry injection, which cannot restrain the segments in time and provide the first waterproof protection, and the segments were easy to float up and then misalignment between rings occurs.

2) The segment design of this project was a concave and convex tenon structure, the stiffness between pipe rings was large, but the segment is prone to stress concentration failure after the relative displacement, resulting in the cracking of the pipe segment concrete and the formation of leakage channel.

(3) Targeted measures

1) Strengthen segment prefabrication quality control: avoid large transverse cracks forming leakage channels.

2) Improved synchronous grouting slurry: shorten the initial setting time and enhance the anti-dilution ability of the slurry, so that the mortar solidifies early, constrains the segment and provides the first waterproof effect.

3) Strengthen secondary grouting: double liquid injection was carried out at the leaking position to restrain segment displacement in time and provide the rear waterproof effect of segment wall.

4) Tightening measures for strengthening segment bolts: strictly implement the triple

tightening system of segment bolts, especially for the newly removed shield tail segment to strengthen segment bolts, and further enhance the overall stiffness between segments.

3.4 Deterioration of excavation parameters and severe tool wear

(1) Briefing

1) Deterioration of excavation parameters

According to the rock and mineral identification report, the clay mineral content of the shield through the formation at the initial stage was about 30%. Slurry shield tunneling in the stratum with high clay mineral content for a long time was very easy to lead to the deterioration of tunneling parameters, serious tool wear, limited tunneling efficiency, and even the phenomenon of the cutter head opening burning and the cutter head forming mud cake.

Due to the large excavation section of super-large diameter shield, there may be great differences in formation lithology and weathering degree, so the adaptability of tool configuration and selection was very important for shield tunneling efficiency. According to statistics, a total of 77 cutting tools were sampled during the excavation of the project, of which 48 were normal wear and 29 were abnormal wear (5 were ring damage and tooth breakage).

(2) Cause analysis

1) The stratum through the excavation was mainly muddy siltstone with high clay mineral content. In the process of excavation, under the condition of low specific gravity, most of the residue disintegrates into the mud, resulting in a rapid increase in the specific gravity of the mud, and at the same time, the burden of centrifugal equipment was increased, the centrifugal effect was poor, and the slurry abandonment pressure was large. After the specific gravity increases, the residue no longer disintegrates, and was easy to attach to the cutter head and gradually form accumulation. If not controlled, a large number of panel friction torque provides a large amount of heat, resulting in clay minerals mixed with other residue to burn into secondary rock blocks, and then form mud cake.

2) The driving parameters were adjusted during the driving process, and it was found that the cutter head torque changed periodically, with a fluctuation close to 8MN*m, and the driving speed was inversely proportional to the cutter head torque (Figure 3). It was concluded that the slagging delay has caused the blockage of the slagging mouth in part of the cutter head, which further aggravates the slagging delay in front of the cutter head.

3) The sludge in front of the cutter head caused the sludge to enter the inside of the cutter

Figure 3. Line chart of shield tunneling parameters for the western route.

head and accumulate, which led to the increase of starting torque and serious secondary wear. At the same time, due to the mud formation in front of the tool barrel, the actual partial extrusion pressure was transmitted to the palm surface through the slag accumulation, and was not transmitted to the palm surface through the tool, resulting in the starting torque of the tool was not enough to rotate, and the formation of partial grinding.

Figure 4. Photo of tool partial grinding.

Figure 5. Tool secondary wear.

- (3) Targeted measures
 - 1) Strictly control the density of mud and increase the circulation flow
Increase the centrifuge and filter press, improve the mud processing capacity, control the specific gravity of mud in 1.1~1.15, and constantly wash the slurry circulation with large flow and low specific gravity to improve the environment in the warehouse.
 - 2) Staged washing According to the torque as the criterion, when the overall torque was too large, the washing operation was carried out to reduce the accumulation of slag in front of the cutter head. In order to avoid overexcavation caused by warehouse washing, the standard for the end of warehouse washing was subject to the reduction of cutter head torque to idle torque.
 - 3) Using inlaid gear hobs
Due to the low hardness and poor wear resistance of the smooth hob, the secondary wear was seriously affected by the accumulation of slag in front of the superimposed cutter head. Meanwhile, according to the detailed survey report, the uniaxial saturation compressive strength of the breezy argillaceous siltstone is 20-30 MPa. Therefore, the inserted tooth type hob was more suitable for the geology of this project.
- (4) Auxiliary pressure driving mode or center scour aeration
According to the previous experience of similar formations in South China, after adopting measures such as auxiliary pressure driving mode or central scour gas filling, the driving parameters and driving efficiency will be greatly improved. However, there was sand layer in the excavation section at the initial stage, which was prone to breakdown and formation of channels due to strong gas flow, and there was a risk of pressure loss. In the subsequent excavation process, due to the gradual reduction of rock weathering degree, it was expected that the slag stagnation and drainage conditions and excavation parameters will develop well. If the deterioration continues, auxiliary pressure excavation mode or central scour aeration excavation can be adopted after judging the air tightness of the face of the face.

4 CONCLUSION

The double-line shield of Haizhuwan Tunnel has been successfully launched, and the key technologies were summarized below:

- 1) In order to offset the impact of “upward drift” that may occur due to shallow soil cover, it was necessary to strictly control the reinforcement quality of the control end. When the shield was driven,

the deviation between the shield center and the design elevation of the tunnel was controlled within -30mm, and the plane deviation was controlled within ± 30 mm. At the same time, the main excavation parameters were strictly controlled, and the low speed excavation were adopted to avoid large disturbance to the soil mass and prevent overexcavation.

- 2) When the tunnel door was broken, the I-steel support face can be set up according to the situation, and the end reinforcement area was enclosed during the breaking period, and large-scale equipment was prohibited to walk;
- 3) Before starting, confirm the position of the anti-planting head cushion, curtain rubber plate and folding plate in the tunnel door ring to prevent the tunnel door seal from being damaged. After the leak of the tunnel door seal, fill the internal void of the tunnel door seal device in time, and made a secondary seal of the tunnel door in advance at the position of the external tunnel door ring to block the leakage;
- 4) In the process of excavation, the cut pressure was properly increased, and the mud effect was injected into the shield shell through the radial grouting hole of the shield machine to prevent the natural settlement of the formation. Shorten the initial setting time of synchronous grouting slurry and enhance its resistance to water dispersion, timely secondary grouting to avoid misalignment, cracking, leakage, and effectively guarantee the quality of formed tunnel; If necessary, increase the monitoring frequency, feedback the monitoring data in time, and strictly implement the monitoring guiding construction principles;
- 5) Affected by the high content of clay minerals in the starting formation, there was a hysteresis in the driving process, and in serious cases, the cutter head opening forms a mud cake. During the process, the efficiency of shield tunneling has been greatly improved by strict control of

tunneling speed, mud gravity, strengthening central scour, stage washing of silo and replacement of insert cutting tools.

Experimental research on foam performance and intelligent injection control of foam additive system of tunnel boring machine

Chengjie Zhang*

Shanghai Urban Construction Tunnel Equipment Co., Ltd., Shanghai, China

Yixin Zhai

Shanghai Shield Research Centre Co., Ltd., Shanghai, China

ABSTRACT: As an important soil conditioner in TBM tunnel construction, foam additive system composition, foaming effect and injection control mode have a great impact on the actual construction, especially in complex formations. Aiming at the problems of poor foaming effect and low degree of automation control in the foam additive injection system of tunnel boring machine, this paper develops an experimental platform, by simulating and setting the TBM's actual construction parameters, six possible factors affecting the foaming and spraying effect (such as different foaming ratios, etc.) were explored and tested. The intelligent monitoring and automatic control logic of foam injection were matched, through the collection, analysis and comparison of test data, it was verified that the developed control system could meet the adaptive driving requirements of the tunnel boring machine.

Keywords: TBM, Foam additive, Foaming Performance, Intelligent Control, Experimental Research

1 BACKGROUND

Figure 1. Foam injection diagram.

With the continuous development of rail transit construction, tunnel boring machines^[1,2] have become the main underground excavation process equipment for urban tunnel construction due to their advantages such as less impact on the surrounding environment, safe and efficient construction, and low labor intensity. However, in complex soil conditions such as sand, pebble, and clay layers, especially in round gravel and pebble layers, tunnel boring machine may encounter varying degrees of difficulties in the following aspects during excavation construction:

The problem of difficult to achieve dynamic balance of soil pressure on the excavation surface. In the

formation of round gravel and pebbles, the plastic flow of the debris and soil cut by the cutterhead during tunnel construction is poor, the working pressure cannot be smoothly transmitted, making it difficult to achieve continuous dynamic balance. The working face is prone to instability, leading to over excavation.

The problem of excessive torque on the cutterhead and screw conveyor. After the soil layer is disturbed by the cutterhead, the sand and gravel layer will become soft, and larger particles of pebbles are prone to accumulate at the bottom of the cutterhead, causing excessive torque during TBM mining operation and “blockage” of the cutterhead. However, in clay layers, the phenomenon of “mud cake” on the cutterhead is prone to occur frequently.

The problem of abnormal wear and rapid wear of cutting tools. Due to the high friction of the pebbles, the impact between the cutting tools and the pebbles, and the locking effect of the excavated soil on the cutting tools, which is prone to cause rapid wear, impact wear, eccentric wear and abnormal wear of the cutting tools.

During the tunnel construction in strong permeable layers of sand and gravel layers, excessive water pressure on the excavation surface can lead to

*Corresponding author: zhangchengjie@stecmc.com

soil erosion, resulting in gushing^[3]. In severe cases, can cause surface subsidence and affect the smooth construction of the project.

Since the foam improvement technology was developed in Japan in the early 1980s, the research on the effect of foam additive has been ongoing for more than 40 years. It has been confirmed from relevant research and engineering practice that foam additives^[4] have obvious effects on improving the characteristics of slag soil, such as improving the fluidity of soil in excavation chamber, stabilizing the cutting surface, reducing the torque of cutterhead and screw conveyor, reducing structural wear, and reducing the permeability coefficient of soil and sand. The research on foam additives is mainly focused on the development and characteristics of foam agent materials^[5], the improvement of foam additives on the construction soil layer and the impact of construction parameters^[6,7,8], and the exploration and research on the factors affecting the foam performance is relatively lacking. At the same time, with the development trend of automated driverless tunneling machines, the foam injection control based on the operator's construction experience now is lack of accurate monitoring, fault diagnosis and adaptive adjustment of the injection process, with high blindness and low intelligence. The development of automatic injection control of foam additives is urgent.

2 EXPERIMENTAL RESEARCH

2.1 Test method and process

This test is based on building an experimental platform for testing and research^[9]. By simulating the setting of the TBM's actual construction parameters, a single factor contrast injection test is carried out on the foam generator, air control valve, pipeline "Q" device, foam generator setting position, foaming ratio, foam solution concentration and other factors that may affect the foaming performance effect, while matching adaptive data acquisition and fault monitoring, intelligent control logic programs, the foam automatic injection control adjustment and accuracy of the TBM in the unmanned mode are optimized through experiments. The main line revolves around design (experimental system principles, control program development, experimental technical solutions, etc.), experimental platform construction, exploration and testing of factors affecting foam performance, intelligent injection control testing, scheme and program optimization, and acceptance report process execution. The experimental process is shown in Figure 2.

2.2 Composition of testing platform

The experimental platform shown in Figure 3 is designed in conjunction with the tunnel boring

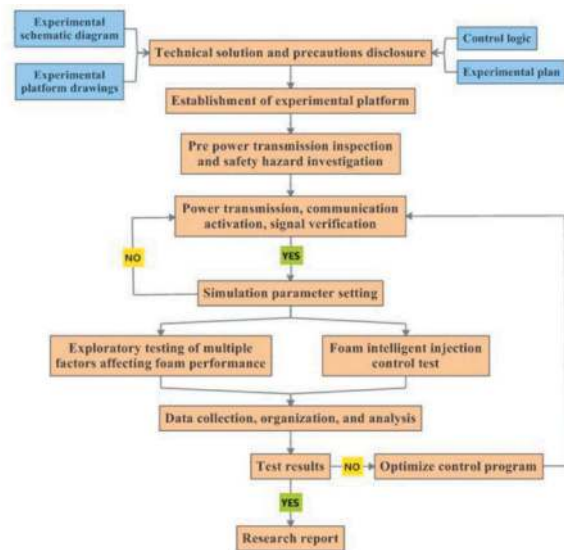

Figure 2. Foam experimental flow chart.

Figure 3. Composition and physical diagram of the test platform.

machine additive injection system, mainly consisting of a simulated cutterhead, injection pump, agitator, valve components, additive tank, monitoring sensors, control room, and pipeline components. This test platform can simulate and set up various functional controls of foam injection system under the tunnel construction condition through the man-machine operation interface, including foam solution proportioning supply, solution mixing, solution regulation, air conditioning, foam manual injection, semi-automatic injection, automatic injection, data monitoring and fault alarm. At the same time, it can also conduct comparative exploration, test and research on factors that may affect the foam performance.

2.3 Principle of foam injection test

As shown in Figure 4, the foam injection test system is mainly composed of foam solution proportioning, solution injection circuit and foaming circuit. The ratio of foam solution is transferred from the submersible pump of Part 9 located in the foam stock solution tank of Part 31 to the foam solution tank of Part 32 through the control of the pneumatic ball valve of Part 13, and mixed with the industrial water transferred to the solution tank through the pneumatic ball valve of Part 14 to form foam solution. The ratio concentration of foam solution can be

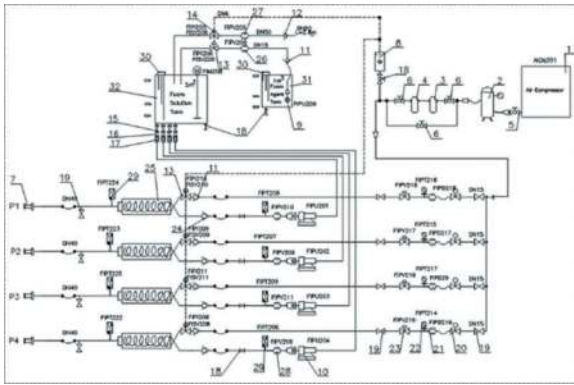

Figure 4. Schematic diagram of foam injection.

adjusted by changing the transfer amount of foam stock solution and industrial water. The transfer amount of stock solution and water is converted and accumulated through the flow meter of Part 26 and Part 27 respectively. At the same time, both the foam stock solution tank and the solution tank are equipped with a 30 liquid gauge to monitor the liquid level of the medium in the tank and participate in the liquid level alarm and control; The foam solution is pumped and filled through the solution pump of Part 10. The outlet of the solution pump is equipped with a flow meter of Part 28 and a pressure sensor of Part 29 to monitor the flow and pressure of the circuit. When the flow is too low or the pressure is too high, the operation status of the pump is interlocked; The foaming circuit injects foam solution into the foam generator of Part 25 at a certain rate of air to make the solution produce more bubbles foam to achieve foaming effect. The foam solution after mixing foam solution and air is sprayed to the front through the nozzle of Part 7. The air entering the generator is generated by the air compressor of part 1 and adjusted through the regulating valve of part 23. At the same time, the air circuit is equipped with a pressure differential flow meter of part 21 and a pressure sensor of part 22 to monitor the air flow and pressure. In automatic mode, it is matched with automatic interlocking control for injection.

2.4 Experimental contents

In foam injection system, factors such as foam generator structure, air control valve form, foam generator setting position, foaming ratio and foam solution ratio concentration may affect the foaming performance. In order to verify the influence of the above factors on the foaming performance, comparative injection tests were conducted on each factor, measuring the visual state of the foaming effect, fading time, and pipeline pressure. At the same time, combined with the actual excavation parameters of a tunnel project, the adaptive control program of the foam injection system was compiled and revised to verify that the quantitative indicators of automatic interlocking function control and

feedback adjustment in the automatic mode were within the deviation of the theoretical calculation value^[1].

Figure 5. Two foam generators with different structure (1st: specification 1; 2nd: specification 2).

2.4.1 Influence test of foam generator on foaming performance

The contrast test of two foam generators with different structure as shown in Figure 5 was conducted under the same injection conditions (the injection flow of foam solution pump was consistent with the air input). The test results showed that the foam solution of specification 2 foam generator was sprayed fully and continuously, and the foam path was fluffy and spongy, while that specification 1 foam generator was sprayed intermittently, and the bubbles were scattered, as shown in Figure 6. This may be because of the foam channel internal structure of the foam generator in Specification 2 and the volume of the ceramic ball in the cavity are more reasonable, which enables better mixing of foam solution and air, so as to obtain better foaming effect. Monitoring the fading time of two types of foaming agents, it was found that the fading time of foaming solution for specification 1 and specification 2 was 210 minutes and 170 minutes respectively. The fading of foaming agents for specification 1 in discrete state was faster.

Figure 6. Comparison test diagram of foaming effect of different foam generators.

Figure 7. Different forms of air regulator used in foam injection system.

2.4.2 Response and accuracy testing of regulating valves on air conditioning

The amount of air injection will directly affect the mixing and foaming performance, and its adjustment mainly depends on the control valve 23 in Figure 4. At present, there are several commonly used forms of control valves on the market with different adjustment characteristics (control mode, adjustment response, and control accuracy). Three different forms of control valves, pneumatic, electric (with locator), and electric (without locator), are selected for injection simulation tests. The tests include the time required for valve opening from closed to fully open, and the response speed when adjusting to the same flow value. The test results in terms of control accuracy (flow stability) and ease of operation are shown in the table below.

Table 1. Comparison test with different types of air regulators.

Test item	Pneumatic regulator	Electric regulator (with locator)	Electric regulator (without locator)
Time taken from close to fully open	5s	38s	44s
Air regulator response and accuracy in automatic mode (flow rate increases from 0NL/min to 600 NL/min)	Flow rate stabilizes at 626 NL/min after 10s	Flow rate stabilizes at 630 NL/min after 32s	Flow rate fluctuates between 500-600NL/min in 40s, and stabilizes at 620 NL/min after 72s
Drive mode	Pneumatic +4-20mA	24V voltage +4-20mA current	24V voltage AC
Ease of operation	Interface percentage input	Interface percentage input	Interface percentage input
Cost	High	Low	Lower

2.4.3 Influence test of pipeline “Ω” device on foaming performance

In the actual foam injection system, the foam generator is often positioned at the rear gantry frame. The

Figure 8. Distribution diagram of foam additive in pipeline.

length of the pipeline from the foam generator outlet to the shield and then into the cutterhead injection port is at least 30m. At this time, the mixed foam from the generator may appear gas-liquid stratification in the long-distance pipeline. The air is dispersed on the top of pipeline, and the foam quality decreases, as shown in Figure 8. In order to explore the influence of giving appropriate back pressure and mixing in long-distance pipelines on the foam foaming effect, the “Ω” device was designed, and comparative tests were conducted under the same injection conditions (foam solution flow and air flow), as shown in Figure 9. From the test results, it can be seen that the circuit equipped with an “Ω” device has a more fluffy and spongy effect on the foaming liquid. Whether the “Ω” device is set horizontally or vertically, both method have a promoting effect on the foam performance.

Figure 9. Foam injection test with “Ω” device.

2.4.4 Influence test of foam generator different position on foaming performance

When the foam generator is placed far away from the injection port, the pressure loss will increase due to the long pipeline, which will also have a certain impact on the foaming performance. Select the distance between the foam generator and the injection port as 10m and 30m respectively, and conduct the contrast test of foam injection under the same conditions.

It can be seen from the test results that when the foam generator is 10m away from the nozzle position (Figure 10-4 #), the distance of foam injection is longer. According to the mechanical pressure

Figure 10. Comparative test on foaming effect of different distance between foam generator and nozzle.

gauge installed at the injection port, the injection pressure is 2.3 bar, and the foaming effect is flocculent. When the foam generator is 30m away from the injection port (Figure 10-2 #), the injection pressure is 2 bar, there is a pressure loss of 0.3 bar compared, and the foam is dispersed and fluid.

2.4.5 Influence test of foaming ratio on foam fading degree

In the foam automatic injection system, the foaming ratio will affect the output of foam solution and air, making the foaming solution produce different performance. In order to explore the influence of different foaming ratios on the fading degree of foam, under the same foam concentration and injection conditions, respectively adjust the foaming ratios to 10 times, 15 times, 20 times, and 30 times to test the fading degree of foam. The test results are shown in the following figure.

Figure 11. Comparative test on foam fading of different foaming ratios.

Table 2. Comparative test on foam fading time of different foaming ratios.

Foaming ratios	Fading time (in half cup)
10 times - 1# cup	230 min
15 times - 2# cup	210 min
20 times - 3# cup	160 min
30 times - 4# cup	140 min

It can be seen from the test results that when the foaming ratio is 10 times and 15 times, the fading time of foaming is more than 200 min, while when the foaming ratio is 20 times and 30 times, the fading time of foaming is around 150 min. This indicates that the foaming ratio is not as larger as better. When the foaming ratio exceeds a certain ratio, the hollow gas content of foam increases, the solution content decreases, and it cannot reach the high-quality foaming solution.

2.4.6 Influence test of foam solution concentration on foam fading degree

The foam concentration in the foam solution will affect the stability and performance of the foam solution. To explore the influence of foam concentration on the foam fading degree, under the same injection conditions, compare and test the foam fading time of three concentrations: 1%, 3% and 5%, and record the fading speed of the foam solution at different concentrations, as shown in the following figure.

Figure 12. Comparative test on foam fading of different foam concentration.

It can be seen from the data in Table 3 that under the same test conditions, when the concentration of foam solution is 5%, the fading time of bubbles is 230 min, and the foaming effect is also good. When the concentration of foam solution is below 3%, the decay time of bubbles becomes shorter, and the foaming effect becomes worse with the decrease of concentration. This is because the proportion of

Table 3. Comparative test on foam fading time of different foam concentration.

	1% foam concentration Figure 12 - 1# cup	3% foam concentration Figure 12 - 2# cup	5% foam concentration Figure 11 - 1# cup
Test item			
Foaming effect	Large amount of bubbles	Foam dispersion	Foam fluffy
Fading time (in half cup)	120 min	140 min	230 min

foam agent in foam solution decreases, and the proportion of water increases.

2.4.7 Test of foam automatic injection control

The foam automatic injection control can adapt to the automatic driving of the TBM, and intelligently realize functional control in the unmanned operation mode. Its injection volume adjustment is based on the actual injection demand of the tunneling construction calculated according to the tunneling speed of the shield machine, the excavation area of the shield machine, and the injection rate of foam mixture, and then calculate the flow required for foam solution pump and gas supply according to the foaming ratio, by averaging the number of actual injection circuits, the required output flow of each solution in use is obtained^[11], which is feedback to the PLC control program. After comparing with the PLC program, the frequency output value of the frequency converter of the solution pump in actual injection is adjusted (the speed of the solution pump is adjusted to adjust the output flow of the solution pump) and the opening of the gas supply regulating valve, so that the output flow of the solution pump and the gas supply is matched with the injection amount required for construction, this stage is a dynamic matching compensation process. Figure 13 shows the mechanism diagram of foam automatic injection control.

Advanced Mitsubishi Q series CPU is used for foam automatic injection control, and CC Link communication mode is used. The CPU is connected with the proface human-machine interface through Ethernet. PLC can collect digital input signals such as start/stop of motor and opening/closing of valve, as well as analog input signals of foam pressure, flow and liquid level. PLC can output digital output signals for valve switches, as well as analog signals for adjusting valve opening output from frequency converters^[12]. Only to set the excavation area, foam mixture injection rate, thrust speed, foaming ratio of the TBM on the operation interface, so that the foam system can be activated adaptively. At the same time, the liquid level, flow, pressure and other states during the injection process can be observed in real-time, as shown in Figure 14.

Figure 13. Control mechanism of foam automatic injection.

Figure 14. Foam automatic injection operation interface.

Calculation formula of foam automatic injection demand flow:

Mixed foam demand flow Q_{mix} (L/min) = excavation area (m²) * excavation speed (mm/min) * injection rate (%);

Foam solution demand flow Q_{sol} (L/min) = Q_{mix} (L/min)/foaming ratio;

Air supply demand flow rate Q_{Air} (NL/min) = Q_{mix} (L/min) * [Pearth (MPa)+0.1] * (foam rate -1)/Foam rate /0.1.

It can be seen from the test data in Table 4 that under the simulated setting of different thrust speed, injection rate and foaming ratio parameters, each

Table 4. Foam automatic injection test data record.

Test data record of foam volume when injection rate is 105% and foaming ratio is 10 times				
Thrust speed mm/min	Theoretical demand of foam solution L/min	Actual measured value of foam solution L/min	Theoretical demand of foam air NL/min	Actual measured value of foam air NL/min
10	43.68	46	393.12	390.2
15	65.52	68.3	589.68	555

10	36.05	38	504.75	483
15	54.08	56	757.12	712
20	72.11	75	1009.5	960
20	72.11	75	1009.5	960

function of the foam injection system is controlled normally under the automatic mode, and the output of the actual solution and air filled is within the deviation of the theoretical calculated value ($\pm 5\%$), which meets the design and construction requirements.

3 CONCLUSION AND PROSPECT

By setting up a test platform to simulate the TBM actual construction parameters, a comparative injection test was conducted on the foam generator, air control valve, pipeline

“ Ω ” device, foam generator setting position, foaming ratio, foam solution concentration and other factors that may affect the foaming performance in the foam injection system. The test results can be obtained as follows:

- 1) From the foaming effect and fading time, it can be concluded that the foaming quality of specification 2 foam generator is superior to specification 1 foam generator in terms of foaming quality;
- 2) Combined with the response speed and control accuracy test of the three types of air control valves on air conditioning, the pneumatic type response speed and accuracy control are optimal, which is suitable for the automatic control of the foam system under the automatic driving of TBM, while the electric control valve with positioner has more advantages in cost performance;
- 3) Adding “ Ω ” device (horizontal installation and vertical installation) to foam concentrate pipeline can improve the performance of foam concentrate;

- 4) When the foam generator is set close to the fill port, it will have better foaming performance than that set far from the fill port;
- 5) The foaming rate will affect the fading of the foaming solution. Under the same injection conditions, the fading time of the foaming solution at 10- and 15-times foaming rate is longer than that at 20- and 30-times foaming rate;
- 6) The foam concentration will affect the foaming performance. Under the same injection conditions, the foam test results with the concentration of 1%, 3% and 5% show that the foam with the concentration of 5% has the slowest fading speed and the highest stability.

At the same time, by optimizing the foam automatic injection control logic and integrating data monitoring and sensing, collection, deviation correction, control and fault alarm, it can actively adjust the transmission parameters of foam solution and air to meet or close to the theoretical demand of foam additives, and the test shows that the control of each function is normal under the automatic mode of foam injection system. The output of the actual solution and air injected is within the deviation range of $\pm 5\%$ of the theoretical calculated value.

This test provides technical support for the design, development and intelligent control of the foam additive system of the tunnel boring machine, and also conforms to the development demand of the current tunnel boring machine towards intelligence and automation. However, there is also a lack of foam solution matching for different soil layers and the verification of the control effect of foam automatic injection during actual stratum excavation. In the future, the optimal foaming solution can be obtained by combining automatic ratio adjustment for different soil layers, and an automatic control system that is adaptive to the excavation parameters of the tunneling machine can be used.

Visualization study on stability of shield tunnel face with transparent soil model

Honghua Zhao*, Zhi Jia & Yang Liu

The School of Mechanical and Aerospace Engineering, Dalian University of Technology, Dalian, China

ABSTRACT: Due to design optimization and geological conditions, shield tunnels often work with different longitudinal inclination angles. In this case, it is very important to understand and master the failure mode of the tunnel face. In this study, a transparent soil model was set up in the laboratory to visualize the full 3D deformation field of the tunnelling. The failure mechanism of tunnel face in soft clay stratum is studied under different longitudinal inclination angles δ and the ratio of buried depth to diameter C/D . The results show that the failure shape of the shield tunnel face shows a ‘ring’ mode under different longitudinal inclination angles δ and C/D conditions. The deformation process of soft clay has different development stages, and the failure modes in different areas vary. The deformation zone is mainly divided into subsidence areas and uplift areas. With the increase of the longitudinal inclination angles, from $\delta = -20^\circ, 0^\circ$ to 20° , the instability area, the maximum displacement, and the vertical pressure all changes, and the 3D reconstruction also obtains the same failure mode. Compared with other cases, the tunnel has a higher collapse risk with shallow buried and upward inclination angles. Long-term upward inclined excavation in soft clay stratum should be avoided in engineering practices.

Keywords: Tunnelling, Transparent soil, 3D visualization, Failure, Soft clay

1 INTRODUCTION

Tunnel construction is commonly used in urban metro construction in China due to its distinct advantages and the country’s rapid infrastructure growth. Mastering failure mechanisms ahead of the tunnel face is essential to ensure a stable construction process. Due to complex engineering geological conditions or design optimization, the shield machine’s running route may not always remain horizontal in reality. And it has been demonstrated that the stability of the tunnel varies significantly under different longitudinal inclination angles. Thus, this study focuses on investigating the failure mechanism of the excavation face with various longitudinal inclination angles.

The damage mechanism in the vicinity of the shield face has been well investigated by previous researchers, using three main types of analysis: (1) Indoor tests, (2) Theoretical analysis, and (3) Numerical methods. Indoor tests are mainly carried out by centrifuge experiments and 1-g model tests etc. (Weng et al., 2020; Yin et al., 2021). Alternatively, simulation of tunnel face collapse by rigid

plate retreat was adopted in several research works (Ads et al., 2021; Ahmed and Iskander, 2011a; Cheng et al., 2021; Kirsch, 2010; Ma et al., 2022; Yin et al., 2021). The impact of tunnel face opening and anisotropy of seepage conditions on tunnel face stability was investigated undergoing a series of centrifuge experiments and finite difference numerical simulation analysis (Yin et al., 2021). The findings demonstrate that tunnel face stability benefits from the seepage caused by water ingress. By applying water pressure to the shield face, Ahmed and Iskander (2011) estimate the minimum support pressure, the failure mode, and the expansion of the failure area. Weng et al. (2020) investigated the failure of the excavation face driven by the longitudinal slope angles and steady-state seepage using centrifuge experiments and numerical simulation analysis. Researchers (Ma et al., 2022; Sang et al., 2019; Zhao et al., 2022) carried out a systematic study on the destabilization patterns of excavation faces in transparent clay with different burial depths and clay-gravel composite strata. They undertook it by controlling the retreat of the excavation face to simulate the lack of support pressure.

*Corresponding author: zhaoh@dlut.edu.cn

Huang et al. (2019) conducted six indoor tests to investigate the specific failure pattern of excavation face in dense sand layers at various longitudinal inclination angles.

Limit analysis and limit equilibrium methods are the two primary categories of theoretical methods, with the majority of the remaining approaches being variations of these two types (Hou and Yang, 2022; Huang et al., 2022; Lee and Nam, 2004; Li et al., 2021; Man et al., 2022; Perazzelli et al., 2014; Zhang et al., 2011; Zou et al., 2019). Using the upper limit solution from the limit analysis, Lee and Nam (2004) estimated the seepage pressure on the tunnel face. The 3D kinematic tolerance mechanism for upper limit analysis has been enhanced by Tang et al. (2014) to predict potential damage within various strata. Cheng et al. (2021) developed a three-dimensional failure mechanism in dense sand, segmenting the unstable area into a fracture slip zone and an upper loosening zone, based on the limit equilibrium theory and findings from previous model tests. Senent and Jimenez (2015) proposed that the recent rotating surface collapse mechanism could be expanded to estimate critical pressures for tunnels in stratified (or layered) strata in the context of the upper limit analysis. Zhang et al. (2011) adopted an improved wedge prism model based on the limit equilibrium approach as well as an improved three-dimensional rotation failure model based on the limit analysis method.

In numerical methods, the finite element method (Ahmed and Iskander, 2011b; Alagha and Chapman, 2019; Han et al., 2021; Huang et al., 2019; Ukritchon et al., 2017; Wang et al., 2020) and discrete element method (Chen et al., 2011; Zhang et al., 2011) are also widely used to discuss the stability of tunnel face under different conditions. Based on 140 numerical analyses, Alagha and Chapman (2019) determined the collapse pressure required for tunnel excavation in homogeneous or layered soil. According to the analysis of the water head, Huang et al. (2019) performed a three-dimensional coupled pore fluid flow and stress finite element simulation to estimate the seepage pressure in the limit equilibrium and took a novel wedge mechanism into consideration. The spatial variation of soil mechanical characteristics can be explained by the gradient between soil masses. Chen et al. (2013) investigated the failure mechanism and limit support pressure of the tunnel face in a dry sand layer using the discrete element method. This method has unique advantages in revealing the mechanical properties of granular materials. Zhang et al. (2011) develop a 2D particle flow approach to explicitly consider explicitly soil excavation from the face, effects of varying face support pressure, and the influence of buried depth.

The main focus of the aforementioned study and analysis is on the stability of the horizontal tunnel and the failure mechanism, including the impact of layered soil, seepage, weak and cracked zones, and layered soil. Shield tunnels frequently operate at varying longitudinal inclinations in practice as a result of design optimization and the influence of

stratum qualities, but there is little research on this topic, particularly in the clay stratum. Knowing the failure characteristics and instability mode of tunnel at varied longitudinal inclinations can greatly simplify selecting support parameters in engineering. In addition, considering the development of transparent soil technology, it is now possible to detect soil deformation in three dimensions in a more intuitive and non-intrusive manner (Ahmed and Iskander, 2011a; Guzman et al., 2014; Iskander et al., 2015; Liu et al., 2022; Sang et al., 2019; Yuan et al., 2019; Zhang et al., 2019). Hence, utilizing the self-designed shield model test device along with image processing and 3D reconstruction algorithm, this study analyzed the failure mechanism of the tunnel face under various longitudinal inclination angles and burial depths in the clay stratum.

2 EXPERIMENTAL SETUP

In this study, the preparation methods of transparent clay are as follows: 1) Take an appropriate amount of Laponite RD powder and deionized water (the ratio of powder to total mass is 4.5%); 2) To avoid the influence of bubbles, the deionized water is evacuated and monitored until no bubbles escape from the liquid surface; 3) After evacuation, pour deionized water into the container and swirl vigorously for 30 minutes or more while slowly putting in Laponite RD powder; 4) After vacuuming the mixture, then settling and consolidate for 14 days. After vacuuming the mixture, it is allowed to consolidate for 14 days. Tracer particles (refraction index: 1.582, size: 50 μ m, density: 1.03g/cc) are added to the dispersion procedure to enable clear image capture (Ads et al., 2020b; Ma et al., 2022). The strength of samples undergoing self-weight consolidation for 14 days was 0.44 kPa, 0.50 kPa and 0.63kPa for 5cm, 15cm and 20cm below the surface.

A model box and a shield tunnelling device was design for the test as shown in Figure 1.

Figure 1. Schematics of the model box and tunnel.

The model box is mainly composed of the main body and plugging device. To reduce the effect of the model border, the diameter of the tunnel D was set to 80 mm and placed in the center of the side wall, 120 mm from the bottom of the model box and 250 mm from the top of the box.

The shield simulator, as shown in Figure 1. The shield shell consists of a round Plexiglas tube with an inner diameter of 70 mm, a thickness of 10mm, and a length of 200 mm. There are two rubber cushions around the outer wall where it contacts the shield shell. The back of the model is 20 mm thick, and two holes with a diameter of 15 mm are opened to balance the pressure when the center distance is 39 mm. A bearing is installed 10 mm behind the support panel, and a wire rod with a 1mm pitch and a length of 250 mm is secured with its rear end through the locking cap. The screw rod's back end is connected to the rotating motor via the processed sleeve, so that during motor rotation, the central connecting rod drives the support panel backward using the thread of the locking cap, replicating the tunnel excavation face's insufficient support force.

Meanwhile, to investigate the effect of overburden depth C on the damage pattern of the shield face, assume that the model conditions are $\delta = \pm 10^\circ, 0^\circ$ and $C/D = 1.5, 3$. The definitions of the ratio of overburden depth to model diameter (C/D) and inclination angle δ are shown in Figure 2. The surface of the model box and shield model is roughened to minimize laser reflections.

Figure 2. Layout of shield inclination.

A loading subsystem, two measuring systems, a transparent soil model, a laser, a CCD camera (charge-coupled device camera), and other components were designed for a scanning and image acquisition device as shown in Figure 3. Continuous laser speckle images are recorded by an industrial camera during the experiment. The camera is a model USB3 Vision TL from Daheng Galaxy Device Lt., with a 3840×2748 pixels resolution. Image processing is mainly used with MATLAB software programming.

The CCD camera and laser are controlled by two high-precision linear platforms to maintain synchronous motion, and the entire model is scanned to obtain cross-sectional photographs at various places as shown in Figure 4 (a). The displacement field at various positions is then obtained by using MATLAB software to analyze the slice photos captured at various deformation times at the same position. Finally, the whole three-dimensional displacement field is constructed by a reconstruction algorithm.

Figure 3. Experimental setup for the transparent soil tunnelling model.

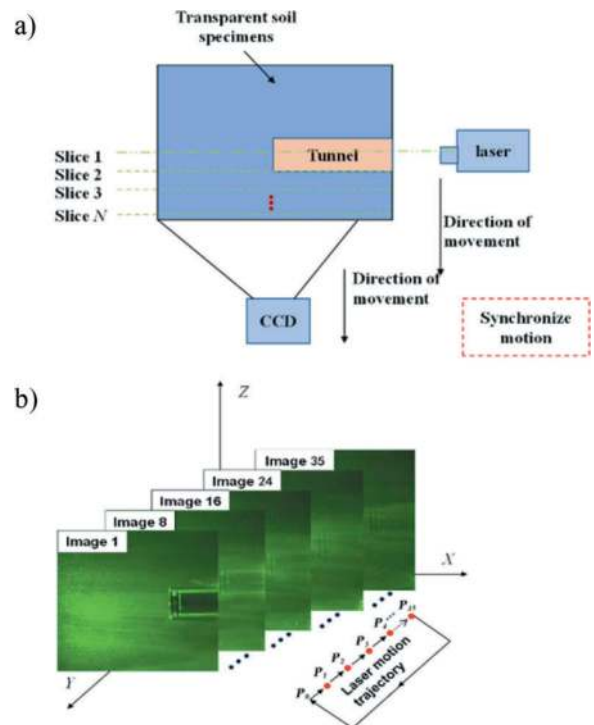

Figure 4. Test principle: a) Principle of tomographic scanning; b) Principle of laser speckle image scanning.

3 RESULTS AND ANALYSIS

3.1 Horizontal deformation analysis

Figure 5 depicts the evolution of the displacement field with $\delta = -10^\circ, 0^\circ, 10^\circ$, and $C/D = 1.5$ or 3. The ground begins to deform as the rigid plate begins to travel backward. The failure area that forms in front of the tunnel face varies depending on the three conditions. The failure area is different from the typical 'wedge + prism' shape in sandy soil stratum. The failure of the excavation face in the soft soil stratum presents an 'ellipsoidal' flow to the tunnel, with a wider influence area than the sandy soil stratum in

front of and above the excavation face. It's consistent with the failure mode of excavation face in clay stratum established by Mollon et al. (2013) based on continuous velocity field distribution.

The soil in front of the tunnel flows smoothly into the tunnel, and the failure pattern and influence zone are basically consistent with Schofield et al. (1980)'s experimental results and the numerical simulation of Huang et al. (2019).

Figure 5. Two-dimensional horizontal displacement of central axis plane.

Figure 5 is a horizontal displacement contour map of different inclined angles and different buried depths at varying rigid plate retreat distances. Figure 5(a) - (d) show that when ΔS increase, the damaged area in front of the tunnel gradually forms, extending vertically from the tunnel invert and center to the top of the tunnel in a 'ellipsoidal' expansion. As shown in Figure 5 (a) - (c), when $\Delta S = 19$ mm, the influence area and deformation increase as the inclination angle δ increase, and the failure zone extends to the surface, from $\delta = -10^\circ$ corresponding to 100mm to $\delta = 10^\circ$ corresponding to 50 mm. Figure 5 (a) shows that when the inclination angle $\delta = -10^\circ$, the horizontal deformation gradually increases with the increase of the retreat distance. However, compared with Figure 5 (b) and

Figure 5 (c), its horizontal deformation is smaller, thus the soil around the tunnel with a downward inclination angle shows better stability. According to the displacement contour map in Figure 5 (b) and Figure 5(d), when the C/D ratio is 1.5 and 3, the deformation area and value gradually decrease with increasing C/D due to the soil arching effect of clay (Lee et al., 2006).

3.2 Vertical deformation analysis

Figure 6 is a vertical displacement contour map of different inclined angles and different buried depths at various rigid plate retreat distances. According to Figure 6 (a) - (d), when the pressure is reduced to very small ($\Delta S = 2$ mm), the displacement is small except for the displacement of 0.3-0.5mm in front of the tunnel. The vertical displacement increased together with the retreat distance. When the retreat distance reaches 10 mm, the deformation in front of the tunnel increases sharply. As the inclination angle changes from downward to upward, the influence range further expands, and some areas begin to bulge (As shown in the blue lines below the model in Figure 6 (b) and (c)). When $\Delta S = 19$ mm, the maximum value of the displacement is developed from 2mm corresponding to $\delta = -10^\circ$ to 2.8 mm corresponding to $\delta = 10^\circ$. In other words, with the inclination angle increases, the soil deformation is gradually increasing, and the failure zone develops toward and eventually reaches the ground. Figure 6 (b) and 9(d) show that for various overburden depths, the vertical influence area is bigger for smaller C/D , whereas the vertical influence area declines as C/D increases, and the maximum failure zone is approximately 2/3 of the shallow overburden.

3.3 Deformation mode analysis

The displacement vector field under various retreat distances is analyzed as follows in order to investigate the disturbance and deformation with the retreat of the rigid plate.

As shown in Figure 7, the size of the vector arrow represents the displacement, and the angle represents the direction of motion. According to Figure 7 (a) - (c), the excavation of a cohesive soil layer presents a stage-by-stage failure process. At the initial stage of deformation, the tunnel moves slowly backward, causing the loosening zone in front of and above the tunnel, and slipping along some of its micro-crack surfaces, resulting in soil moving into the tunnel. In the expansion stage, driven by the early sliding soil, the soil moves along the vertical and longitudinal direction, and the influence area are further expanded. The soil close to the surface eventually moves as a result of the retreat distance growing farther. The deformation of the soil mass in front of the shield can be approximately separated into three portions, as shown in Figure 7(b) and (c). The uplift area beneath the tunnel makes up one portion. The

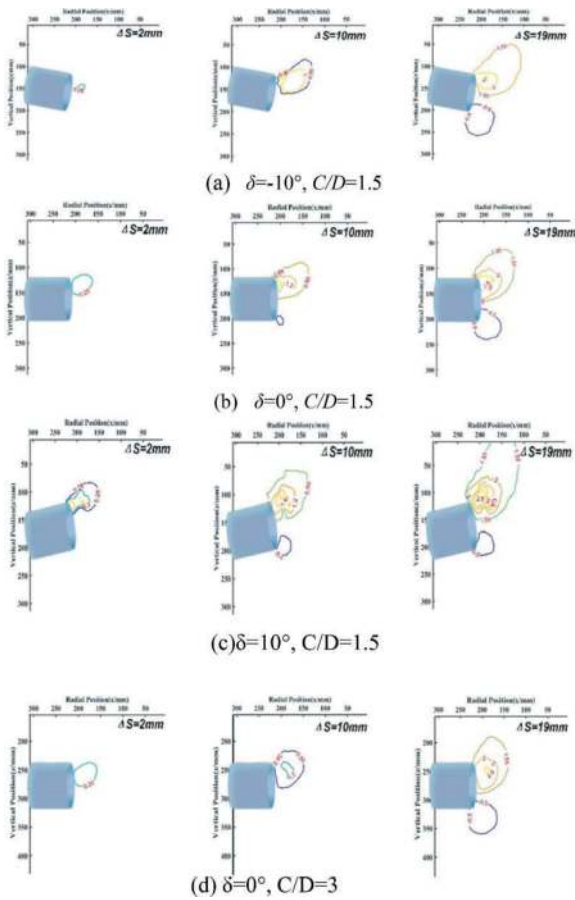

Figure 6. Two-dimensional vertical displacement of central axis plane.

Figure 7. Deformation vector diagram of clay shield tunnel.

soil is driven toward the tunnel's interior as a result of the shield tunnel's retreat. The soil underneath is raised as a result of cohesiveness between the particles, and the uplift area rises with the retreat distance. The settling zone is the other part where soil masses pour into the tunnel as a result of shield retraction. Between these two parts, there is a transition area as well.

The displacements under different working conditions are shown in Figure 8. According to continuous velocity field and upper bound theory of limit analysis, the region enclosed by the black curve represents the region envelope of clay failure (Li et al.,

2019; Mollon et al., 2013, 2011). The dotted line is the area with the maximum velocity.

$$\dot{W}_D \geq \dot{W}_e = \dot{W}_\gamma + \dot{W}_s \quad (1)$$

Where \dot{W}_e represents the total rate of the external forces' work; \dot{W}_D is the rate of the energy dissipation within the soil mass undergoing plastic deformation; \dot{W}_γ and \dot{W}_s refer to soil gravity and overload power respectively.

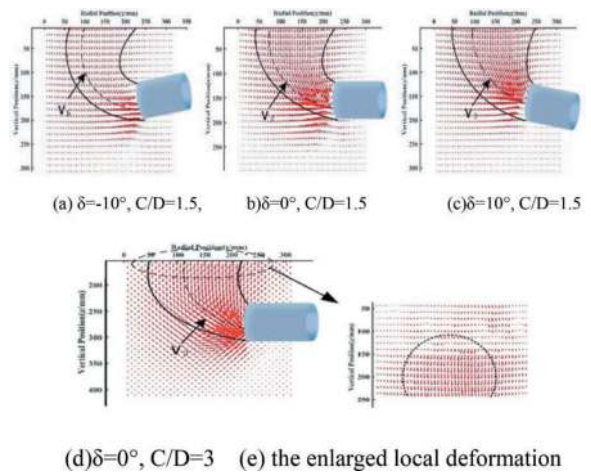

Figure 8. Displacement vector diagram of shield tunnel in clay stratum.

From Figure 8(a) - (d), the shape of the failure zone is essentially the same as Mollon's theory (see Figure 8(c), Mollon et al., 2013). The instability area reaches the ground in an ellipsoidal shape (Klar et al., 2007).

In addition, it can be clearly seen from Figure 8-(a)-(c) that the failure area in front of the tunnel expands laterally as the inclined angle of the tunnel decreases. Vertical settlement starts to happen as the failure area's circular curvature steadily reduces above the tunnel. This is similar to the engineering example where there is a high risk of instability in upward sloping tunnels. Figure 8(d) is the deformation vector diagram with $C/D = 3$. Since the observation area is concentrated near the tunnel, the analysis should be combined with Figure 8(f) (soil deformation above the tunnel). The results show that when the buried depth is higher, the failure area does not reach the surface, but gradually tends to be stable within about $1.5D$ above the tunnel.

The relationships between different retreat distances and the maximum ground subsidence are shown in Figure 9. The ground subsidence starts to build up as the retreat distance grows, with the maximum ground settlement occurring in the $1D$ range in

front of the shield tunnel. The influence on soil deformation is minimal in the early stages of deformation because of the tiny change in the supporting force. As can be observed from Figure 9(c), when the supporting force is reduced quickly, the ground settles quickly and the upward inclination's influence is more noticeable, which causes the deformation to occur more quickly. Furthermore, when taking the overburden depth into account, it is evident that as it increases, the soil mass tends to remain completely stable, regardless of the growth rate of settlement or the maximum deformation. This might be caused by the transparent clay's high compressibility and initial high initial water content. Long-term compression will contribute to consolidation, which will increase the material's strength. This confirms the viability of using this substance to simulated clay and is similar to the characteristics of soft clay.

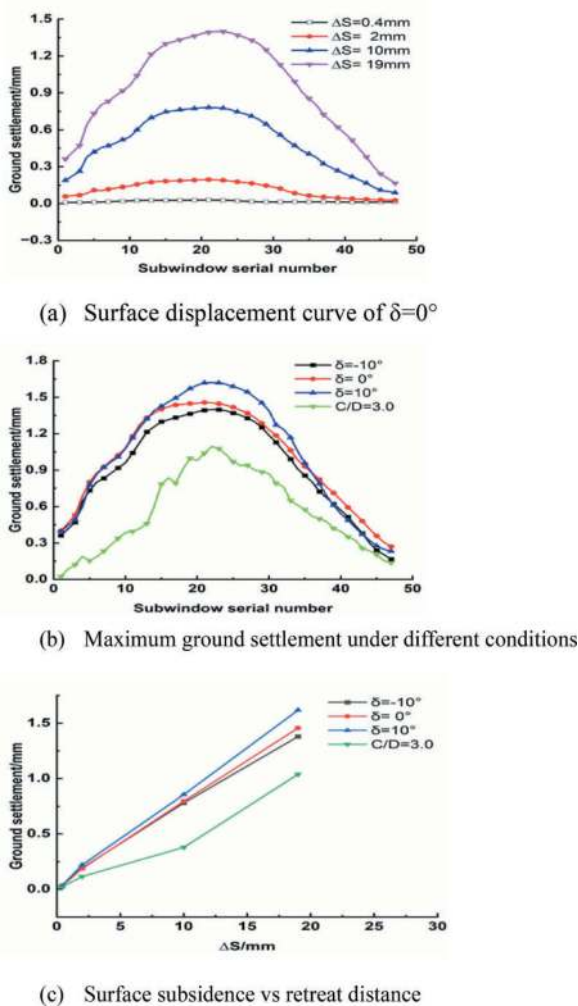

Figure 9. Ground subsidence of shield tunnel in a clay stratum.

3.4 Analysis of 3D reconstruction results

The 40 2D slice scanning images are first calculated using the improved adaptive image measurement

method to determine the deformation matrix of the corresponding slice position, and then the 3D displacement field is created using the 3D reconstruction method, which can reflect the out-of-plane displacement to a certain amount.

Figure 10 shows the 3D reconstruction failure model of the tunnel face under various inclination angles δ and ratio of C/D . Compared with the two-dimensional analysis, the movement trajectory and failure mode of the soil can be observed more intuitively. In the Figure s, the positive value of vertical displacement represents compression and settlement, while the negative value represents uplift, and the unit is mm. According to Figure 10 (b), (d), (f), and (h), the soil deformation may be approximately separated into the settlement area in front of and above the shield, the uplift area below, and the transition area between them. This essentially corresponds to Zhang et al. (2011)'s description of the failure mode of clay. The shear strength of the soil will withstand this deformation as the rigid surface gradually moves backward, generating a force that will flow into the tunnel due to soil particle friction and cohesion. On the other hand, a tiny pore will be created for pressure release when the soil above and in front of it moves. The soil below will swell as a result of the unloading and the cohesiveness between particles, and it will gradually change as the damaged region grows. As demonstrated in Figure 10(a)-(f), the maximum horizontal displacement in front of the tunnel changes as the inclination angle changes. This

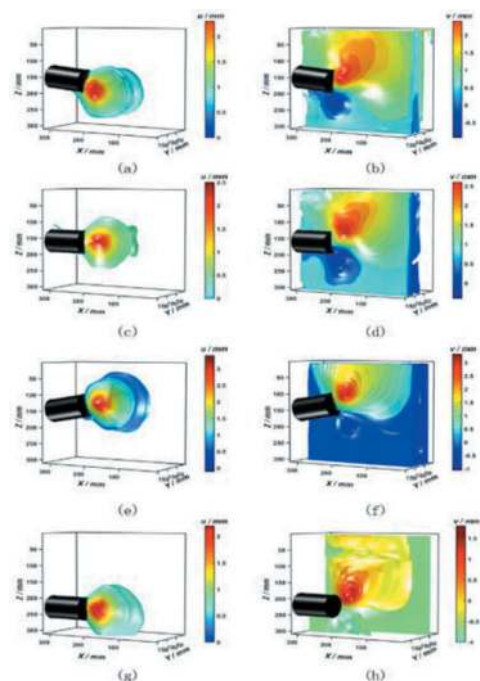

Figure 10. Three-dimensional reconstruction results of the failure zone (Horizontal displacement on the left, Vertical displacement on the right, (a) and (b) are for $\delta=-10^\circ$, $C/D=1.5$, (c) and (d) are for $\delta=0^\circ$, $C/D=1.5$ (e) and (f) are for $\delta=10^\circ$, $C/D=1.5$ (g) and (h) are for $\delta=0^\circ$, $C/D=3.0$).

displacement follows a similar trend and gradually decreases in the horizontal direction with this angle. The maximum displacement ranges from 2.3 mm at the downhill inclination to 3.2 mm at the upward inclination at a distance of 0.5D in front of the tunnel. The vertical displacement diagrams in Figure 10(b), (d), (f), and (h) show that the influence area gradually moves towards the ground as the inclination angle increases. It develops to the surface when the angle $\delta = 10^\circ$, and the influence zone is likewise larger than under other conditions.

As demonstrated in Figure 10(c), (d), (g), and (h), the maximum soil deformation decreases to 0.4mm as the C/D ratio increases, and the deformation zone similarly shrinks. The increase in C/D improves the soil's vertical stability from the perspective of vertical displacement. While the maximum displacement value has decreased by roughly 1mm, the deformation zone has shrunk and is located farther from the ground. This deformation progressively stabilizes once it reaches a particular height. The soil is more stable when the inclination angle is downhill as opposed to upward under the same C/D ratio. The soil with deeper buried depths is more stable at the same inclination angle.

4 CONCLUSIONS

This study conducted a series of shield model tests using transparent soft clay. The failure modes of the tunnel face under various longitudinal inclination angles δ and buried depths are simultaneously depicted and methodically investigated. The following are the primary conclusions:

- 1) Using transparent soil experimental technology, a set of model test systems for shield tunnel excavation under various longitudinal angles were established. By precisely managing the motor's tunnel face withdrawal, the shield tunnel's insufficient support force is reproduced.
- 2) The deformation process of soft clay has different development stages, and the failure modes in different areas vary. The soil in front of and above the excavation face drives the soil in the instability zone to move together towards the interior of the tunnel, gradually extending the disturbance and eventually causing overall subsidence of soil ground. The soil under the shield tunnel will have a small uplift zone due to drag force, which will be more obviously when the angles downward.
- 3) Under various inclination angles and buried depths, the damage shape of soil in front of tunnel shows an 'ellipsoidal' deformation pattern. The same failure mode was obtained by 3D reconstruction. When the failure occurs, soil settlement on the surface and above the tunnel rises along with the longitudinal inclination angles and the maximum velocity point also gradually moves downward. The increase of

buried depth ratio not only reduces the critical support force required by the face, but also limits the soil settlement of the surface and tunnel roof, and improves the stability of the soil mass. Compared with other conditions, shallow buried, upward sloping tunnels have a higher risk of collapse.

The 3D reconstruction results are more effective and intuitive than the traditional 2D displacement field analysis. It shows that the deformation and instability of the shield tunnel is a three-dimensional problem.

Application study of combined machining in the cutterhead design for hard rock tunnel boring machine

Michael B. Zhou*

Independent Advisory Engineer, USA

ABSTRACT: The principle of Hard Rock Tunnel Boring Machine (TBM) is to use the roller cutters to grind, drill, and break hard rock and smash it locally as big piece by rotating cutterhead and roller cutter into a depth from rock surface by depth with the pushing forward jacks electrically or hydraulically thrust. Since the mechanics compressive and tensile strength of hard rock is similar to the metal materials with different basic crystal and joint size, and strength scale MPa ($10^6\text{Pa} = 10^6 \times 1.02 \text{ kgf/cm}^2$), or 145 psi, it is exaggerated to say the principle of TBM were a machining process, too.

The efficiency of the TBM is dependent on the cutter head design and being machined rock material. In light of this, adopting the principles of the proper combined machining could raise the efficiency of the cutting, possibly.

It is a good idea to explore to transplant the proper process of combined machining to the hard-rock machining to get a good rate of penetration (ROP) and performance of tunneling of TBM. It also proposes its new design principle and outlines the design process and mechanics analysis with the pneumatic machining process. The paper tries to evaluate a new machining method combined with conventional hard rock TBM to seek its feasibility as potential alternative machining process for hard rock to advance a new generation of the TBM. It might save construction cost and shorten construction duration of tunneling capital contract for a better project performance.

1 INTRODUCTION

In the contemporary, TBM is undoubtedly the first chosen and critical equipment and tool of digging and excavating for the hard rock tunnel construction. Many study papers and summarized reports have concentrated in the analysis of the TBM function and work performance including some typical technical specifications, costs, geological conditions with TBM capabilities and adaptabilities, and case studies. A few experts are aimed in the general future development, such cutter technology, RPM, ROP, cutter replacement, instrumentation and monitoring, manufacturing and assembly. A few cutterhead designers dealt with the detailed cutterhead design sceneries and profile, and TBM performance with the cutter layout and structure design.

This paper is trying to use mechanical engineering principles to analyze the regular and special combined machining process as well as counter directional mechanical design measure to degrade rock strength parameter. In this way, it can promote TBM relative

thrust force, raise rate of cutter penetration and abrasive ability, decrease downtime, extend whole TBM life, and save tunnel construction time and cost.

Hard rock tunnel is applied in many engineering and business field, such as water works, rail road, and transportation road, etc. The current machining process combined with the TBM cutterhead design improvement might cause some technical advance and breakthrough in the tunnel digging velocity and specific energy, utilization percentage, and cutter and TBM life cycle.

2 HARD ROCK TBM PERFORMANCE

Hard rock is generally classified by its unconfined compressive strength (UCS) and with three categories as below Table 1.

Sometimes, information used in the paper and magazine uses the uniaxial compressive strength as MPa, that is consolidated, drained, and lateral confining process test is not equal to zero. More papers

*Corresponding author: mbzengineerpc@yahoo.com

Table 1. Hardness and unconfined compressive strength of rock materials (1).

Hardness category	Typical range in unconfined compressive strength (MPa)	Strength value selected (MPa)	Field test on sample
Hard rock	50-100		Handheld specimen requires more than one hammer blow to break it. Can be faintly scratched with 20d common steel nail. Resistant to abrasion or cutting by a knife blade, but can be easily dented or broken by light blows of a hammer.
Very hard rock	100-250		Specimen breaks only by repeated, heavy blows with geologic hammer. Cannot be scratched with 20d common steel nail.
Extremely hard rock	> 250		Specimen can only be chipped, not broken by repeated, heavy blows of geologic hammer.

and specifications use unconfined compressive strength (UCS) stands for the maximum axial compressive stress that a cohesive soil or rock specimen can bear under zero confining stress. To secure the lasting proper work status, it is sometimes to select to layout the water work tunnel in the deep hard rock layer to protect it from structure damage or cracking and water leaking.

There are several water tunnels with the hard rock strength and TBM tunneling information and performance to be listed as following two cases.

- NYC Delaware Aqueduct Hard Rock Bypass Water Tunnel: 12,448 ft (2.357 mile = 3.792 km) over 582 days, 270 m (900 ft) maximum deep with penetration rates of 6m (20ft) per hour, 6.8 m (22.3 ft) diameter Robbins Single Shield TBM, tunneling completed in August 2019; TBM excavated 27.4 m (89.8 ft) m on its most productive day, 108.1 m (354.8 ft) during its best week, and 288 m (945 ft) during its most productive month, tunnel completed 2019 (2).
- Atlanta Water Tunnel, 3.8 m (12.5 ft) diameter Robbins Main Beam TBM, 8.5 km (5.282 mile) length, extremely hard rock condition as 117 and 310 MPa (17,000 and 45,000 psi USC, best day of 38.4 m (126 ft), completed on October 4, 2018 (3).

Therefore, the practical measurement of tunneling construction performance with TBM are based on the advanced distance m (ft) best hourly, daily, weekly, and monthly operation and total days for completion of tunneling because it will consider many encountered conditions, such as fault area, water flooding, TBM stuck and downtime including maintenance and replacement of roller cutter, etc. However, it could not be precisely evaluate the TBM cutterhead real efficiency as rate of penetrated (ROP) and as depth by per TBM revolution. In light of difficult evaluation, it has better improve the tunneling efficiency of TBM cutterhead system to get its performance with a good completed day for the performance.

3 IMPACT TO HARD ROCK TBM PERFORMANCE WITH CUTTERHEAD FUNCTION

The TBM cutterhead is consisting of opened space central disc rotor and outer circular shell, inner muck ring and chamber, muck guide segment, roller cutter with shaft and bearing, connection nuts and screws between central disc and outer circular shell, connection parts between central mechanical rotating and transmission and power system, and joint back base and frame between with articulation joint and thrust articulation cylinder as the Figure 1 and 2 (4) (6).

Figure 1. Hard rock TBM cutterhead and main beam structure section view (4).

The cutterhead cutting performance is based on its load force capacity KN and Torque. That is to determine the depth of penetration (ROP), width of cutter tip, cutting space, velocity limit for disc cutters, cutterhead shape and profile, etc. Its rotational speed on hard rock TBMs is a function of disk cutter size and velocity limit, and the diameter of TBM and cutting geometry, cutting force, spacing and location of cutters on the profile (5).

Figure 2. Hard rock TBM cutterhead central disc rotor and outer circular shell front view (6).

The first step of cutterhead design is to evaluate its given geology (7) and decide to select ideal cutterhead structure and materials to adapt to the geological condition for smooth and efficient digging. Some evaluation has progressed to establish the assessed index of geology adaptation to TBM in the linear algebra, such as assessment of uniaxial compressive strength > 200 MPa for TBM as less adaption (8). Otherwise, the cutters of cutterhead would be damaged, stuck, changed more often, down time-increased. But the real operation function is a little far to the theoretic design of hard rock TBM due to the depth of the tunnel structure and geologic deviation, and rock sampling restriction. Therefore, the macro improvement of the TBM cutterhead is a good way for its mechanical process and tunneling innovation.

4 POSSIBILITY OF SIGNIFICANT IMPROVEMENT FOR FUNCTION OF HARD ROCK TBM CUTTERHEAD

As mentioned above, TBM is a special machining except the materials being machined is difference between hard rock and metal. Generally, the upper limit of compressive (USC) and tensile stresses of hard rock Granit, limestone, quartzite is around 250/25, 300/25, 250/30 MPa, Concrete 42/5 MPa, and steel 250/750 (tool) MPa (9).

TBM is a merely machine to break the hard rock locally by tool roller cutter pressing, grinding, cutting, and twisting, then transporting and excavating muck. Compared with the general turning machine (lathe), its work piece is static and machining cutter is rotated with the cutterhead, vice versa to the turning machine. However, the uniaxial compressive strength of hard rock is sometimes close to the low carbon steel compressive one as 250 MPa. It might consider the material similarity then pay more attention from the mechanical process principles.

Due to the weak tensile strength of hard rock, it might adopt clockwise and enter counter clockwise rotating of the central disc rotor with the short hock alternately to generate some tensile force except the designed compressive force system.

More importantly, it needs to change its machining function from sole work machine system. Considered its large volumetric inner muck ring as chamber of cutterhead and huge forged steel mass and high mechanic strength, there are some avenues to insert another alternative machining system to raise TBM working function or use it to degrade the hard rock mechanical strength referencing other conventional and custom machining process and technology.

5 APPLICATION OF COMBINED MACHINING TO IMPROVE CURRENT SINGLE MACHINING OF CUTTERHEAD

Current popular TBMs use one machine to obtain mechanical pressing of roller cutter and cutting to

hard rock of passive rotated cutter, twisting moment by roller and cutter circular-moving with cutterhead rotating. Due to the high hard rock compressive strength and surface hardness, and narrow cutter tip width, it cannot provide too large rotating energy due to cutter side areas as TBM revolution per minutes, sometimes only 8.3 revolutions per minute (10). Excessive rotating velocity and twist energy of TBM can cause the cutter break from its side resistant moment. This is because the energy as work done and power of rotating rigid body is proportion to the machine angular rotation speed ω and rotating angles Θ from the circular motion formula (11).

The work done and power for one roller cutter and whole cutterhead with rotating of TBM Central Disc Rotor (12) can be calculated roughly from following formulas.

$$\text{Work done} = \text{Torque (RF)} \times \text{angle in radians} = R m a \times \Theta = R m v^2 / R \times \Theta = R m (\omega R)^2 / R \times \Theta = m^2 \omega^2 R^2 \Theta \quad (13)$$

$$\text{Power} = \text{Torque} \times \text{Angular Velocity} = R F \times \omega = R m v^2 / R \times \omega = R m (\omega^2 R^2) / R \times \omega = m \omega^3 R^2 \quad (14)$$

Figure 3. TBM roller cutters and cutterhead circular Motion.

From the above analysis of the energy and work done by the TBM roller cutter and high USC for hard rock, it is propose to improve the mechanical process efficiency referencing special mechanical process system.

The special machining has included the multiple work machines and processing systems, such as machining center with combination of drilling, turning, milling and grinding; four-cylinder combined die with press machine to form metal end and die cutting circle to cut four sides by the press stroke downward to automatic produce the ends of metal container.

It might imitate the combined machining concept and try to add another machine transmission and mechanical process system to the current popular TBM cutterhead to improve its penetration depth per TBM machine revolution then prompt the TBM performance.

Due to the limited space of interior cutterhead chamber as muck ring with being optimized mechanical process and transmission mechanism, it is difficult to insert the second mechanical machine into the chamber or outside chamber. The other better way is

to utilize the pneumatic and hydraulic with water or oil. The hydraulic oil processing system has the problem in the oil leakage and low work speed and cycle, and water press machine with its thrust force needs big system and less function than current motor thrust system and low work speed.

Finally, it is explored to adopt the transmit system of pneumatic work with the pneumatic control components. With the available pneumatic system on site or remote air compressor system, the operation process of pneumatic working system could be compacted and fit it to interior chamber space of cutterhead and TBM work process. The advantages of pneumatic are less impact to environment due to leakage and rapid action frequency, and easy maintenance, adapt to dust and explosive site (15).

There are many kinetic mechanism of pneumatic work system, for instance piercing hole, light forge, cutting material, and breaking rock. In term of the pneumatic work system, the impact cylinders that can generate the not light forge and break materials will be a good candidate to combine it with the current TBM cutterhead mechanical system to increase it work performance.

6 DESIGN PRINCIPLE OF COMBINED PNEUMATIC IMPACT CYLINDER WITH TBM CUTTERHEAD SYSTEM

The impact cylinder is a special cylinder with simple structure and less power to produce a big impact striking force. The impact cylinder is classified as two types: quick air discharge and non -quick air discharge. But, the quick air discharge possesses a higher work impact frequency and it is satisfactory to hard rock breaking.

The quick air discharge cylinder is consisting of 1. guide cover of quick discharge 2. rubber seal gasket of quick discharge, 3. piston of quick discharge, 4. cylinder of quick discharge, 5. middle cover of quick discharge, 6: push bar, 7. gas resistor, 8. gas storage. The function of quick mechanism can make cavity below piston has enough avenue of flow area to connect to outside atmosphere quickly. It can let the back pressure of low cavity to lower air pressure to a very small quickly. This system is operated and controlled by three electrical and pneumatic solenoid valves: two – two ways and three ports and one two ways and four ports (Figure 4) (16).

Application of impact cylinder is very broad, such as metal rivet, bending, piecing hole, press-assembly, forging, crushing ore, and big hammer-striking. It can add the impact cylinder into the interior muck ring as chamber of cutterhead to form the second mechanical system or said second work system to generate the impact force on the hard rock surface before the TBM initial mechanical process for each cycle. In this way, the pneumatic striking on the hard rock surface can result in cracking the fracture of hard rock near by the striking area then

degrade hard rock USC and other mechanical strength.

Figure 4 . Pneumatic quick discharge impact cylinder.

Hereafter is the Table 2 to list the referenced structure dimension and specification of the quick air discharge cylinder for the possible application in combination with the current popular TBM cutterheads.

Since the quick air discharge cylinder is especially for vertical gravity falling to the object, its maximum impacting work, when applied in the horizontal impact striking, will be changed roughly with the supplied air pressure and stroke distance neglecting its front pressure for the case to the back. Therefore, it will only count for the force acting on the piston times its stroke for the work done horizontally.

However, the method and process of quick air discharge cylinder can only be utilized to generate the striking work on the hard rock and result in the fractures inside rock to degrade the compressive strength of hard rock horizontally.

Roughly to calculate piston thrust force and impact work from forge steel acted horizontally for 200 mm diameter impact cylinder D, neglecting the masses (G) of piston and piston rod, and pressure P_a in the piston rod cavity (20) as

Table 2. Referenced structure size and specification of Quick air discharge impact cylinder (17) (18) (19).

Application,		Forge Steel, Compressive Stress MPa= 250 x 1.3 = 325 (17)	Crushing Cast Iron Compressive Stress MPa = 220 – 2,520 (18)
Diameter of Cylinder, D,	mm	200	250
Piston Rod, d,	mm	120	150
Width of Piston, b	mm	70	75
Length of Air- storage, l	mm	220	250
Stroke Distance, l ₁	mm	460	525
Length of Quick Exhaust, Cylinder, l ₂	mm	90	110
Max Impacting Frequency, times/min	#/s	30	25
Gravity of Moving Part, G	Newton	900	1500
Impacting Work, W	Newton-m	2500	4650
Efficiency, η	%	24	24.5
Application to Hard Rock Grade, MPa		Very Hard 100 - 250	Extreme Hard >250

$$\begin{aligned}
 F (\text{NewTon}) &= 0.785 \times D^2 (\text{m}) \times p (\text{bar}) 10^5 \text{ Newton/bar} \\
 &= 0.785 \times (0.2)^2 \times 5 \times 10^5 \\
 &= 15,700 \text{ Newton} \times 70\% (\text{resistant force } 30\%) \\
 &= 10,900 \text{ Newton}
 \end{aligned}$$

$$\begin{aligned}
 W (N - m) &= 10,900 \text{ Newton} \times 0.23 \text{m} (50\% \text{ stroke dis.}) \\
 &= 2,527 \text{ Newton} - m
 \end{aligned}$$

It is close to 2,500 vertical gravity impact work $W = 2,500 \text{ Newton-m}$ (21)

However, its exact mathematic solution of the impact work for the cylinder can be obtained by the differential and integration equations. (20)

7 POSSIBLE PASSIVE MACHINING TO DEGRADE OF HARD ROCK MECHANIC PROPERTY TO IMPROVE TBM WORK

So far it has predicted that the passive machining measure with the quick air discharge cylinder can change the material property being machined. It provides a feasible way for lowering difficulty extent of cutterhead to cut and excavate hard rock.

Study of hard rock property is a very important task before the TBM and special cutterhead is designed. Most rock properties include mass, type, hardness, strength, color, particle size and texture, permeability, consolidation, shearing resistance, rock structure, discontinuity, water content, compressive stress (USC), friction angle, etc. In addition to, there are some Lab test items, such as DRI (Drilling Rate Index), porosity, brittleness, and mass degree of fracturing %. But for cutterhead, unconfined compressive strength (UCS) is more directly to the TBM performance and to the popular performance grading as m (ft) advance per day, week and month, or total days of complete, and or mm/rev. (22).

Degrading USC of the hard rock by generating the fractures with impact work and energy of impact cylinder will lower its popular index MPa and offer a chance to increase the rate of penetration per machine cycle. If the hard rock MPa is really closed

to the forge steel and cast iron MPa or similarity during the case, it will be a good opportunity like getting the striking and crunching cast iron and deforming the steel and dramatically improve the rate of penetration of TBM with the combination of machining process.

8 NEW LAYOUT OF ROLLING CUTTER AND IMPACT PNEUMATIC CYLINDER ON THE CUTTERHEAD

Generally, the friction angle of hard rock is round 30 degrees (23) and it is proposed the impact cylinders are layout with 60 degree interval to affect left and right 30 degrees that means 6 cylinders per circle with 2 circles beyond the central roller cutter set. It results $6 \times 0.2 \text{ m} = 1.2 \text{ m}$ opening per circle on the profile of cutterhead. It should be fines compared to one 18" (0.4572m) and one 19" (0.4826m) roller cutter linear length. Meanwhile, it is necessary to add the cast steel outside of cylinder to protect the abrasive damage of cylinder shell.

In addition, the depth of the inner muck ring chamber of cutterhead is possible to room the impact cylinder length around 0.9 m with the one stroke distance. But the opening structure of back based plate might be redesigned to fit the connection between the cylinder and cutterhead disc and with cushioning part to reducing vibration.

The front end structure of hole for stroke of piston rod in the impact cylinder needs to be fabricated as sunken head. When impact cylinder is not working it will not be protrusion outside the cutterhead. Moreover, end of piston rod should be machined as screw to be connected with the tip or flat end tool pit pal.

9 CONCLUSION

- a) Combined machining can increase the efficiency of machining by reducing preparation and mutual connection of individual work step. It also adapts to TBM cutterhead machining to improve its performance.
- b) Potential increasing TBM rate of penetration to obtain better TBM performance can degrade hard rock UCS. With the technical development of TBM, to make opposite effort for degrading material strength can get further success to break technical bottle neck.

This potential degrade of hardrock process strength is also application of strength of materials, advanced theory. That means there will be appeared some circular holes on the hardrock surface after it is impacted by tool pit pal striking with piston rod stroke of the pneumatic cylinder. If the random hardrock segment is modeled as similar to are rectangular plate being compressed, there will be 3σ compressive stresses at the

contract point n intersected between circle and horizontal n-n axis perpendicular to vertical compressive stress, Figure 5 (24).

In the term of above theories, the stress concentration of material being compressed at the circular point n of hole, will be similar to the structure shape resulted in by the compressive force of roller and cutter with rotated twist moment and cutterhead trust compressive stress.

If the smashed area of hardrock after being striking by impact cylinder is 30% by 30° angle interval rotating, it could degrade 50% compressive strength with increasing compressive stress with the 1.5 σ effects. And overall degrade effect and rate of penetration and tunneling performance increasing would be 30% x 50% = 15%

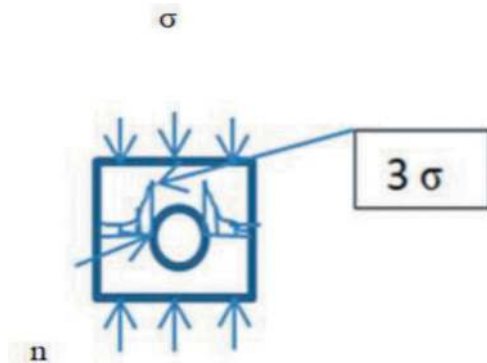

Figure 5. 3σ compressive stresses at n on plate with circular hole being compressed.

- c) It is feasible to add the pneumatic discharge impact cylinder to TBM cutterhead with its high strength steel-forged disc frame, around 3-ft big inner muck ring chamber space, 6 cylinders' circle length per circle equal to 3 (three) roller cutter linear length per circle. It is forecasted that pneumatic transmitted machining is going to be formed first machining system. The second popular pressing, cutting and grinding, twisting, and machining system for the hard rock is the current and breaking mechanical process by the sole work machine. Meanwhile, it could install LIDAR laser scanning to get the point clouds by software with the fracture distribution and depth, and percentage of cracked hard rock area, then start to run the second machining system main disc cutterhead imitated to CNC machining.
- d) Pneumatic impact cylinder application can be applied to degrade hard rock mechanic property. If the degrade of hard rock UCS could be reaching to 30% fractured areas to lower grade level by the impact cylinder striking like forge and crush, the rate of penetration would be advancing a big advanced step. The benefit of the cost aroused could be significant if the rate of

penetration per minute could be increased by 20% due to fractures of hard rock, its specific energy could save $20\%^2 = 4\%$ due pneumatic less energy consumption.

- e) It is predicted that the rate of penetration for TBM could have big progress and increase penetration by 1.0 mm/ revolution compared to theoretical values between 3mm – 8 mm per revolution (25) to save cost and time of tunneling construction by 15%. It will definitely cause some interests from construction business and develop this breakthrough in theory and practical application for the combined machining with TBM cutterhead design and manufacture and tunneling.

ABSTRACT: With the continuous growth of the demand for underground space construction, shield self-driving technology has become a research hotspot in recent years. In this paper, focusing on the characteristics and difficulties of shield tunnel construction, inspired by Rasmussen's human performance model, we design an intelligent decision-making and control system for shield tunnelling, called Zhiyu_IDCS. In addition, we propose a series of technologies, such as autonomous and fast recognition of the environment based on the conceptual drift, control model reconstruction mechanism based on explanatory machine learning, and multi-model collaborative control based on reinforcement learning, to cope with the challenges brought by complex, changing and uncertain construction scenarios. The shield tunnelling intelligent decision-making and control system includes shield attitude control, ground settlement control, soil improvement, soil-cutting, muck-discharging control, tunnel sealing control, etc., to accomplish long-distance tunnelling tasks without human intervention. The "Zhiyu" shield self-driving intelligent controller, developed by Zhiyu_IDCS, has been installed on shield machines of different manufacturers and models and has been applied in tunnelling in many cities such as Shanghai, Zhengzhou, Nanjing, Ningbo, and Shaoxing. The shield machines have crossed various soil layers, such as clay, sand, rock, and composite soils, and diverse engineering scenarios like rivers and bridges. Its cumulative advancing mileage has exceeded 10 km. The paper analyses the tunnelling performance and features of the "Zhiyu" intelligent controller from four aspects: tunnel quality, environmental safety, tunnelling efficiency, and control stability, and compares it with manual control. Finally, we give opinions and suggestions on the future development direction of shield self-driving technology.

Keywords: Shield, Tunnelling, Self-driving, Intelligent, Autonomous control

1 INTRODUCTION

With the rapid development of underground space, the size, length, and complexity of underground construction are increasing, and the demand for shield tunnelling has also risen significantly. However, the complex construction environment and tight construction schedule make the traditional

manual tunnelling mode face significant challenges, and the potential risk of tunnelling projects is increasing. The tunnel construction industry faces a significant shortage of experienced construction personnel. In addition, even for experienced construction personnel, whose construction experience is limited to the tunnels they have driven through. They often get into trouble when an entry into a new

*Corresponding author: zhouwb@stec.net

geological environment or an unmet engineering phenomenon occurs. Tired workers and blind acceleration pose a great threat to the quality and safety of tunnelling projects. Therefore, it has become a consensus to use automation and intelligent means to change the existing construction methods and improve project safety, quality, and efficiency.

Since 2018, shield autopilot has been accelerating, and the research results have increased significantly. In 2018, Shimizu Corporation of Japan and Nagoya University cooperated to complete the shield attitude trajectory planning by using AI technology; in 2019, MMC AMUDA MRT of Malaysia developed the A-TBM automatic tunnelling module, which realizes the automatic control according to the attitude target given by the expert, which was applied in the Kuala Lumpur Metro Line 2 project. In the same year, Shanghai Tunnel Engineering Co., Ltd. and Shanghai University cooperated to develop the “ZhiYu” shield self-driving control system V1.0, which was installed in an articulated earth-pressure balance shield tunnelling machine, realizing the independent planning and control of the shield attitude, ground settlement, and tunnel sealing, and achieving success in the Hangzhou-Shaoxing Intercity Railway Project. In 2020, Shimizu Corporation of Japan developed an automatic shield attitude guidance system, which achieved good results in a small horizontal radius of curvature axis control of tunnels. In 2021, Tokyu Construction Co. of Japan realized automatic earth pressure and attitude control, and Ohayashi Group of Japan developed the “OGENTS® intelligent shield,” which completed the automatic control of shield attitude. In 2022, China Railway Tunnel Bureau Group Co., Ltd. realized a one-button start for shield intelligent tunnelling in the 12th section of Shanghai Airport Line. In June 2023, the “Zhiyu” shield self-driving control system V2.0 developed by Shanghai Tunnelling Engineering Co. Ltd. in cooperation with Shanghai University completed the independent tunnelling of the whole line (5695 meters) of the 12th section of the Shanghai Airport Line (7# wind shaft ~ Lingkong Road), creating the records of 19 rings of tunnelling in a single day, 461 rings of tunnelling in a single month, and 829.8 meters of tunnelling of 9-meter-diameter shield. Moreover, shield self-driving decision-making and control systems (Zhiyu_IDCS) is applied in different geological environments, brands, and EPB shield machines in many cities, with a total tunnelling distance of more than 10 kilometres. Self-driving shield technology is gradually moving from research to practice. Shield intelligence and automation have become an inevitable trend in tunnel construction development, promoting underground space development into a new era.

2 SHIELD SELF-DRIVING DECISION AND CONTROL SYSTEM

Shield tunnelling engineering is a complex and massive system, which has the following difficulties:

- 1) The tunnel construction situation is complex, changeable, and incompletely knowable. With the shield tunnelling, the surrounding geology, force environment, and shield machine properties may change, and the whole tunnelling process is characterized by time lag and sudden change.
- 2) A shield machine is a complex, large-scale equipment, including cutting, propulsion, sealing, grouting, soil improvement, and other independent subsystems that affect each other.
- 3) The relationship between the control systems and control tasks is complex. The shield machine accomplishes attitude, settlement, and sealing control through more than ten independent control subsystems in cooperation. However, these tasks own complex relationships, coupled control parameters, and conflicting control objectives in different situations.

Aiming at these problems, we introduced human performance model (Rasmussen,1983) to design the “ZhiYu” shield self-driving decision-making and control system(Figure 1), which is divided into four levels: real-time perception, control and execution, system coordination and planning and decision-making. The perception layer is the “eyes” of the whole system, which utilizes various sensors and monitoring devices to obtain the ground deformation, shield machine work and movement characteristics, and the state of the completed part of the tunnel; the execution layer is the “hands” of the system, which consists of controllers of various subsystems. The execution layer is the “hands” of the system, which consists of the controllers of each subsystem and operates according to the control target given by the coordination layer; the coordination layer is the “cerebellum” of the system, which coordinates the relationship of each subsystem according to the requirements of the decision-making layer, determines the targets of the subsystems, and ensures the balance of the system; the decision-making layer is the “brain” of the system, which judges the engineering situation and predicts control effects and plans the control strategy of the whole system according to the engineering objectives dynamically.

Therefore, reinforcement learning (Sutton,1998) is adopted in the decision-making layer to continuously learn and optimize autonomously by receiving rewards (feedback) from the environment and simulated environment, with the exploration-exploitation phase balancing mechanism to ensure that the shield machine maintains good performance in complex or incompletely knowable scenarios. Since reinforcement learning requires a large amount of data for training, the environment simulator is trained using historical engineering data.

In Zhiyu_IDCS, environment identification, situation simulation, collaborative control, and objective evaluation are the most important key technologies, which will be described in detail in Section 3.

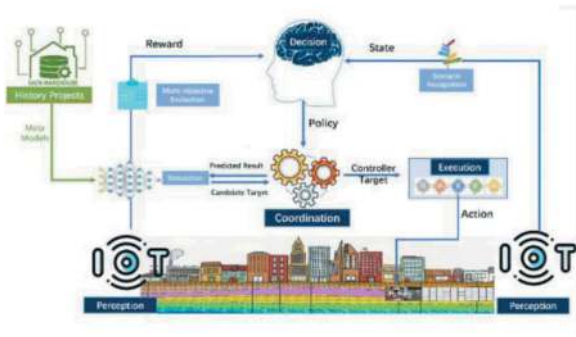

Figure 1. “ZhiYu” shield self-driving decision and control system.

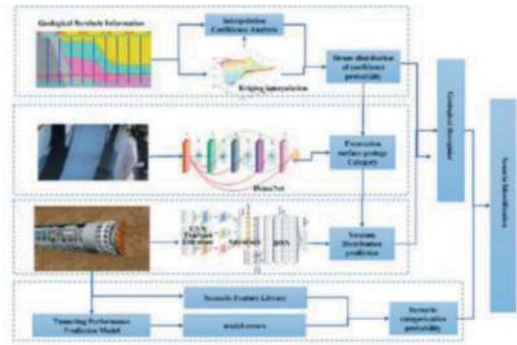

Figure 2. Tunnelling scenario identification.

3 KEY TECHNOLOGIES

3.1 Scenario self-identification mechanism based on multi-source information

During the shield tunnelling process, factors such as location movement, human activities, and equipment wear and tear lead to gradual changes or sudden changes in the tunnelling scenario, which triggers the drift of the control model. Therefore, correctly and quickly recognizing the context changes is the basis for improving shield structure control.

The mechanism of scenario identification is studied from two perspectives: mechanism tracing and difference analysis. Sudden geological change is the most crucial reason for contextual change in tunnelling. Although the geological exploration information and the state of excavated soil cannot accurately reflect the geological changes, they can be an essential basis for scenario identification. In addition, the deep learning model for geologic identification based on shield tunnelling data also provides a reference for scenario analysis. When the model drift analysis is performed, this information is used as the a priori condition, combined with controlling the model error and the data distribution changes in the adjacent time windows and finally completing the autonomous recognition of the tunnelling scenario based on the Bayesian classifier.

Figure 2 shows the process of scenario identification. First, the initial confidence probability of stratum distribution is determined based on exploration information. Then, deep learning is used to determine the geological type of the excavation surface using the slag monitoring video. Then, based on the geological distribution prediction model established from the shield excavation information and the drift of the excavation performance prediction model, the probability of a change in the context is calculated. Finally, based on multiple diagnostics and the Bayesian principle, synthesize the feature recognition results and the likelihood of occurrence of scenario change to realize the fast and accurate identification of engineering scenarios.

3.2 Predictive model reconstruction based on XAI

Since the shield tunnelling system has significant hysteresis characteristics, if the judgment is only based on the current system feedback, it will lead to the instability of the control system. Therefore, an environment simulator with predictive capability is essential in the control system, which can improve the control strategy and parameter accuracy, especially to overcome the problem of poor adaptability of the shield structure into a new situation. Considering the characteristics of small data sample size and complex situation, we utilize the interpretive machine learning idea, combined with transfer learning, to guide the model reconstruction and avoid the application risk brought by the black-box model.

First, we start from the engineering scenario, cluster the historical engineering construction according to the basic information of tunnels, shields, geology, and environment, and extract several typical scenario categories; then, classify and train according to the scenario, constituting the scenario base model library; then, adopt the LIME (Local Interpretable Model-Agnostic Explanations) interpretive method (Ribeiro,2016) is used to rank the importance of the core features of the model and the directional interpretation of the control relationship, to form intellectual control rules, and to form a scenario knowledge base where the model and the rules coexist. Finally, when a new engineering situation occurs, according to the engineering characteristics and the statistical characteristics of the data, the base model with a certain degree of situational similarity is selected as a sub-model for constructing the control model. The model transfer from the multi-source domain to the target domain is accomplished through model reconstruction to quickly adapt to the new situation. (Figure 3).

3.3 Reinforcement learning-based cooperative control of multiple intelligences

As a large-scale mechanical equipment, the shield machine accomplishes attitude control, settlement control, sealing control, and performance enhancement

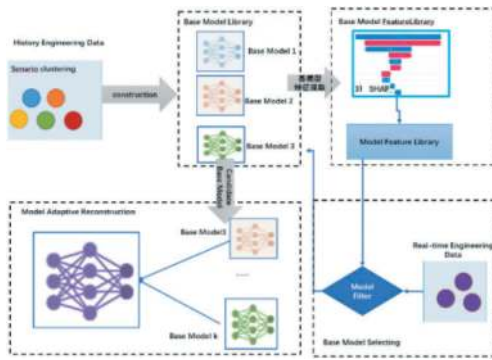

Figure 3. Shield excavation prediction model construction.

through more than ten independent control subsystems cooperating. However, these tasks have complex relationships in different scenarios, coupled control parameters, and conflicting control objectives.

Therefore, we design a collaborative optimization control method. First, from the perspective of the comprehensive performance of tunnelling, we construct a complete evaluation index system of tunnelling in the short, medium, and long term, focusing on the four dimensions of environmental safety, tunnel quality, tunnelling efficiency, and control performance.

Based on the shield tunnelling mechanism and engineering data, deep learning and other methods are used to design a relationship model for settlement, attitude, and performance prediction, construct a shield tunnelling simulator, analyse the possible changes of the shield tunnelling machine and the surrounding environment under different

control strategies, and analyse the control effect. The strategy's reward value is calculated using the simulator and the control feedback. The strategy optimization is carried out with the goal of the maximum reward value. On this basis, each control parameter's importance ranking and search direction are determined according to the optimization strategy, and the control value of each subsystem is determined after passing the constraint check. (Figure 4).

4 ENGINEERING APPLICATIONS

4.1 Application overview

Zhiyu_IDCS has been applied in many cities such as Shaoxing, Zhengzhou, Nanjing, Shanghai, and Ningbo, traversing a variety of geologies such as clay, pulverized soil, sandy soil, rocky and composite soil layers, etc., with the diameter of the shield machine ranging from 6-9 m, and the list of completed projects is shown in Table 1.

Table1. List of completed self-driving projects.

Project	Tunnel	Mileage(m)	Shield Maker	Geologic	Automation Rate	Evaluation of control effects		
						HD	VD	S
Hangzhou-Shaoxing Intercity Railway	Ke-Di Left	528	STEC	Silt\muddy clay\Clayey silt	0.871	6	6	13

Note: HD is horizontal deviation of shield Tail, VD is vertical deviation of shield tail, S is cumulative ground settlement; Evaluation of control effects is calculated by average of absolute values

4.2 Performance analysis

We take the Shanghai Airport Line Ling-Feng right line as an example to analyse the control performance of shield self-driving from attitude control, settlement control, propulsion speed, and cutting energy consumption. We compared a similar tunnelling section (200 rings) to the Ling-Feng right line, which is manual tunnelling. The working conditions are: the horizontal line shape is a gentle curve (left), the elevation line shape is a downward straight section, and the traversing geology is a mixed layer of gray silty clay and gray clay.

4.2.1 Engineering background

Shanghai Rail Transit City Line Airport Liaison Line, with a total length of 68.627km, is a fast channel connecting the east and west areas of Shanghai, which will not only be responsible for transporting most of the passengers between Pudong and Hongqiao airports but also be an essential channel for external railroad passenger transportation in Shanghai. Shanghai Airport Line Ling-Feng tunnel length is 5.7 kilometres. The right line adopts a 9.3m “Zhiyu” self-driving EPB shield machine (Figure 6) for construction. The shield machine of left line was equipped with the Zhiyu_IDCS. The Ling-Pudong tunnel is tunnelled manually (Figure 5).

Figure 5. Shanghai Airport Line.

4.2.2 Performance analysis

1) Attitude Control

The attitude control of “Zhiyu” adopts the dual control mode of shield head and tail positions. Figure 6 shows the distribution of the horizontal deviation of the shield head, the vertical deviation of the shield head, the horizontal deviation of the shield tail, and the vertical deviation of the shield tail under autonomous driving. It can be seen that the deviation variation of the whole shield machine is between -50mm and 50mm for both the head and tail, and the symmetry of the deviation distribution is better, with most of the deviations between -20mm and 20mm.

Figure 6. Distribution of shield attitude deviation.

Figure 7 illustrates the box plots of attitude deviations for automatic and manual control (box plot quantile are 5%, 15%, 85%, and 95%, respectively). The comparison shows that horizontal and vertical attitude autonomous control is superior to manual control, the distribution of deviation intervals is more reasonable, and the advantage is more evident in elevation deviation control.

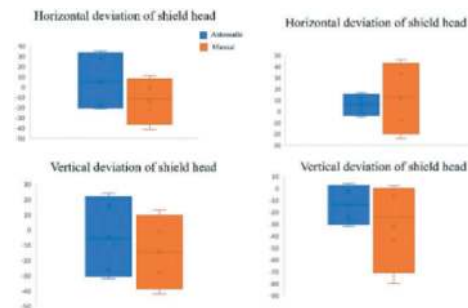

Figure 7. Attitude deviation comparison between automatic and manual controls.

2) Settlement Control

The autonomous tunnelling control system of the “Smart Driver” shield structure controls the whole process of ground settlement utilizing cutting-face pressure control and grouting control at the end of the shield. Figure 8 shows the distribution of the cumulative settlement in front of the shield, the cumulative settlement behind the shield, and the final ground settlement. It can be seen that the ground settlement is between -8mm and 10mm during the whole excavation process, and the settlement mainly varies from -5mm to 5mm, with little disturbance to the environment.

Figure 9 compares the ground settlement under automatic and manual control, with box plots at quartiles of 5%, 15%, 85%, and 95%, respectively. It can be seen that both have excellent settlement control with little difference.

3) Tunnelling speed

Zhiyu_IDCS allows on-site technicians to set the upper-speed limit. Figure 10 shows the trend of ring average speed change after the field technicians released the upper-speed limit (after 1800 rings). The

Figure 8. Distribution of ground settlement.

Figure 9. Ground settlement comparison between automatic and manual controls.

self-driving system can motivate the potential capacity of the shield machine as much as possible to realize high-speed and balanced construction when conditions allow.

After the statistics, the average speed of the automatically controlled section reached 85mm/min after the upper-speed limit was raised. In comparison, the ring average speed using the same type of shield machine was 70mm/min when manually controlled.

Figure 10. Tunnelling speed.

4) Cutting energy consumption

Shield machines are large power consumption equipment, so how to save energy and reduce emissions is also a problem to be considered. Therefore, the Zhiyu_IDCS continuously optimizes the energy consumption in the tunnelling process. Figure 11 shows that the upper limit of propulsion speed is gradually released, and the electric energy efficiency per unit distance of the shield machine changes (calculated by dividing the propulsion speed by the current). The utilization efficiency of electric energy is constantly optimized and improved during the tunnelling process.

Figure 11. Tunnelling energy efficiency.

5 CONCLUSIONS

With the development of information technology, shield self-driving has shown a bright future, and its unique advantages have been reflected in engineering applications. Zhiyu_IDCS V2.0 adopted the ideas of reinforcement learning and transfer learning, and compared with V1.0, the control effect is more stable in complex geological situations. Of course, for the Zhiyu_IDCS, there are still problems, such as poor control flexibility and lack of timely response in some cases. Therefore, if the shield autonomous driving technology can be more widely accepted and applied, it should learn more historical engineering data, adapt to various engineering situations faster and better, and always maintain safe, stable, and efficient performance. However, although the informatization level of shield machine construction is improving now, the data between each company is independent, with inconsistent data meanings and low data quality, which makes it challenging to learn big data in the later stage. Therefore, constructing the standardization of data and improving data quality are very important.

This paper describes the autopilot architecture and key technologies from the perspective of intelligent control. However, the success of the autopilot technology is also related to the performance of the communication system of the shield machine, the shield machine equipment, and the supporting equipment. All of these factors can constrain the performance of the autopilot capability. Developing a more high-speed and efficient shield machine based on self-driving is also a future development direction that should be emphasized. In addition, there must be a digital and lean project management mode to improve the efficiency and quality of tunnelling projects.

Research on frontier technology of shield machine/hard rock machine selection and mode innovation

Weibin Zhu*

Chinese Society for Rock Mechanics & Engineering, Beijing, China
Guangzhou Metro Group Co., Ltd, Guangzhou, China

Junbin Wang & Wenda Xie

Guangzhou Rail Transit Construction Engineering Consulting Co., Ltd, Guangzhou, China

ABSTRACT: The classical theory of shield machine selection is based on single or homogeneous formation, and the essential risks while TBM tunnelling, such as “mud cake”, “screw conveyor blow-out” and “hindered mucking”, are mostly presented separately. These essential risks would occur together while TBM works at mixed face ground condition, result in extra difficulties and even surface collapse. In general, preventive measures of improving TBM design, to enhanced single mode shield machine adaptability and safety, such as adding cutterhead agitators and foaming pipes, optimizing the cutterhead opening ratio, using accessible cutterhead, etc., or taking auxiliary civil measures prior to machine crossing.: such as blasting boulders or rocks, filling karst formation caves, etc. However, in the past 10 years, big number of projects is increasing together with larger diameter, deeper overburden and longer distance tunnel, the probability of essential risks combination and the losses of project caused by mixed face ground condition and/or “mud cake”, “screw conveyor blow-out” and “hindered mucking” have increased significantly, even led to major engineering accident. Author establishes the elements and principles of mixed face condition shield/hard rock machine selection system, based on experience and lessons learned from the application of 30 years of experience and systematic summary, as well as more than 1,000 shield machines under various geological and working conditions. By studying the upgrade and limitation on single mode shield machine/hard rock machine, provides original and ground-breaking key technology of TBM mode integration and explores the paths of overcoming the challenges. Expect to inspire you to similar projects.

Keywords: shield machine type selection, mixed face ground condition, essential risk, superposition of essential risks, mode integration and innovation, frontier key technology

1 INTRODUCTION

The “type” and “mode” of the shield machine, e.g. type of EPB, mode of Slurry, must be “tailor-made” according to specific geological conditions and other construction environments, machine’s adaptability determines the success or failure of the project.

Since the development of the closed-face mechanical balanced shield machine in the 1960s, especially after the Guangzhou Metro took the lead in trying to use the balanced shield machine to build tunnels in rich water mixed face ground condition in the 1990s, the shield construction method has been rapidly promoted in China. During this period, many difficulties were encountered, which led to thorough reflections on the theory of the traditional shield machine selection and mode choice based on uniform stratum

conditions by industry aspirants. At the same time, the engineering geological conditions are becoming more and more complicated: the same project section has both uniform strata and composite strata; some sections are greatly lack of water, and some sections are extremely abundant in water; there are both full face complete rock masses and broken rock masses formed by the development of fracture joints, uneven weathering, etc.; there are both super-hard ($\geq 90\text{MPa}$) monoliths and holes formed by karst development. The series of concrete difficulties further promote the innovation and optimization of the theory of the shield machine selection and mode choice.

With the rapid development of China’s tunneling equipment industry and the application of nearly 5000 modern shield machines, especially the practice of super-large diameter ($\geq 12\text{m}$) shields in water-rich

*Corresponding author: Wang.Junbin@hotmail.com

mixed face ground condition in recent years, China's shield machine selection and mode innovation research has made significant progress and is at the forefront of the world. For example, in 2012, Guangzhou Herrenknecht factory produced 6 no. $\phi 6.6\text{m}$ slurry/earth pressure tandem dual-mode shields for the karst composite strata in Malaysia; at the same time, Guangzhou Metro led China Tunnel Construction Co., Ltd. and Mitsubishi to develop a 6-meter parallel slurry/earth pressure dual-mode shield machine. In 2020, China Railway Engineering Equipment Co., Ltd developed a 6-meter three-mode tunneling machine for the second phase of Guangzhou Metro Line 7; the $\phi 12.84\text{m}$ slurry/earth pressure dual-mode shield machine produced by China Railway Engineering Equipment Group Co., Ltd (CREG) successfully penetrated the pebble under mudstone composite strata in Chengdu Zirui Tunnel. In April 2022, CREG developed a $\phi 15.09\text{m}$ super-large diameter accessible cutterhead dual-mode shield to across the Wuhan East Lake; in the same year, Tianhe Mechanical Equipment Manufacturing Co., Ltd. developed the world's largest diameter ($\phi 16.07\text{m}$) accessible cutterhead dual-mode shield machine (with spiral conveyor + accessible cutterhead slurry shield machine) to deal with the overlapping risk sources of composite strata coexisting with mudstone, limestone, quartz sandstone and developed fractures, reducing safety risks and improving efficiency.

At present, the multi-mode shield tunneling machines manufactured in China, which are independently innovated, developed, has become the best option or cutting-edge technology to tackle the challenge of shield construction in mixed face ground conditions.

2 SHIELD /TBM SELECTION PRINCIPLE

Geological body is the object of underground space development. Understanding the characteristics of geological body and scientific classification is the basis of shield /TBM selection and innovation.

For shield construction method, the construction object is generally divided into two categories: one is homogeneous stratum and the other is composite stratum. Among them, composite strata are further divided into soil/soil, soil/rock, rock/rock and other multiple combinations of composite strata.

2.1 Conventional shield machine/hard rock machine selection theory

The conventional theory of shield machine selection is established for a single or homogeneous soil layer (Quaternary/Q 2 million years before present/Q4 10,000 years before present). That is, the selection is based on the permeability coefficient and particle grading of the soil layer (Figure 1 and Figure 2).

According to the conventional shield selection theory, the slurry balanced shield machine is

Figure 1. Relationship between permeability coefficient and shield machine selection.

Figure 2. Relationship between particle gradation and shield machine selection.

generally chosen for water-rich sand, pebble, gravel strata with large permeability coefficient; and for sandy soil, silt, clay strata with permeability coefficient less than 10^{-4} m/s earth pressure balanced shield machine are often being used.

However, in the actual decision-making phase of the selection, cognition, experience, habits, as well as soil conditioning technology and economic considerations will also affect the selection of shield machine. With the development of soil conditioning improvement technology, soil discharging compatibility can improved EPB machine application in water-rich sand layer. Therefore, in China, the proportion of choosing EPB shield is much more than slurry shield, accounting for more than 80%.

2.2 Elements and principles of shield machine/hard rock machine selection system for mixed face ground condition

Composite stratum and its geotechnical properties are far more complex than single or homogeneous stratum, the traditional selection theory is simply not applicable, the selection of the shield machine need to take into account the following system elements.

- (1) Geological elements: including rock strength, rock integrity, geotechnical composition and structure, geotechnical stability (excavation surface flatness), water content (permeability) and so on. Adopt the technical route from macro (geomorphology + geohistory + stratigraphic

lithology combination) to micro (site geotechnical properties) to analyze;

- (2) Tunnel burial depth and its deviation;
- (3) Tunnel section diameter size;
- (4) The nature of the soil (particle size, specific gravity), the amenability and its conditioning improvement system;
- (5) Advance speed (decreasing speed results in mechanical energy converted to thermal energy leads to mud cake and other series of problems);
- (6) Environmental requirements (ground settlement, groundwater level control requirement).

Therefore, the selection of composite formation shield machine /hard rock machine is more based on the comprehensive analysis and selection of geological elements, engineering section diameter, buried depth, environmental control requirements, the drainage of residual soil, the controllability of “dynamic balance”, as well as the production capacity of shield manufacturers, the experience and economy of the construction party. Of course, after the selection process, the shield type is determined, there may still be local adaptability and engineering risks. Generally, the adaptability and safety of the shield structure when the shield machine in single mode are enhanced by improving the design of the shield machine, such as increasing the cutterhead mixing agitators and foam pipes, optimizing the opening ratio of the cutterhead, and adopting the accessible cutterhead or adopting auxiliary measures outside the shield, such as millisecond blasting of the rock beforehand and filling up the caves in karst strata.

3 THE PROBLEM OF SUPERPOSITION OF ESSENTIAL RISKS IN MIXED FACE GROUND CONDITION WHILE SHIELD CONSTRUCTION

From 1995 to 2005, Zhu Weibin and Ju Shijian put forward the concept of defining the basic risk sources of composite formation shield construction as “mud cake”, “screw conveyor blow-out” and “hindered mucking” according to the subway construction practice of Guangzhou Metro Line 1, 2, 3 and 4 and Shenzhen Metro Line 1. In the past 20 years, thousands of shield construction cases have proved that the essential risks of shield construction, whether uniform formation or composite formation, are still “mud cake”, “screw conveyor blow-out” and “hindered mucking”, as shown in Figure 3. These three factors are the main factors that affect the progress of shield construction and induce engineering safety accidents. In the homogeneous formation, most of them are independent. For example, when the earth pressure shield is constructed in the formation of water-rich sand gravel and water-rich fracture zone, it is mostly manifested as “screw conveyor blow-out” and rarely occurs “hindered mucking” and “mud cake”. Slurry shield tunneling in the stratum with high viscosity content, the

common risk is “mud cake”. However, in the construction of mixed face ground condition, a single mode shield machine will experience superposition of essential risks altogether, as shown in the following examples: (1) In Chengdu, China, the upper part of the tunnel is sand and pebble, and the lower part is mudstone. If a single mode slurry shield machine is selected, mud cake will be formed on the cutter head, and at the same time, pebble “hindered mucking” will occur in the excavation chamber and slurry circulation pipeline. (2) In the composite strata of Qingdao, Jinan, Xuzhou, Shenzhen and other places of China, there are water-rich sand layers overlying the tunnel, the upper part of the section is a clay layer, and the lower part is a limestone or granite layer. Earth pressure shield machine was used in early year construction, and the phenomenon of “screw conveyor blow-out” and “mud cake” superposition was frequent, and the subsidence or collapse events induced by it were frequent. After the summary and analysis, the root causes are as follows:

- (1) The understanding of the adaptability of shield machine using under mixed face ground condition is limited or misled by the traditional classical selection theory, resulting in improper selection.
- (2) The limitations of the development of shield equipment technology.
- (3) There is insufficient risk awareness of single mode boring in composite formation, and no timely adoption of enhanced technical measures.

4 SINGLE-MODE SHIELD MACHINE /HARD ROCK MACHINE TECHNOLOGY UPGRADE AND ITS LIMITATIONS

The most direct result of the essential risks and superposition of those risks in composite formation shield construction is cutter or cutterhead wear/damaged and machine stuck, which need to be replaced and repaired frequently by accessing excavation chamber. It not only affects the tunnelling progress, but also has safety risks such as unbalanced over the face and collapse. At present, the “mud cake”, “screw conveyor blow-out” and “hindered mucking” caused global engineering losses (direct + indirect) more than 10 billion.

4.1 *Single-mode shield machine/hard rock machine technology upgrade*

In response to the above problems, industry pioneers continue to innovate technology to upgrade shield equipment, including:

- (1) Earth pressure shield: the cutter head equips with one foam pump to one nozzle design for improving soil condition efficiency, add the active agitators and strengthens the mixing capacity in support arms behind the cutterhead

Figure 3. Risk source of shield construction.

- centre area to improve the “workability” of soil; Double screw or double discharge gate is adopted to strengthen the muck improvement design in the screw cylinder to prevent the superposition of “mud cake” and “screw conveyor blow-out”.
- (2) Slurry shield: Increase the cutter flushing system, install additional crushers, rock collecting boxes and cutterhead active agitators to prevent the superposition of “mud cake” and “hindered mucking”.
 - (3) The conventional cutter head is equipped with a tool wear detection device to monitor tool wear in real time. Figure 4.

Figure 4. Schematic diagram of real-time detection device for conventional cutter hob mode.

- (4) Auxiliary pressure balanced excavation, that is, the lower part of the excavation chamber is slag soil, the upper part is compressed gas, and the slag gas jointly balances the excavation surface. Figure 5.

Figure 5. Mechanism of auxiliary pressure balancing.

- (5) Equipped with freezable cutterhead (patent of CTC).
- (6) Develop a variety of dispersants and polymers.
- (7) Large diameter shield (>12m) adopts “scraper type atmospheric pressure cutter” (Figure 6) at full-section soil layer.

Figure 6. Jinghua: (16.07m) spatula type atmospheric pressure cutter head.

- (8) Large diameter shield (>12m) adopts “disc cutter + scraper combined type atmospheric pressure cutter” (Figure 7) composite formation.

Figure 7. Tuodao: (13.42m) hob and scraper combined type atmospheric pressure cutter head.

- (9) hard rock machine: open type → single shield → double shield.

The upgrade of shield machine/hard rock machine technology in single mode greatly improves the security and adaptability of shield. However, with the

dramatic increase of large diameter, large buried depth and long distance tunnel projects, the probability and the degree of loss caused by the superposition of the risks such as “mud cake”, “screw conveyor blow-out” and “hindered mucking” and the encounter of the complex formation have significantly increased, and even induced major engineering events.

4.2 Limitations of shield equipment technology development

- (1) Limitations of cutter tool wear detection and exchange safety assurance for conventional cutterhead in mixed face ground condition.

It is difficult to allocate the “first damaged cutter tool” in time, there is the problem of not changing the cutter tool in time, and under the joint action of “mud cake”, “screw conveyor blow-out” (earth pressure) and “hindered mucking”, it is easy to cause the “domino effect” type of damage of cutter tools (Figure 8).

Figure 8. Damage of conventional cutter head of shield tunnelling machine.

- (2) Limitations of medium and small diameter (<12m) shield machine/hard rock machine configuration with accessible cutter head in composite formation

If the disc cutter is applied, the area of the central closed area of the cutter head is increased, and the opening rate is reduced, the risk of mud cake and “hindered mucking” - stagnation superposition - will be increased. For example, the Nanjing Metro Line 10 crossing Yangtze river tunnel $\Phi 11.6\text{m}$ slurry balance shield machine, Changde Yuanjiang crossing River tunnel $\Phi 11.7\text{m}$ slurry balance shield machine (Figure 9), during the construction, the “hindered mucking” and “mud cake” superposition events occurred, lead to the need to have shield machine maintenance and extraction process which result in the extension of the construction period.

5 SHIELD MACHINE/HARD ROCK MACHINE MODE INNOVATION AND PRACTICE

Based on the limitations of shield machine/hard rock machine in dealing with complex geological and

(a) Nanjing Metro Line 10 crossing River tunnel

(b) Changde Yuanjiang Crossing River Tunnel shield machine cutter head

Figure 9. Superposition of “hindered mucking” and “mud cake”.

construction risk sources and their superposition in a single mode, a breakthrough can be achieved only by combining the advantages of slurry, earth pressure and hard rock single shield mode.

In 2012, Guangzhou Metro and CTC developed the world’s first “slurry and earth pressure parallel” dual-mode shield machine (Figure 10), and successfully applied to Guangzhou Metro Line 9. In a variety of composite strata such as clay and karst combination, sand and karst combination (Figure 11), the system design of integrating different driving modes and soil discharge modes on the same TBM is realized. According to actual needs, the driving function of specific modes can be set, and can be quickly switched in the tunnel.

Figure 10. Cutter head of shield machine in Hua-Guang section of Guangzhou Metro Line 9.

Based on the success application of dual-mode shield construction, as it is difficult for single-mode shield machine to adapt to the complex and changeable geological conditions in the granite distribution area (Figure 12) and meet the construction schedule requirements, in 2018, Guangzhou Metro again proposed the world’s first three-mode TBM integrating

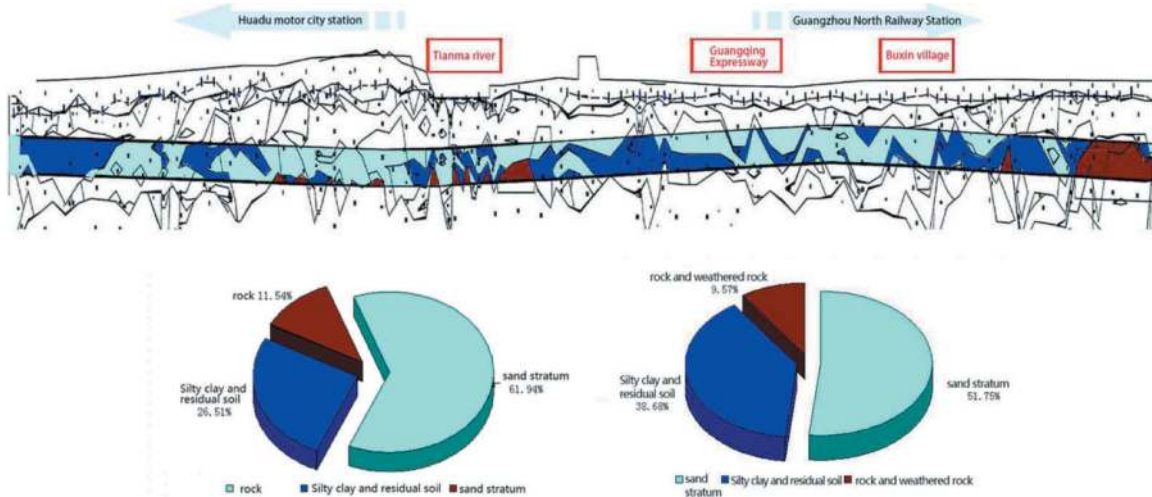

Figure 11. Geological profile of Hua-Guang section and stratigraphic distribution of left and right lines of Guangzhou Metro Line 9.

Figure 12. Geological section of the shield section between Luogang Station and Shuixi Station of Guangzhou Metro Line 7 Phase II.

Figure 13. A three-mode TBM completes the first tunnel boring.

“slurry, earth pressure and single shield” jointly developed by CREG and CRTG (Figure 13). In 2020, it was successfully rolled off the production line and applied to the section of Luogang to Shuixi Tunnel of Guangzhou Metro Line 7 Phase II.

6 CONCLUSION

The shield machine mode fusion innovation has gradually been widely used in shield design, the

“type” of shield, from the past earth pressure balance, slurry balance and hard rock single shield. It has evolved into slurry/EPB dual-mode, EPB/single shield dual-mode, EPB/double shield dual modes, slurry/ single shield dual modes and EPB/slurry/ single shield three modes. There are three different methods of soil discharging at EPB/slurry dual mode machine: serial, parallel and double channel. EPB/shield shield dual-mode machine capable of the center belt and center screw conveyor two kinds of discharge method while applying single shield mode. According to the characteristics of the stratum, the dual-mode or multi-mode shield machine can choose the appropriate mode to balance the excavation face, and the soil discharge method is more reasonable, so as to avoid the risks of “mud cake”, “screw conveyor blow-out” and “hindered mucking”.

The integrated innovation of construction technology theory comes from large-scale engineering practice, and has been verified, improved and promoted in guiding problem solving. At present, the challenging problems in front of us still need to be overcome, such as: the selection of the shield and the configuration of cutter tool in the rich water and large buried depth of mixed face ground condition;

The utility of earth pressure shield foaming system; Timely and accurately discovery of the “first damaged cutter tool”; Shield, especially super large diameter shield main bearing seal lifespan extension or protection problems; Timely detection of excavation face and rock face flatness and effective contact thrust force and stress distribution problem; The performance monitoring and protection of tailskin seal brush still need to be studied and required breakthroughs in the industry.

“Methods are always more than difficulties”, as long as perseverance, large-scale engineering practice as the basis, always problem-oriented, adhere to “geology is the foundation, shield is the key, management is fundamental”, theory with practice, superposition of essential risks in mixed face ground condition and induce engineering difficulties will eventually be overcome, mixed face ground condition shield construction theory will continue to walk in the forefront of the world.

Shanghai Tunnel Engineering Co., Ltd., Shanghai, China

ABSTRACT: To solve the problem of long construction period caused by the application of traditional shield construction method in long-distance shield projects, a synchronous shield tunnelling technology combining advancement and segment assembly was proposed. Then, a super-large mixed shield machine equipped with this technology was successfully applied in Shanghai Airport Railway Link Line project.

The on-site test results showed: the actual oil pressure fluctuated around the target values with the error rate of $\pm 5\%$, and the other two response conditions were also discovered; the phenomenon of the quick recoveries after the sudden changes of the total thrust force were observed, and the error rate of which was controlled at $\pm 3\%$; shield speed was directly affected by the total thrust vector, while the shield postures was not sensitive to it since the shield machine was wrapped in the surrounding soil, and the deviations of which in both of the horizontal and vertical directions were controlled in the range of ± 10 mm of the initial values. The construction data of 351 segmental rings achieved in a single month was analysed to find that: approximately 2.4 blocks per ring could be assembled synchronously, and the construction efficiency had been improved by about 27% compared with traditional method; the starting stroke of the oil cylinder for the synchronous operation and the segment assembly proficiency had the greatest impact on the construction efficiency, and the time management was suggested to be improved. Finally, a continuous slurry pipe connection technology was provided as a supportive method to further promote the construction efficiency through adopting two pipe system alternately employed during the shield tunnelling.

Keywords: Shield tunnelling, Segmental assembly, Synchronous operation, Engineering application, Efficiency analysis

1 INTRODUCTION

The traditional shield construction method connecting the shield excavation and segment assembly in series has been solidified for over a hundred years, which requires the assembly operation to be conducted after the propulsion hydro-cylinders reach the

maximum stroke, and the times for excavation and assembly are often similar in length. With the increasing demand for long-distance shield tunnels, construction period has become a decisive but uncontrollable issue that needs attention and breakthroughs, although the working performances of shield machines and related supporting technologies

*Corresponding author: zhuyeting@stecmc.com

have been well-optimized or developed to improve construction efficiency (DING et al., 2019; WEI et al., 2019; ZHANG et al., 2020).

From a construction perspective, low-speed continuous advancement is preferred for long-distance shield tunnel projects in urban core areas, as shortening shield downtime will significantly reduce the risk of shield machine failure and excessive ground surface settlement, while high-speed shield driving combined with synchronous assembly may improve construction efficiency and shorten the construction period in open terrain areas. Therefore, the synchronous shield tunnelling technology combining advancement and segment assembly is undoubtedly a feasible solution, and the total tunnelling duration can be reduced by increasing the overlapping time of these two procedures, i.e., by synchronising the fabrication of the segment with the advance of the shield.

Japan has conducted corresponding technical research and equipment development since 1970s as the first country in the world, and the main technical solutions can be divided into four categories as showed in Table 1: double hydro-cylinders in front and rear shield, front shield equipped independent steering function, total thrust vector control method, and special-shaped segments. The obvious limitations such as large structural size, high economical cost and control difficulty, complex design for segment and its erector could be discovered after a particular comparison. Several equipment manufacturers and construction enterprises in China also have inversed considerable time and efforts to develop related synchronous shield methods in recent years, but no publicly available data from engineering application could be found. Overall, regardless of the technical paths, the shield machine will have to be stopped and wait until the assembly is completed, if the assembling time for a single ring exceeds the advancement time. Therefore, the overlapping time that can be used for synchronous operation is a core factor for selecting the technical path.

Given that the stock of conventional shield machines in the domestic market is gradually becoming saturated, how to revitalize the “old” shield machines and how to upgrade the new are a hot topic for us. This article proposed a synchronous shield tunnelling technology based on the steady-state control of the total thrust vector (ACTT method) by adding control valves, improving sensor accuracy, and upgrading the hydraulic control system, which is suitable for both the old and new shield machines without changing the original structural design of the shield machines and segments as well as the operation experiences of the working staff. Then, this technology was applied in a super-large slurry balanced shield tunnelling project. After the analysis of construction data, the feasibility of this technology was verified, and some referable suggestion was provided to promote the construction efficiency furthermore.

Table 1. Comparisons of existing synchronous technologies.

Program	Institutions	Main technical features
Double-cylinder synchronous tunnelling method (HIROSHI, 2005)	KAJIMA	Double hydro-cylinders in front and rear shield, difficult turning, large size of the shield machine
Lattice hydro-cylinder shielding method (SUZUMI et al., 1999)	HONGCHI	
“F-Navi” shielding method (HAYASHI et al., 2008)	SHIMIZU	Front shield equipped independent steering function, high economical cost, difficult sealing method
“LoseZero” shielding method (FUKUAKYOSI, 2007)	TOBISHIMA	Inaccurate thrust vector control method, transform existing shield machine, partial synchronization
ASC-OM system	OBAYASHI	
Honeycomb-typed segment (OKUMURA, 2006)	OKUMURA	Special-shaped segment, complex structures of the segments and its erector

2 OVERVIEW OF DEMONSTRATION PROJECT

As figured in Figure 1, Shanghai Airport Railway Link Line project achieves the connection between the Pudong International Airport and the Hongqiao International Airport with the length of 68.66 km. Lot 3 of this project (JCXSG-Lot 3) consists of two section tunnels: one from Meifu Road working well to Huajing Station receiving well, and the other from Meifu Road working well to No. 2 air shaft receiving well, and the later with the length of 5658 m was constructed by “Jiyue” super-large ($\Phi 14.07$ m) mixed shield machine equipped with ACTT system.

The sketch maps of the shield machine and segmental lining structure were shown in Figure 2. “Jiyue” had a cutterhead with an excavation diameter of 14.07 m, the propulsion system of which comprised 34 sets of dual hydro-cylinders, and the inner diameter of the hydro-cylinder, the diameter of the piston-rod, and the largest cylinder stroke were 360, 280, and 3600 mm, respectively. The segmental ring was divided into 9 blocks with the outer diameter of 13.6m, the width of 2m, and the thickness of 0.65m. 4 groups of hydro-cylinders were located in each standard and adjacent block, and 2 in key block. The assembly sequence was B3, B4, B2, B5, B1, B6, L1, L2, and K, one more group on both two sides of the segment to be assembled retracted to provide enough space during the actual synchronous operation.

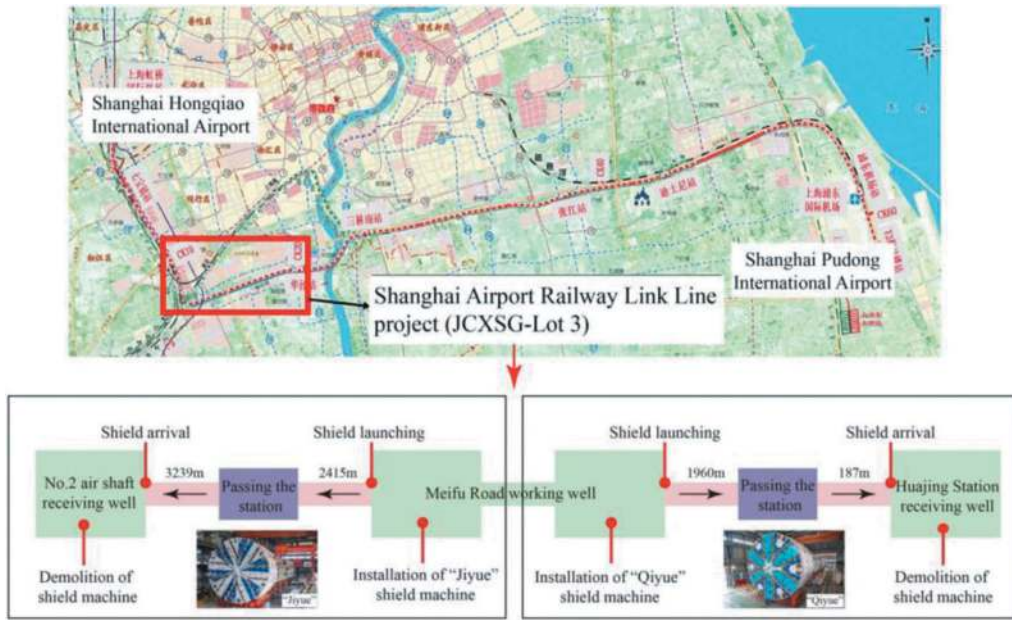

Figure 1. Project overview.

Figure 2. “Jiyue” shield machine and segmental blocks.

3 DATA ANALYSIS OF SYSTEM RESPONSE

3.1 Control algorithm of total thrust vector

As illustrated in Figure 3, the distribution method of the total thrust vector in the full cylinder mode and redistribution method of the missing thrust in the synchronous assembly mode have been explained in corresponding references (Zhu et al., 2023). The number of the dual hydro-cylinder groups in propulsion zone A was equal to zone B in the former mode, and which of the first pressurization zone was also equal to the second in the later mode. Effective range of target oil pressures (f_{min} , f_{max}) for all dual hydro-cylinders was set in advance to ensure that the calculated values were executable, where f_{min} is the lower limit as the minimum force to support the segment being assembled and prevent it from falling, f_{max} is the upper limit to avoid the calculated values that exceed the output capacity of the propulsion pump.

It should be noted that the numbers of the groups for the propulsion zone A and the decompression zone could be self-adaptively adjusted according to the preset rules. More specifically, when certain target oil pressures calculated by the preset grouping

method were judged to be less than f_{min} , the numbers of the groups of propulsion zone A and decompression zone would be increased one after another to raise them, and the opposite operation would be conducted if the maximum calculated pressure exceeded f_{max} . The segment would be prohibited to be synchronously assembled if the calculation finally failed.

Figure 3. Calculation modes of total thrust vector.

3.2 System response of shield machine

The section tunnel from Meifu Road working well to No. 2 air shaft receiving well with total ring number of 2846 was completed on September 8th, 2023, and over 2000 rings were constructed by adopting ACTT synchronous technology. Among them, Ring 1022 with the overburden thickness of 15m which was marked in Figure 4 in the form of five-pointed star was selected as a characteristic rin to demonstrate the actual system response, and the total thrust force (F_T), its resultant horizontal (M_{Th}) and vertical (M_{Tv}) moments during the synchronous operation were 60869 kN, -20901kN·m, -93795kN·m, respectively. As shown in Figure 5, three blocks were synchronously assembled when the cylinder stroke extended from 2302 mm

to 2955 mm, which took about 16 minutes at the shield speed of approximately 40 mm/min.

Figure 4. Geological map and arrangement of the segments.

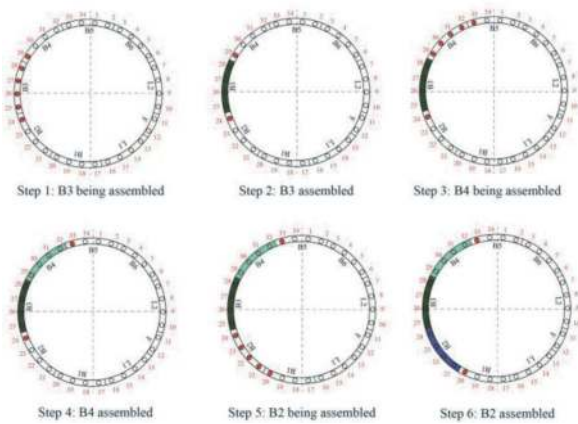

Figure 5. Assembly sequence of ring 1022 in synchronous period.

As shown in Figure 7, based on the assembly condition of ring 1022, one hydro-cylinder from the corresponding range of each segment (9 in total) was selected to present the execution of the target oil pressures. It can be seen that, consistent with the model test results (YUAN et al., 2023), the actual pressure fluctuated with a small amplitude near the target pressure values under PID closed-loop control (with the error rate of $\pm 5\%$), and a short-term response delay was observed once the target pressure changed. Owing to the fluctuations of the water-soil load on the excavation path, response performances of proportional reduction valves, shield deviation correction operations and et al., the execution of target pressure also shows the following two typical conditions: (1) obvious overshoots happened if the target pressures were slightly higher than that the hydraulic system could respond, and the error rate was controlled within 10%; (2) although the executed oil pressures could not reach the target values that exceeded the response capacity of hydraulic system, fixed deviations between the two could be remained. Overall, no significant irregular fluctuations were discovered during the whole applying process.

Figure 6. Oil pressure response of each cylinder in the whole process.

The total thrust force was generally stable during the synchronous period because of the effective responsiveness of the propulsion system to the target oil pressures (Figure 7), the error rate of which was controlled at $\pm 3\%$. an interesting phenomenon was discovered that the total thrust showed a sudden drop and quick rebound when the hydro-cylinders in the range of the segment to be assembled retracted, and a quick fall after a rise when the abovementioned hydro-cylinders extended and touched the segment assembled. The fluctuation amplitude of the resultant vertical moment was more significant than its total thrust force, and a timely recovery after a sudden change also happened at the moment of mode switching.

Figure 7. Total thrust vectors of shield propulsion system.

It could be observed from Figure 8 that the performance of the total thrust force when the hydro-cylinders retracted and extended reflected in the same pattern of changes in the shield speed, which was controlled at $\pm 5\text{mm/min}$ of the initial value, and small drops and rises were always allowable in the actual construction.

Different from the results of the model test, the fluctuation of the total thrust vector did not cause unstable changes in the shield postures due to the shield machine being wrapped in the surrounding soil. During the synchronous operation period, the shield postures in both horizontal and vertical directions were controlled at $\pm 10\text{m}$ of the target values. This result was within a completely acceptable range since the accuracy of the guidance system during conventional shield tunnelling is also 10mm.

Figure 8. Shield tunnelling speeds and attitudes.

4 DATA ANALYSIS OF CONSTRUCTION EFFICIENCY

As shown in Figure 10, 351 rings were constructed in Lot 3 of Shanghai Airport Railway Link Line project in a month from December 4th, 2022 to January 4th, 2023 (a total of 31 days), which was also a tunnelling record (702m) of 14-meter slurry balanced shield machine in soft strata. An average of 11.3 rings per day and a maximum of 15 rings one day were achieved. Among them, 289 rings accounting for 82.3% were conducted by ACTT synchronous technology, and the rest 62 rings were done by the conventional method as the strategy of shield advancement firstly and waiting for the subsequent segments to be in place was adopted since the cleaning of shield tail grease took a long time, and the delay of the segment transportation inside and outside of the site was another main reason. Slurry pipe connection was a key factor affecting the construction efficiency, and a creative continuous connecting method as a supportive technology will be proposed in section 5.

Figure 9. Number of rings completed for each day.

The cylinder stroke that could be used for synchronous segment assembly was a main factor affecting the construction efficiency of this technology, and the ideal cylinder strokes at the beginning and end of the synchronous operation were suggested to be 2200mm (200mm wider than the width of the pipe segment) and 3100mm for “Jiyue” shield machine, respectively. As shown in Figure 10, the end strokes were stably controlled at around 3000mm, while the starting strokes

fluctuated slightly around 2250mm. Among them, 28 rings began to be assembled when the starting strokes exceeded 2500mm, which was mainly due to the failure to achieve the seamless shifting of duty between two working teams. The average values of the starting and end stroke were approximately 2280mm and 3006mm, respectively, which were both close to the ideal values, and average cylinder stroke of 706mm could be used for the synchronous operation.

Seen from the actual on-site construction, time management should be improved if other external factors were not considered, the hydro-cylinders in range of the first segment should wait to retract after the stroke of which exceeded about 1900mm since the hydro-cylinder retraction also took some time, and the grabbing of the first segment could be conducted in advance.

Figure 10. Usages of hydro-cylinder strokes in the synchronous operation mode.

Figure 11 provided the average shield driving speed for each ring. It can be seen that except four rings ranging from 321 to 324 with the speed approaching 60 mm/min, the speed for the remaining rings was generally controlled within the range of 40-50 mm/min, with an average of approximately 45.4 mm/min. The efficiency analysis of this synchronous technology (ZHU et al., 2023) indicated that although improving the shield driving speed would reduce the overlapping time, the total time spent on a single ring would still be shorten. After considering the performance and safety of the shield machine, as well as the disturbance to the ground, this project had decided to maintain the conventional driving speed and only explore the efficiency potential from the perspective of system management.

Given the stable shield speed, the variation of the overlapping time was similar to which of the hydro-cylinder strokes used for synchronous operation (see Figure 11), and approximately 18.11 minutes per ring was calculated to be an average value.

Figure 11. Shield speed and overlapping time for each ring.

Time consumptions of shield tunnelling and segment assembly for each ring were figured in Figure 12, and the average tunnelling time was about 45.0 minutes due to the stable driving speed.

The assembly time was obviously another main factor that affected the application efficiency of this synchronous technology, while the prerequisite of this technological development was to basically not change the operating habits of the construction teams, mainly by upgrading the control system and optimizing the operation process. Therefore, the workers of the three construction teams were not intentionally adjusted, the optimized operation method with high acceptance was verified to be simple and easy to understand. Finally, the assembly time for each ring was relatively discrete, with an average of about 57.0 minutes.

Figure 12. Time consumptions of shield tunnelling and segment assembly for each single ring.

The number of segmental blocks synchronously assembled for each ring was given in Figure 13. Apparently, it always took relatively longer time to install the first segment compared with the rest ones as no adjacent segments were available to assist in positioning. An average of approximately 2.4 blocks per ring (with a maximum of 5 blocks) was calculated to indicate that the proficiency level of the assembly workers significantly affected the number of the synchronously assembled blocks. Improving the proficiency in assembly operation or combining it with the upcoming automatic segment assembly technology would greatly improve the construction efficiency.

According to statistics, an average of 83.9 minutes was finally obtained adopting this synchronous technology for a whole ring, which was 27.0% shorter than the traditional operation time (average of about 115 minutes).

Figure 13. Numbers of segments assembled synchronously and efficiency promotion for each ring.

5 SUPPORTIVE TECHNOLOGY: CONTINUOUS CONNECTION METHOD OF SLURRY PIPES

During the advancement of the slurry balanced shield machine, the rigidity slurry pipes with no retractility has been fixed on the internal tunnel surface, and cannot move forward in the tunnelling direction. The pipeline has to be extended to ensure the circulation of the slurry feeding and discharging after shield driving a distance equal to the length of a pipe, which is always integral multiple of the corresponding segment width. The slurry circulation system has to be shut down, and the original pipeline path will be disconnected. Then, a new pipe will be welded between the front and rear ones. The entire connection operation may take approximately one to two hours, which is a repetitive and time-consuming process that plays an important role in the construction efficiency of slurry-balanced shield machines.

Therefore, it is extremely necessary to develop a continuous connection method of slurry pipes, i.e., integrating the connection time into the shield tunnelling. Then, an original continuous connecting technology of the slurry pipe was then proposed. As shown in Figure 14, a Y-typed branch pipe was designed through drilling a hole in the main pipe where a branch pipe was welded to. Then, two pipe systems including the main and auxiliary connecting devices with respective slurry hoses could be interchangeably employed.

As shown in Figure 15, the general operation process was as follows:

Step 1: the main slurry hose was connected to the main pipe by the main connecting device, and the auxiliary pipe system followed the same way, the main connecting device was at the forefront of the track at this point; the slurry circulation was switched in the main pipe system;

Step 2: shield tunnelling began, and the main and auxiliary connecting devices remained stationary relative to the tunnel; shield machine moved forward a distance exactly equal to the length of the slurry pipe;

Step 3: the shield machine continued moving, and the slurry circulation was switched in the auxiliary pipe system; after the main connecting device was pulled to the forefront of the track, the pipe connecting operation began;

Step 4: after the pipe connection was done, the slurry circulation was switched in the main pipe system; the auxiliary connecting device was pulled forward, and the auxiliary slurry hose was connected to the branch pipe as showed in step 1; one cycle of the work completed, repeat steps 1 to 4 until the tunnel construction was completed.

This continuous connection technology can greatly save time and cost, and is of great significance for improving the shield construction efficiency. The detailed operation procedures and control methods will be provided in the following research articles.

Figure 14. Y-typed slurry pipe.

Figure 15. Continuous connection technology of slurry pipes.

6 CONCLUSIONS

A synchronous technology combining shield tunneling and segment assembly was developed through the active closed-loop control on the oil pressure of the shield propulsion system. The effectiveness of the proposed technology was evaluated through onsite application in the Shanghai Airport Railway Link Line project. The major findings are given below:

- (1) The response characteristics of the oil pressures of the propulsion system could be generally divided into three categories in the synchronous tunnelling mode. Benefiting from the accurate setting of the target thrust vector, the fluctuations of the propulsion oil pressures were overall stable, and no irregular jumping happened;
- (2) During the synchronous operation process, the phenomena that the total thrust suddenly dropped and then quickly rebounded when the

oil cylinder retracted was observed, as well as a quick fall after a rise when the abovementioned hydro-cylinders extended and touched the segment assembled, the error rate of the total thrust was controlled at $\pm 3\%$.

- (3) Due to the sudden change in total thrust force, there was a synergistic change in the shield driving speed, but which was controlled within the set speed of $\pm 5\text{mm/min}$. The shield machine was wrapped in the surrounding soil, and the shield posture was not sensitive to small changes of the total thrust vector, and was in a fully controllable range;
- (4) On the premise of maintaining the conventional shield tunnelling speed, the starting stroke of the propulsion cylinder and the proficiency of the segment assembly workers were the main factors affecting the total operation time of a single ring. An average of 2.4 blocks were synchronously assembled in a ring, and the total operation time for a single ring taken by adopting this synchronous technology was reduced by approximately 27% compared with the traditional method.
- (5) An original continuous slurry pipe connecting technology was proposed to integrate its operation time into the shield tunnelling, which as a supportive method could improve the construction efficiency furthermore.

Achieving sustainable immersed tunnel projects

Jonathan Baber*, BEng, CEng, FICE

Technical Director, Tunnels Practice Leader Australia, Mott MacDonald Ltd., Sydney, Australia

ABSTRACT: Guidance for applying sustainability targets and the Three-Rs principle of the circular economy to immersed tunnel projects has not been published to date. Principles have generally been developed project by project according to local practice. This paper consolidates work undertaken on immersed tunnel projects worldwide to give insight into the construction activities and project components that can be targeted to make a tangible benefit to carbon reduction. The two major material components for an immersed tunnel that have significant impact on the carbon usage during construction are the concrete works and the marine earthworks. Projects where extensive or wholesale re-use of dredged materials has been achieved during construction are described and the challenges explained. In particular, projects in Scandinavia have demonstrated success in this area with early planning by the projects Clients.

Immersed tunnels have particular requirements for watertightness and durability due to their marine environment. Historically this has driven the use of cement replacement material in concrete mixes to control heat of hydration during curing and to produce dense impermeable concrete. The reduction in cement gives a naturally improved carbon footprint but this outcome has been driven by other factors. This approach should now be used as a default for sustainable outcomes. Another area for consideration is the re-use of facilities for prefabrication of tunnel elements. The opportunity for this is outlined with case studies presented for successful examples. In addition some commonly applied initiatives such as the use of recycled aggregates are described and their applicability to immersed tunnels.

The paper gives Owners, designers and contractors some guidelines and case study examples showing how carbon reductions can be made to immersed tunnel projects. It highlights the items that need specific attention from Clients during the early planning of the project and the development contractual frameworks for delivery.

Keywords: Submerged tube, Sustainability, Reduce, Reuse, Recycle, embodied carbon

1 INTRODUCTION

The three Rs of the circular economy – Reduce, Reuse and Recycle - are a long established foundation of sustainability thinking. They are applicable across a multitude of industries, but the detail of how they can be realised within a specific industry is necessarily different. There are well developed strategies in place and continually emerging initiatives for the construction industry due to the ever-increasing focus on sustainability, managing greenhouse gas emissions and minimising the embodied carbon in construction projects.

Guidance for specific subsectors is not always available and for niche construction methodologies there can be a need for new thinking each time. In the case of immersed tunnel projects, this is a unique and distinct construction methodology of which there are fewer than 200 examples in the transport sector

worldwide, so understandably, there is no specific guidance published to date. However there are some significant opportunities available to enable a highly sustainable approach, and there are some excellent examples of initiatives taken in the past that meet the three R's principles. This paper aims to draw together some guidance on these opportunities, illustrated by some past examples, so that clients, planners, designers, builders and operators can consider them and hopefully deliver their immersed tunnel projects in a sustainable manner.

It also reviews how immersed tunnels compare to other forms of tunnel, how ongoing industry initiatives can be applied, which forms of immersed tunnel offer the most carbon efficient solutions, how specific considerations can be made in design to reduce embodied carbon, and draws attention to previous immersed tunnel projects that have adopted good sustainable approaches. It looks at the opportunities for

*Corresponding author: jonathan.baber@mottmac.com

extending asset life that are specific to immersed tunnels, and makes some recommendations for clients to consider in future project development.

It is not the intention to discuss efficiency in operation, or the broader benefits of transport corridors. Nor is it the intention to look at the different frameworks that can be applied for managing sustainability, as these are much broader topics.

2 WHY CHOOSE AN IMMERSED TUNNEL

Immersed tunnels historically have often been chosen as a solution to overcome particular circumstances. For example there are a number of projects where an immersed tube tunnel was selected in preference to a bridge that might interfere with airport flight paths. They have also been selected where land is not available for the long approaches required for a deeper bored tunnel, where there is soft marine geology, or where multi-modal transport solutions are required with multiple tunnel tubes. More recently there have been a number of projects where immersed tunnels have been found to be the optimal solution on cost and environmental grounds, such as the Fehmarnbelt Tunnel in Denmark. But what about from a sustainability perspective? If this were to be the key driving criteria for selection would an immersed tunnel be favoured over other forms of construction?

To answer this question a comparison was made between the immersed tunnel and bored tunnel design solutions developed as options for the Silvertown tunnel in the UK during the early planning phase. This comparison considered the river crossing element of the project only and the main construction components of concrete, earthworks and interior fill/mass concrete. The conclusions drawn from the study were:

- Concrete volumes: The bored tunnel utilised 43% more reinforced concrete. It is noted that the use of SFRC in the bored tunnel lining concrete would improve the carbon footprint for the bored tunnel. However, there is greater opportunity for use of substitute cementitious materials (SCM) in the immersed tunnel. These two opportunities broadly balanced in the assessment of embodied carbon. Hence the volume increase remains a significant factor.
- Infill beneath the roadway: The bored tunnel utilised >300% more imported material vs the mass concrete required in an immersed tunnel. However granular fill in the bored tunnel will have significantly lower embodied carbon per m³ compared to mass concrete.
- Earthworks spoil: The immersed tunnel generated >100% more spoil. The impact of this will be largely determined by whether a beneficial re-use of materials from either the immersed tunnel dredging or the bored tunnel excavated spoil can be realised.

The conclusion from the comparison was that the bored tunnel required a 40-50% increase in embodied carbon compared to the immersed tunnel. This difference is primarily driven by the fact that the bored tunnel overall length is approximately 50% greater due to the extra depth required for the bored tunnel. Therefore the benefit of utilising an immersed tunnel solution in keeping the overall tunnel length as short of possible is clearly an advantage to minimising material quantities and therefore embodied carbon.

2.1 Concrete vs steel immersed tunnels

Two main structural forms are available to immersed tunnel projects – concrete or steel. Although it should be noted that concrete tunnels contain a high proportion of steel and, vice versa, steel shell tunnels rely on a high volume of structural concrete. Many immersed tunnel projects have undertaken options studies in their early stages to confirm the optimal structural form from the point of view of cost. This is often done by contractors bidding Design and Construct contracts, where cost is the primary driver, as means to secure a contract. But what about the relative sustainability benefits? Using one such past study it is simple to compare the embodied carbon between two solutions.

The project utilised for this was the Marmaray Tunnel beneath the Bosphorus Strait in Istanbul, a twin bore rail tunnel. During the tendering of this project a comprehensive options study was prepared looking at alternative structural forms - reinforced concrete, single steel shell, and double steel shell. Multiple cross section shapes were also considered, but for this comparison the most economic rectangular section for the reinforced concrete tunnel was compared to the curved binocular cross section for the steel single and double shell solutions as these were the most cost effective options considered. These tunnel sections are shown in Figure 1.

Figure 1. Marmaray tunnel options study cross sections.

The primary components of the construction were considered only, namely the structural and mass concrete, reinforcement, structural steel, and formwork. The marine earthworks and casting facilities were taken as common across all solutions. The conclusions drawn from the comparison were:

- The reinforced concrete tunnel was the most carbon efficient design.
- The segmental form of reinforced concrete construction is slightly favourable compared to

a monolithic form of construction due to the heavier reinforcement requirement in the monolithic tunnel elements.

- The double shell steel sandwich construction required 10% more carbon usage than the reinforced concrete solutions.
- The single steel shell tunnel required 17% more carbon usage than the reinforced concrete options.

So in this instance the reinforced concrete solution is seen to offer the best solution for minimum embodied carbon. It happens that this was also the conclusion of the cost evaluation between the solutions. Whilst this is informative, the project specific circumstances and local market conditions will always need to be taken into account for any particular project. What the study shows however is that the differences are relatively small and so it is worthwhile to make this type of detailed comparison to arrive at a clear conclusion for a specific project.

3 OPTIMISING IMMERSED TUNNEL DESIGN

There are some key topics to consider when optimising the design of an immersed tunnel to achieve a sustainable outcome. These are predominantly associated with minimising embodied carbon but some relate to re-use opportunities. They are:

- Reinforced concrete
- Mass concrete
- Steelwork
- Earthworks re
- Temporary works
- Tunnel element casting facilities

3.1 Reinforced concrete

The majority of recent immersed tunnels have been built as reinforced concrete structures. There are two forms of concrete tunnel that can be adopted: 1) using segmental tunnel elements with regular articulation joints through the structure at 20-25m spacing, and 2) using monolithic tunnel elements where articulation can occur at the immersion joints between the tunnel elements only.

A tunnel with monolithic tunnel elements will have a significantly higher reinforcement content to carry longitudinal bending moments in the tunnel structure. It will also feature an external membrane to achieve watertightness. There are circumstances where this type of structure is preferred for the site conditions but there is likely to be a modest cost penalty. In addition there will be an increased embodied carbon with this type of structure due to the increase in material quantities.

3.1.1 Optimisation of concrete vs steel

In the design process for an immersed tunnel structure, the normal optimisation of concrete sections takes place in the transverse design of the tunnel

cross section. This is the same process irrespective of whether the tunnel elements are segmental or monolithic. However there is a design step before this section optimisation is performed that is to balance the cross section to achieve the desired buoyant behaviour. This ensures the tunnel elements are able to float in the temporary condition, be immersed with the application of a sensible amount of water ballast, and then be secured against permanent uplift using ballast concrete within the tunnel.

Often the sizing of the tunnel cross section results in thicker sections than would be needed for structural adequacy. The temptation to optimise the structural sections further and manage buoyancy using other means is strong and deemed to be beneficial to achieving low cost solutions. However is this the correct approach for an optimal sustainable design solution?

To test this a simple parametric study was undertaken for a typical load level on a structural slab. The section thickness was gradually reduced and reinforcing steel increased to maintain a constant section capacity. Total embodied carbon was then measured for the resulting quantities and the results can be seen in Figure 2. It can be seen that there is a sweet spot for minimum embodied carbon where the balance of section thickness vs reinforcement ratio is optimal. In the example investigated, it can be seen that this is typically when reinforcement ratios are in the order of 250kg/m³ to 300kg/m³. For the thick sections in an immersed tunnel structure this is actually quite a high reinforcement content. It shows that there is merit in slimming down the sections beyond what is needed just for structure buoyancy control. However as soon as the reinforcement design begins to feature multiple layers of large diameter reinforcement bars or bundles of bars it can be seen that the overall embodied carbon will begin to increase rapidly compared to a moderately reinforced thicker section.

To incentivise designers to reach the optimal embodied carbon, mechanisms could be introduced within the contract requirements to ensure designers demonstrate that the sustainability objectives are being achieved. A possible approach to this would

Figure 2. Idealised curve indicating optimal reinforcement density.

be to require that structural design aims to achieve the optimal point of the steel-concrete sustainability curve within a tolerance of, say, +/-10%. This could be easily demonstrated in the design output using simple automated algorithms to enable quick efficient testing of designs section by section, or for the structure as a whole, to show they are in the desired range. This approach would not be specific to immersed tunnel projects of course and could be adopted more widely.

3.1.2 *Cement replacement in concrete mixes*

High percentages of cement replacement materials have been used in concrete mixes for immersed tunnel structures for decades. This is because immersed tunnels are designed to be watertight structures, and to achieve this with the thick sections required (to carry the external loading on the structure) requires a sophisticated approach to concrete curing. In many countries a simplistic approach to controlling thermal gradients in the concrete during curing has been used in conjunction with the application of an external membrane or permanent prestressing of the structure. In Europe a more sophisticated approach of cooling the concrete by passing chilled water through a network of embedded cooling pipes has been adopted. For either approach it is highly beneficial to minimise the heat of hydration in the concrete and this is done by replacing Portland Cement with GGBFS or PFA. Cement mixes with up replacement levels in the order of 70% have therefore been relatively commonplace.

However, in recent years tunnel structures have become wider with larger internal spans to accommodate greater number of traffic lanes, meaning structures are working harder. Coupled to this, longer tunnels using factory style production techniques demand higher concrete strength and early strength gain to support rapid construction programmes. Also in general terms there is a continued drive for achieving structural efficiency and reducing cost that has often resulted in thinner structural sections and higher reinforcement ratios. These factors mean that high cement replacement ratios may not be preferred as they result in slower strength gain.

However, compared to optimising section thickness where typically a 10% improvement in embodied carbon may be achieved for a 20% thickness reduction, significant gains can be made by using cement replacement materials. Moving from zero SCM content to 70% SCM content will give in the order of 50-60% reduction in embodied carbon. To realise these benefits clients need to be firm in their requirements for achieving a target cement replacement content. If, say, a 70% target was mandated, the tunnel can still be designed, programmes can still be achieved, and the cost premium is likely to be small. This has already been demonstrated in many immersed tunnel projects and so can be considered an achievable approach.

3.1.3 *Recycled aggregates*

It is quite feasible for recycled aggregates to be used in immersed tunnel structures but this has not been widely adopted or investigated. The challenge is to obtain clean reliable materials with the necessary mechanical and durability characteristics in the locality of a project. One concern for an immersed tunnel structure however is the potentially increased porosity of recycled concrete aggregates, as noted by Panda et al. This could be detrimental to achieving the desired low permeability concrete and protection against chloride penetration through the outer cover zone of the structure.

There is however a large quantity of mass concrete used in immersed tunnels for ballasting the structure and this lends itself to the use of recycled materials. There are few durability concerns and only low strength requirements for this component of the tunnel. This could even become a mandatory requirement for projects.

3.2 *Mass concrete*

There is opportunity to use high cement replacement material content in mass concrete used for permanent ballasting of the tunnel. The concrete does not have a high strength or performance requirement. In addition, as mentioned above, recycled aggregates could easily be used. Typically a layer of concrete in the order of 1m thick is placed throughout the width and length of the tunnel, so this accumulates to an appreciable volume of concrete and so it is important to explore these opportunities for a good sustainable outcome. There could be a cost penalty for this and so Clients should consider mandating requirements or incentivising contractors to go down this path.

3.3 *Steelwork*

As mentioned above there is a fundamental choice in the structural form of an immersed tunnel that is taken at a very early stage of design. Contractors may have a preference according to their experience, or the solution may be driven by the market conditions. In recent years the majority of tunnels have been built as reinforced concrete structures being the most competitive market solution.

However, there are other steelwork components used in all forms of immersed tunnel, notably the immersions joints that typically feature a cast-in steel frame to aid the accurate seating of Gina and Omega sealing gaskets. These details have evolved in time and are important for the correct functioning of the joint. Although reducing the amount of steelwork is a good objective, optimisations will result in relatively limited gains and care should be taken in this area to ensure the desired performance is achieved. Initiatives to omit the steelwork need to be considered extremely carefully.

3.4 Earthworks

The construction method for an immersed tunnel requires the dredging of a trench beneath a waterway in which the tunnel elements are progressively placed and backfilled. The nature of dredged material can vary considerably according to the particular site conditions. In marine, estuarine and river environments there is typically a degree of soft alluvial material that must be removed. In harbour and industrial areas there can be a layer of material that is contaminated and may require special treatment. One of the main challenges for an immersed tunnel project is to aim to re-use the material either within the project or for a designated purpose. This is a significant issue for immersed tunnels that should be carefully and continually addressed through the project development and delivery stages.

3.4.1 Re-use within the project

The ability to reuse dredged material depends on a number of factors:

- Suitability for engineering fill material
- Suitability for use as general fill material
- Presence of contaminants or unsuitable content
- Availability of land for temporary storage
- Need for treatment e.g. settling, drying, screening
- Practicality of handling material from the dredger

Assessing the suitability for different uses is an important part of early the planning work. Ground investigation along the marine alignment will be required for this. Backfill for the tunnel comprises different components that will have a different level of opportunity to consider re-use, described in Table 1.

Once a determination has been made of the possibility for re-use the next challenge is to address the practicalities. It is unlikely to be practical to dredge material and immediately place it in its final re-use position. Even if a very long tunnel is being constructed, and the material can be re-used directly without treatment, the plant for placing the material may need to be very different to the barges typically used to carry away spoil from the dredging operation. This infers that double or triple handling of the material may be needed, and land be available for temporary storage. This is generally the reason why dredged materials are not re-used in the works as backfill as the volumes of material are large and so the practicality of stockpiling (on land or at sea) for re-use may make this unachievable.

If a project client wants to achieve this outcome it may therefore come at a cost, and they will need to provide early support with the relevant land acquisition, environmental investigations and approvals if needed. They may also need to mandate the solution in the contract. Otherwise the building contractor will likely prefer to simply dispose of the dredged material and import new material.

Nevertheless, the opportunity for re-use and the need for treatment of the spoil, storage facilities,

Table 1. Opportunities for dredge material re-use.

Marine earthwork	Opportunity for re-use
Sand foundation layer	This has a carefully selected grading curve to facilitate pumping and limit consolidation settlement. Opportunity if dredging uniform sands.
Gravel foundation layer	This has a carefully selected grading for placing and mechanical properties of the placed layer. Unlikely opportunity to use of dredged spoil.
Engineering fill adjacent to tunnel structure	Material will need to be granular and largely self-compacting on placement. Opportunity if dredging granular material.
General fill away from the tunnel structure	Material has few requirements other than reinstatement the bed level. Opportunity for use of all dredged material.
Transition layers between backfill and rock protection layer	Will have carefully selected grading to meet filter requirements. Opportunity if dredging granular material.
Rock protection above the tunnel	Rock size will depend on protection requirements, usually large size stones meeting grading for layer stability and load dissipation. Not suitable for re-use of dredge materials.

handling facilities etc. should be considered as part of any project's planning, so that the project client can make a conscious decision for the project. If left to builder to solve the issue, the best commercial outcome will likely drive the solution which may be sub-optimal for carbon usage.

3.4.2 Use in reclamation works

A more likely approach to managing the dredged spoil is to investigate the possibilities for re-use on another part of the project. On many immersed tunnel projects dredged spoil has been used for creation of reclamation in which the tunnel approaches are constructed. An example of a pro-active approach to this is the Jack Lynch Tunnel in Cork, Ireland where spoil was used to create a new area of landscaped public amenity alongside the River Lee, see Figure 3. The reclaimed land was also used for the temporary casting basin for tunnel element construction. This was a solution decided by the project client from the outset and the necessary work to understand the impacts to the river flow regime was undertaken early to assess environmental impacts and obtain planning approval.

A similar approach was taken for the Øresund Tunnel in Denmark where the Kastrup peninsula was extended for the construction of the tunnel approach. In addition, the dredged limestone was used for the creation of an artificial island that served as the transition between the immersed tunnel and the bridge,

Figure 3. Reclaimed southern approach at Jack Lynch Tunnel.

see Figure 4. This approach, again dictated by the project client, enabled full re-use of the dredged material. Major sea crossings of this type that feature artificial islands particularly lend themselves to this re-use philosophy.

Figure 4. Artificial Island on Øresund Tunnel project.

3.4.3 Off-site beneficial re-use

A further option is to look for opportunities for beneficial re-use outside of the project. Two examples illustrate this well. During construction of the Limerick Tunnel in Ireland material dredged from the river bed was removed and stored in a purpose built lagoon and settlement area adjacent to the tunnel site. The settlement area and lagoons have been subsequently converted into a permanent wetland area for wildlife.

On a larger scale the Fehmarnbelt Tunnel construction will generate some 19million m³ of dredged sand and clay materials that will stored and re-used, partially to reinstate the construction facilities but also to create new beach areas, flood protection dykes, coastal lagoons and wetlands, for environmental, wildlife and recreational benefits.

3.5 DfMA principles

There are many elements of an immersed tunnel project that lend themselves to a Design for Manufacture and Assembly (DfMA) approach. Arguably when factory casting methods are used the whole

construction process becomes a DfMA production process that maximises material and carbon efficiency. On a conventional project where the tunnel works are effectively insitu works, there can still be opportunity that is not often realised:

- Mass concrete infill beneath roadways could be largely precast blocks, with a final topping layer applied to form the base to the running surface asphalt.
- Internal structural walls could be prefabricated as often they are lightly loaded, are thinner and more lightly reinforced than the tunnel perimeter walls and slabs.
- Immersion joint infill sections that are complex to cast insitu can be precast beneath the road construction and also for walls and roof.
- Suspended floors in service galleries should be precast.

Steel fibre reinforced concrete (SFRC) is not generally used in immersed tunnel structures as the structural capacity requirements for the main tunnel structure requires conventional reinforcing. However, for the elements of the structure that can be considered for DfMA this may be a reasonable approach.

3.6 Temporary works

A growing trend amongst the specialist marine contractors who construct immersed tunnels is to manufacture temporary works items that can be re-used from project to project. Items such as ballast tanks, bulkheads, temporary tunnel element supports, access towers survey equipment and specialist barges can be adapted for different projects and the impact of transporting them to a new location is considerably less than fabricating new items for each project. One of the best examples is the Multi-purpose pontoon designed and built for the Øresund Tunnel project for laying the gravel bed foundation and placing backfill. This has subsequently been used on multiple immersed tunnel projects around the world.

3.7 Casting facilities

A variety of facility types can be used for casting the tunnel elements of an immersed tunnel. Historically the industry has often taken the approach to leave it to the builder to determine the most economical solution. If the objective is to arrive at the most sustainable solution, then clients need to take the initiative in this respect and identify the opportunities for a project.

3.7.1 Use of dry docks

The use of a dry dock is highly advantageous for reducing cost and achieving a fast construction programme as it avoids the need to construct a new facility. Recent tunnels that have taken this approach include the Maasdelatunnel in Rotterdam, Netherlands, and the 2nd Midtown tunnel in the USA, see Figure 5. This is a highly sustainable approach.

Figure 5. 2nd Midtown Tunnel dry dock, Virginia USA.

One concern often voiced is that ready-made facilities are not available in the locality of the construction site. However, the cost and risk of towing tunnel elements, even up to hundreds of kilometres, is small so the search for a suitable dock can be quite wide. Political and economic drivers for the work to be carried out in a specific country may also come into the decision making of course.

3.7.2 Use of quarries

This is slightly less common as quarries adjacent to waterways are not plentiful. However, the Shek O quarry in Hong Kong is an example where a disused quarry has been used for the construction of multiple immersed tunnel projects in the region. Again this is a highly sustainable approach.

3.7.3 Use of casting basins

Many immersed tunnel projects have utilised purpose-built casting basins. This is not a good sustainable approach as a large volume of work and material is required. Therefore, this should be the last resort approach. However, if a Re-Use approach is taken then this could become a sustainable approach. A successful example is the Barendrecht casting basin in the Netherlands that has been retained as a facility specifically for immersed tunnel projects and has been re-used multiple times. Another example of re-use is the casting basin at the Conwy Tunnel in the UK, see Figure 6. This was created for the project to build the tunnel element in but afterwards was converted to a marina which in turn stimulated the development of housing and community facilities at the location.

3.7.4 Use of factories

Casting factories are economic for large and long immersed tunnel projects but require high carbon usage to construct the factory. If a programme of tunnel works is envisaged, then such a facility could be beneficial for following projects, but this is a relatively unusual circumstance. Unfortunately, the factory built for the Øresund Tunnel (Figure 7) which was the first of its kind, has never been able to be re-used but there should be greater opportunity with the factory being built for the Fehmarnbelt

Figure 6. Conwy Marina (tunnel approach in foreground).

Tunnel. The factory built for the HZMB tunnel in Hong Kong has been re-used for the Shenzhen-Zhongshan tunnel, albeit with modification, and is a good example of re-use through innovative thinking. The factory was built initially for a concrete segmental tunnel and it has been converted for carrying out the concreting operations for a steel double shell sandwich type monolithic tunnel.

Figure 7. Øresund Tunnel casting factory.

4 EXTENDING ASSET LIFE

Immersed tunnels are relatively simple structures. The most complex items are the immersion joints but the design and construction methods for these is well established, and provisions are readily made to ensure durability for the desired design life. However, experience in their application is necessary to carry through lessons from previous projects. It is not an area to be over-experimental with given the sensitive nature of the details for maintaining watertightness of the tunnel.

Durability provisions for immersed tunnels typically include:

- Concrete mixes feature high cement replacement materials content (GGBFS or PFA) that provides improved heat of hydration performance of the concrete to limit early age cracking, and also

reduces permeability to increase the resistance to chloride penetration through the outer cover zone of the concrete section;

- Additional concrete additives such as silica fume to further introduce fines to the concrete matrix and enhance resistance to chloride penetration;
- Cathodic protection systems are applied to steel-work elements of immersion joints. These can be relatively simple passive systems e.g. connection of sacrificial anodes for cathodic protection;
- Choice of materials for non-replaceable components e.g. uses of high grade stainless steel for embedded items and inaccessible items in immersion joints;
- Structural health monitoring systems are often used. In particular embedded probes to detect chloride ingress and predict corrosion potential. These measure the progression of chloride to enable a choice of when to activate additional protective measures;
- Provision for future intervention is common. This is typically the welding of reinforcement cages and provision of connection points to enable a cathodic protection system to be installed in the future should chloride penetration reach a level that risks onset of corrosion.

Steps are usually taken to protect the asset in the event of extreme or accidental event, such as:

- Passive fire protection is generally applied to the interior of the tunnel. This is to protect against catastrophic collapse from progressive spalling of concrete in the tension zones to the underside of roof slabs.
- Structural adequacy is designed for extreme events such as flooding, fire, explosion, internal vehicle impact and external vessel collision/sinking such that the asset can remain in service or be readily returned to service with minimal disruption.
- In seismic regions there would usually be a performance requirement to maintain the integrity of the structure and joints such that the asset can remain in service or be quickly returned to service. This requires careful design of the immersion joint details to prevent opening and water inundation occurring.

Measures can be implemented to enable ease of inspection and maintenance. As described by Baber et al (2009), access can be provided to the voids formed at immersion joints for camera inspections and for water ingress detection, and measures implemented to manage potential water ingress at the joints. Standardisation of the approach to extending asset life across immersed tunnel projects globally would be beneficial. Not all clients and their advisors are aware of the possibilities that exist, and reference to publications such as the ITA Owners Guide to Immersed tunnels (Annex 25 Cathodic Protection & Annex 32 Durability) is encouraged.

5 CLIENT AND CONTRACT INITIATIVES

Based on the issues and opportunities identified, some recommendations for clients are:

- Consider sustainability outcomes in scheme selection giving it appropriate weighting in MCAs at the early stage of project development e.g. steel tunnels vs concrete tunnels and bored tunnel vs immersed tunnels.
- Set ambitious targets for cement replacement in concrete mixes.
- Request design submissions to demonstrate optimal (minimum) embodied carbon in primary elements of the construction – concrete, steel, earthworks.
- Do sufficient early preparation to identify pre-existing facilities that can be used.
- Do sufficient early preparation to facilitate re-use of earthworks in the construction or in environmental enhancement projects e.g. reclamation and habitat creation.
- Reward contractors through appropriate contract mechanisms for achieving, and going beyond, sustainability targets.

6 CONCLUSIONS

Some excellent examples of good practice with regard to sustainability exist on immersed tunnel projects around the world. By distilling these lessons frameworks can be developed to inform new projects about the possibilities and to help drive some consistent thinking for future immersed tunnel projects. Table 2 summarises the opportunities on immersed tunnel projects that can be considered to maximise the response to the principles of circular economy in construction.

Table 2. Summary of immersed tunnel sustainability opportunities.

3 Rs	Opportunity	Impact
Reduce	Cement replacement materials	High
	Steel/concrete balance	Medium
	Shortest possible tunnel length	High
	DFMA principles	Medium
	Factory casting	High
Reuse	Casting facilities	High
	Earthworks re-use	High
	Recycled aggregates	Medium
	Temporary plant and equipment	Medium
Recycle	Extending asset life	Medium

There are clear benefits that can be realised by early consideration. Project Clients can play the strongest role in realising these benefits, by giving full consideration in the early stages of a project development and encapsulating requirements and incentives into project scopes and specifications.

ACKNOWLEDGMENTS

Mott MacDonald's in-house PAS 2080 certified Moata Carbon Portal tool has been used for the measurement of embodied carbon for the comparisons made in this paper.

ABSTRACT: The Shenzhen-Zhongshan Passage is a super-large cluster project integrating “bridge, island, tunnel and underwater interchange”. The submarine immersed tunnel, main works of the Passage, follows the two-way eight-lane technical standard. It is a new steel-encased concrete composite structure, with both technical indicators and project scale at the world’s leading level. For the steel-encased concrete immersed tunnel, the steel case has dual functions, i.e. waterproofing and load bearing. So, its stability under fire and high temperature is of great significance to the safety of the entire tunnel structure. At present, researches on fire resistance limit standards for tunnel structures are mostly focused on reinforced concrete structures. It is lack of relevant technical reserves for how to establish fire resistance limit standards for steel-encased concrete immersed tunnel structures. This paper proposes a fire resistance limit standard for steel-encased concrete immersed tunnels through standardized research and analysis and high-temperature mechanical testing: for steel-encased concrete composite structures, the fire resistance time in the RABT standard temperature-time curve test is not shorter than 2 hours. (1) For the main segment structure, the maximum temperature of the steel case surface should be lower than or equal to 300°C within 2 hours of fire resistance; (2) for the waterstop of the segment joint, the maximum temperature of OMEGA and GINA waterstops should be lower than or equal to 150°C, and the resistance time for temperatures above 100°C should not be longer than 1h and that for above 70°C should not be longer than 2h.

Keywords: Immersed tunnel, composite structure, fire resistance limit, segment structure, segment joint

1 INTRODUCTION

The steel-encased concrete immersed structure is an application direction of steel concrete composite structure in immersed tunnels. As it is seldom used in projects at present, its fire resistance has been studied scarcely. The existing studies and specifications on fire resistance of steel concrete composite structures focus on composite components in building structures.

Therefore, the research on the fire resistance limit standards for steel-encased concrete immersed tunnel structures can further improve the fire protection regulations for immersed tunnels and provide references for subsequent research on the fire resistance of composite structures of immersed tunnels.

At present, there are few standards for the fire resistance limit of tunnel structures and most research results are based on the fire resistance performance and

*Corresponding author: caopeng1@cmhk.com

protective measures of tunnel structures under the existing fire resistance limit standards. For example, Chen Changqing [1] et al. verified the effectiveness of the designed fire prevention nodes through the fire resistance limit test with full-scale specimens. Li Pingli [2] et al. developed a fire protection decoration system for immersed tunnels of steel-encased structure, of which the fire resistance performance was tested with the 2h RABT temperature-time curve. Xi Yang [3] et al. conducted the fire mechanical response test on the scaled (1:3) components in the roof structure of the steel-encased concrete immersed tunnel, selected the RABT fire standard temperature-time curve and found in the test that the mechanical properties of the steel significantly deteriorated at 300 °C.

The studies on rubber waterstops for immersed tunnel segment joints were also limited to mechanical properties, durability and fire protection design. For example, Chen Zhonghai [4] et al. conducted the thermal oxygen accelerated aging tests and stress relaxation tests on OMEGA rubber and the results showed that both the rubber material and the waterstop product had a design service life of 120 years. Peng Liqun [5] et al. studied the effects of rubber hardness, compression deformation and specimen length on compression load and stiffness as well as the effect of compression displacement on stress relaxation changes. Tuo Yongfei [6] et al. carried out the numerical simulations for tunnel lining segments under three different fire conditions and found that the waterstop would be burnt and damaged when the maximum temperature near the inner waterstop was close to 300 °C under operating conditions if a fire lasted for 2h without fire prevention measures; the waterstop was safe when its maximum temperature should be kept below 100 °C if there is a 30mm-thick fireproof plate for protection and a fire lasted for 2h. However, the above studies have not addressed the fire resistance limit standards for the waterstop of immersed tunnels.

In allusion to main segment joint structure of steel-encased concrete immersed tunnel, this paper proposes a method of researching and analyzing the fire resistance limit standards and specifications at home and abroad so as to summarize and obtain the fire resistance limit standards of the main segment joint structure. The high-temperature mechanical test is adopted for OMEGA and GINA waterstops at the segment joints of steel-encased concrete immersed tunnels to consider the waterproof characteristics of the waterstop rubber and explore the tensile strength, elongation at break, modulus, compression set and stress relaxation of the waterstop rubber at different temperatures. Then, the experimental results are analyzed to obtain the fire resistance limit standard.

2 FIRE RESISTANCE LIMIT STANDARD FOR MAIN SEGMENT STRUCTURE

The existing fire resistance limit determination criteria are studied to obtain the fire resistance limit

standards for the main segment structure of steel-encased immersed tunnels:

The Permanent International Association of Road Congress (PIARC) [9] and the International Tunneling Association (ITA) [10] have recommended the fire resistance limits for main load-bearing structures and some ancillary structures of tunnels based on the type of tunnel structure, working environment, traffic type, etc. The Code for Fire Protection Design of Buildings (GB 50016-2014) [11] divides tunnels into four categories based on their lengths and traffic conditions and specifies the fire resistance limit requirements for each category. The requirements for immersed tunnel structures in these suggestions or regulations are shown in Table 1.

Table 1. Fire resistance limits for immersed tunnel structures.

Institution/ Specification	Condition	Fire resistance target of main structure	Fire resistance target of ventilation duct	Fire resistance target of escape exits
PIARC	Small car	1h (ISO)	1h (ISO)	0.5 h (ISO)
	Large car	2 h (RWS/ HCinc)	2 h (ISO)	0.5 h (ISO)
ITA	Small car	1h (ISO)	1h (ISO)	0.5 h (ISO)
	Large car 1-2	2 h (RWS/ HCinc)	2 h (ISO)	0.5 h (ISO)
	Large car >2	3 h (RWS/ HCinc)	2 h (ISO)	0.5 h (ISO)
GB 50016	Class I tunnel	2 h (RABT)	—	—
	Class II tunnel	1.5 h (RABT)	—	—
	Class III tunnel	2 h (HC)	—	—

There are few profound studies on the criteria for determining the fire resistance limit state of tunnel structures. Some domestic and foreign standards or regulations, e.g. Technical Code for Concrete Filled Steel Tubular Structures (GB 50936-2014) [10], specify the practical calculation method for the fire resistance limit of concrete-filled steel tubular components, of which the temperature fields of the components are calculated and the material data at different temperatures are introduced to calculate the ultimate bearing capacity of the components. The Code for Fire Protection Design of Buildings (GB 50016-2014) and Code for Fire Protection Design of Tall Buildings (GB 50045-1995) [11] also specify the fire resistance limits of concrete-filled steel tubular components, but there is no research on the determination criteria for fire resistance limit of steel-encased concrete immersed structures. Determination criteria for structural fire resistance limit in some national tunnel fire resistance codes are shown in Table 2.

Table 2. Determination criteria for fire resistance limits of some national highway tunnel structures.

Country	Specification/standard	Fire temperature-time curve	Determination criteria		
			Concrete surface	Steel reinforcement	Steel case
Netherlands	2008-Efectis-R0695	RWS	< 380°C	<250°C	—
USA	NFPA 502	RWS	< 380°C	<250°C	< 300°C
Austria	OVBB	RWS	< 350°C	<250°C	—
France	CETU	HCM	< 380°C	<250°C	—
Germany	ZTV-ING	RABT	—	<300°C	—
China	GB 50016	RABT、HC	< 380°C	<300°C(RABT) <250°C(HC)	—

According to the prescribed fire temperature-time curves, these temperature determination criteria can be divided into three categories: RWS fire temperature-time curve represented by the Netherlands, including USA, Austria and other countries; RABT fire temperature-time curve represented by Germany, and HC or HCM fire temperature-time curve represented by France. These fire temperature-time curves are shown in Figure 1.

Figure 1. Common fire temperature-time curves for tunnels.

The criteria for determining the fire resistance limit of concrete are 380 °C in the Code for Fire Protection Design of Buildings (GB 50016-2014) and NFPA 502 [12]. For steel bars, the national standard - Code for Fire Protection Design of Buildings (GB 50016-2014) stipulates that: the temperature of the steel bars at a distance of 25mm from the bottom surface of the concrete is critical when the RABT temperature rises to 300 °C and the HC temperature rises to 250 °C. NFPA 502 specifies that the temperature of the steel bar at a distance of 25mm from the bottom surface of the concrete rises to 250 °C of the critical state.

By comparing the fire resistance limit determination criteria for tunnel structures between the national standard - Code for Fire Protection Design of Buildings (GB 50016-2014) and NFPA 502, it has been found that NFPA 502 stipulates that the temperature of the steel case cannot be higher than 300 °C, while no

relevant regulation is provided in the Code for Fire Protection Design of Buildings (GB 50016-2014).

In summary, based on the analysis of the determination criteria for fire resistance limit of highway tunnel structures at home and abroad, the fire resistance time determined by the RABT standard temperature-time curve test should not be shorter than 2h for steel-encased concrete composite structures and the maximum temperature of the steel case surface should be lower than or equal to 300 °C within 2h of fire resistance for main segment structures.

3 FIRE RESISTANCE LIMIT STANDARD FOR SEGMENT JOINT WATERSTOPS

In order to obtain the fire resistance limits of OMEGA and GINA rubber waterstops at the segment joints of steel-encased immersed tunnels, the model test has been carried out for OMEGA and GINA rubber waterstops.

3.1 Preparation of specimens

Refer to relevant provisions of the Rubber, Vulcanized or Thermoplastic - Determination of Tensile Stress-Strain Properties (GB 528-2009) [13] and the Rubber, Vulcanized or Thermoplastic - Determination of Compression Set at Ambient, Elevated or Low Temperatures (GB 7759-1996) [14]. OMEGA and GINA rubber is used to make dumbbell-shaped tensile specimens to perform the high-temperature tensile testing and make cylindrical compression specimens to perform the high-temperature compression testing, as shown in Figures 2 and 3.

Figure 2. Dumbbell-shaped tensile specimen (unit: mm).

Figure 3. Cylindrical compression specimen (unit: mm).

3.2 Test conditions

The conditions for tensile performance test and compression test of OMEGA and GINA rubber waterstops are detailed in Tables 3 and 4.

Table 3. Tensile test conditions.

Test type	High-temperature duration	Test temperature/°C

3.3 Test method

The test is conducted with an electronic universal tester. As shown in Figures 4 and 5, the specimen should be placed in a constant temperature box before testing, the dumbbell-shaped tensile specimen should be preheated for 6 minutes while the cylindrical compression specimen for 2 hours. The test is performed after the predetermined operating temperature is achieved. The tensile strength, elongation at break and modulus are obtained through tensile

4 ANALYSIS OF RESULTS

4.1 Analysis of tensile test results

The changing trend of tensile strength as function of temperature is shown in Figure 6 and 7. The high-temperature tensile test shows that the tensile strength shows a decreasing trend as the temperature rises. When the thermal treatment temperature is lower than

Figure 5. Electronic universal tester for compression test.

or equal to 150 °C, the tensile strength of OMEGA and GINA rubber waterstops after high-temperature cooling is basically the same as that of direct tensile fracture at room temperature, and the high-temperature cooling process has no effect on the tensile strength of OMEGA and GINA rubber waterstops. When the temperature is higher than 150 °C, the tensile strength at break decreases significantly after high-temperature cooling and the physical properties of the rubber waterstops undergo significant changes. The tensile strength characteristics of OMEGA and GINA rubber waterstops after high-temperature stress and cooling are basically the same as those after high-temperature cooling. Within the test temperature range and under the stress level, the stress during the high-temperature process has little effect on the tensile strength of OMEGA and GINA rubber waterstops after high-temperature cooling.

Figure 6. Tensile strength of OMEGA rubber waterstop.

Figure 7. Tensile strength of GINA rubber waterstop.

The changing trend of elongation at break as function of temperature is shown in Figure 8 and 9. The high-temperature tensile test shows that the elongation at break presents a decreasing trend as the temperature rises. When the thermal treatment temperature is lower than or equal to 150 °C, the elongation at break of OMEGA and GINA rubber waterstops after high-temperature cooling is basically the same as that of direct tensile fracture at room temperature, and the high-temperature cooling process has substantially no effect on the elongation at break of OMEGA and GINA rubber waterstops. When the maximum temperature is higher than 150 °C, the elongation at break decreases significantly after high-temperature cooling and the physical properties of the rubber waterstops undergo significant changes. Within the test temperature range and under stress level, the stress during the high-temperature process has little effect on the elongation at break of OMEGA and GINA rubber waterstops after high-temperature cooling.

Figure 8. Elongation at break of OMEGA rubber.

Figure 9. Elongation at break of GINA rubber.

The changing trend of modulus as function of temperature is shown in Figures 10-13. The high-temperature tensile test shows that 100% and 300% moduli present a decreasing trend along with the rise of temperature. The modulus of OMEGA and GINA rubber waterstops decreases along with the rise of temperature. When the thermal treatment temperature is lower than or

equal to 150 °C, 100% and 300% moduli after high-temperature cooling are basically the same as when direct break at room temperature. The high-temperature cooling treatment has no effect on the moduli of OMEGA and GINA rubber waterstops. When the temperature is higher than 150 °C, 100% and 300% moduli after high-temperature treatment and cooling present a significant increase and the physical properties of the rubber undergo a significant change. Within the test temperature range and under stress level, the stress during the high-temperature process has little effect on the modulus of OMEGA and GINA rubber waterstops after high-temperature cooling

Figure 13. 300% modulus of GINA rubber.

4.2 Analysis of compression test results

The mechanical properties of OMEGA and GINA rubber waterstops are consistent in compression tests. As the temperature increases, the compression stress relaxation and compression set of the rubber present an upward trend. The compression set is about 25% at 100 °C and increases sharply to 65% at 150 °C, as shown in Figures 14 and 15.

5 CONCLUSIONS

This paper proposes a fire resistance limit standard for steel-encased concrete immersed tunnels through research and analysis of current fire resistance limit

standards and specifications for tunnel structures, as well as high-temperature mechanical tests of rubber waterstops at segment joints. For steel-encased concrete composite structures, the fire resistance time tested through the RABT standard temperature-time curve is not shorter than 2h. The conclusions are as follows:

For the main segment structure, the maximum temperature of the steel case surface must be lower than or equal to 300°C within 2 hours of fire resistance;

The high-temperature tensile test of rubber waterstops at segment joints shows that the tensile strength of OMEGA and GINA rubber waterstops decreases along with the rise of temperature. When the temperature is higher than 150 °C, the tensile strength at break decreases significantly after high-temperature cooling and the physical properties of the rubber waterstops undergo significant changes.

The high-temperature compression test of rubber waterstops at segment joints indicates that the mechanical properties of OMEGA and GINA rubber waterstops are consistent in compression tests. As the temperature increases, the compression stress relaxation and compression set of the rubber present an upward trend. The compression set is about 25% at 100 °C and increases sharply to 65% at 150 °C.

For the waterstop of the segment joint, the maximum temperature of OMEGA and GINA rubber waterstops should be lower than or equal to 150°C, and the resistance time for temperatures above 100°C should not be longer than 1h and that for above 70°C should not be longer than 2h.

Stability and deformation analysis of dry dock slope in Haihe Tunnel, Tianjin, China

Chun Ning He*, Ying Qu, Er Chun Qing & Jie Qing Shen

Shanghai Tunnel Engineering & Rail Transit Design and Research Institute, Shang Hai, China

ABSTRACT: This paper mainly deals with the stability and deformation of dry dock slope in Haihe Tunnel, Tianjin, China. For a dry dock to be built in soft soil, the key issue is to set the correct calculation model and use the correct calculation method to develop a safe and economical slope gradient and the proper structure of the slope to meet the requirement of overall schedule and the cost control. The slope gradient of Haihe Tunnel was calculated by limit equilibrium method, then based on the data of vertical and horizontal displacements monitored on site in construction, the study on the whole deformation shape of the slope was carried out. And the monitored data was compared with the theoretical analysis results calculated by PLAXIS. From the analysis conducted in this study, the maximum settlement occurs on top of the slope, about 0.6% of the excavation depth; the maximum horizontal displacement also occurs on top of the slope, about 0.72% of the excavation depth; during construction, the whole slope behaviour changes with the excavation of the slope in different stages. Based on data monitored on site, corresponding empirical formula in expressions of time are set up to predict the deformation of the slope.

Keywords: dry dock, slope stability, settlement, horizontal displacement, slope behaviour

1 INTRODUCTION

The dry dock is named as a place in which the tunnel elements of Haihe Tunnel were prefabricated, see Figure 1. The stability of dry dock is essentially a problem of slope stability. While it is different from the general slope and also different from the general excavation, it is necessary to maintain the stability of the dry dock slope during excavation and also during the construction of the elements. Generally, the whole period as mentioned above will be about two years, much longer than the average exposure time of any other general excavations.

According to the requirements of element fabrication, floating and outfitting, the excavation depth of the dry dock is 11.8m; the bottom transverse width is 157.8 m, and the axis length is 115 m. The complex geological conditions and the poor mechanical properties of the soil on site make the project more complex.

Based on the background of the dry dock slope in Haihe Tunnel, methods such as the Sweden slice method and the Bishop method were used to calculate FS (factor of safety) of the slope in different conditions, to determine the appropriate slope gradient, to carry out the general design and detail design of the

slope. The whole slope was completed in six months. In the construction process, deformation data of the slope with time were monitored and recorded in detail. Then the finite element method was used and the corresponding results obtained were compared with the data monitored on site. On this basis, the distribution of the deformations of the whole slope could be studied and the empirical formulas for the deformation of the slope could also be obtained, see Figure 2.

2 COMPLEX GEOLOGICAL CONDITIONS

The soil layers within the dry dock belong to quaternary new series. Different era and genetic types result the soil on site being different both in horizontal and vertical directions. According to the geological investigation report, from top to bottom, the soil layers mainly constitute of 1-1 backfill, 2-1 clay, 2-2 silty clay, 3-1 silty clay, 3-3 alluvial clay and 3-4 soft clay sublayers, see Figure 3.

The mechanical properties of the soil are generally poor, mostly soft or very soft soils with large natural water content, and are in the soft plastic ~ plastic flow state with high compression and low strength, see Table 1.

3 DETAIL CALCULATION AND DESIGN

3.1 Calculation model

Based on limit equilibrium, the Swedish slice method and the Simplified Bishop method were carried out separately. Totally nine slope gradients and three different methods were assumed for analysis and comparison, to determine the final appropriate slope gradient. Nine slope gradients were considered from 1:3.0 to 1:7.0. Three different methods were considered as total stress analysis (TSA), effective stress analysis (ESA) and effective stress analysis with seepage.

Groundwater was considered as 1.0 m below the ground level.

3.2 Calculation results and comparisons

The overall calculation results of different slope gradients in different methods are shown in Table 2; corresponding curves are shown in Figure 4.

Table 2. Calculation results.

Slope gradient	Swedish slice method			Simplified Bishop method		
	TSA	ESA	with seepage (ESA)	TSA	ESA	with seepage (ESA)
1:3.0	1.61	2.63	1.11	1.74	2.81	1.14
1:3.5	1.75	2.87	1.25	1.86	3.03	1.27
1:4.0	1.91	3.09	1.40	2.03	3.18	1.45
1:4.5	2.09	3.01	1.55	2.19	3.11	1.61
1:5.0	2.24	2.92	1.73	2.36	3.06	1.77
1:5.5	2.43	2.93	1.9	2.55	3.06	1.95
1:6.0	2.59	3.08	2.00	2.7	3.18	2.09
1:6.5	2.77	3.23	2.15	2.88	3.31	2.26
1:7.0	2.97	3.38	2.40	3.09	3.46	2.45

Figure 4. FS in different slope gradients and different methods.

Both the Swedish slice method and Simplified Bishop method regard the slip surface as a circular surface, owing to the brief concept and being able to analyse the slope stability under complex conditions, the methods above are widely used. Because of different assumptions, distinct differences can be found

comparing the two calculation results. The Swedish slice method neglects the interslice forces, results a lower value of FS than the Simplified Bishop method. Generally speaking, for TSA, ratio of the FS obtained by the Simplified Bishop method to the FS obtained by the Swedish slice method is between 1.04 ~ 1.08; for ESA, the ratio is between 1.02 ~ 1.07; and for ESA with seepage, the ratio is between 1.02 ~ 1.05. So for layered soils or in complex conditions, the Swedish slice method should be used combined with the Simplified Bishop method.

For the project, most part of the slope is in the range of soft clay. Because of the low permeability of the soils, during construction process, it's impossible or very difficult to exclude the porewater in the soils, resulting in decreasing the effective stress of the soils and generating seepage force along the slope from the top to the bottom, increasing the sliding force and decreasing the anti-sliding force. Also the above calculation results as ESA with seepage reveal this phenomenon. Therefore, ESA method should be used to determine the stability, considering the impact of porewater pressure, and also this is the most adverse condition.

3.3 Comprehensive evaluation of slope stability

In the process of slope design, not only the stability should be taken into account, but also the economy of the project. High factor of safety would lead to large cost in project. Considering the dry dock project as a temporary work, taking unit investment for slope gradient as 1:3.0, the investments of the other slope gradients could be obtained in proportion with the excavation volume, and the cost effective ratio as FS/cost could also be obtained, see Figure 5.

Figure 5. Cost effective analysis for slope gradients.

In ESA analysis, the cost effective ratio rose up with the slope gradient, and at 1:3.5 and 1:4.0 it reached the peak value. After that it decreased with the increasing of the slope gradient. Through the cost effective ratio analysis, it's obvious that 1: 3.5 and 1:4.0 were the appropriate slope gradients for the project. For more safety, slope gradient 1:4.0 was adopted.

3.4 Slope design

The whole slope was under three excavations, with 1.5 m wide terrace located between each level. $\phi 700$ mm diameter soil cement piles were built up around the dry dock, with a pile length of 20.5 m, reaching into the 4-1 impermeable layer of clay, to form a closed area, which could not only act effectively as waterproof curtain, but could also enhance the whole stability of the slope, see Figure 6.

Protection measures were taken into account as the slope of the dry dock standing for quite a long exposure time. Transverse arc-shaped concrete beams and vertical concrete beams were poured on the slope surface with 80mm thickness C20 reinforced concrete inside. Bamboos were inserted in the concrete beams at spacing 1500 mm, embedded 2 ~ 3 m depth into the soil as to enhance the surface stability, see Figure 7.

Dry dock can be considered as a large excavation, so the drainage system is an important part of design. Drainage system in dry dock can be classified as the surface drainage system and underground drainage system.

Surface drainage system as drainage holes were set on the surface of the slope to dissipate water pressure inside the soil. In the second and the third terrace, 300×200 mm transverse gutter were built up, connecting with the longitudinal gutters, to drain the water into the bottom gutters and finally into collection wells. Underground drainage system named as blind ditch, which was made of $\phi 100$ mm diameter PVC pipes with open holes on its surface and laid perpendicular to the gutters at the bottom of the dock, was mainly used to exclude the groundwater in the soil.

4 MONITORING AND ANALYSIS

Continuous monitoring was carried out from the beginning of the excavation to the completion of the slope. The monitoring data for typical sections were analysed and put into figures, including the vertical and horizontal displacements. The whole slope was with three excavations, each excavation including curing of the concrete lasted about 10 days.

In vertical displacement curves, positive displacement means upheaval, negative displacement means settlement; in horizontal displacement curves, positive displacement means displacement towards the excavation direction, negative displacement means displacement reverse to the excavation direction.

4.1 Deformation relationship of the whole slope

During the whole period, the vertical displacement of the points on top of the slope and the points in the middle of the first slope show settlements, while the other points on the sloop show upheavals or both settlements and upheavals. The maximum settlement occurs

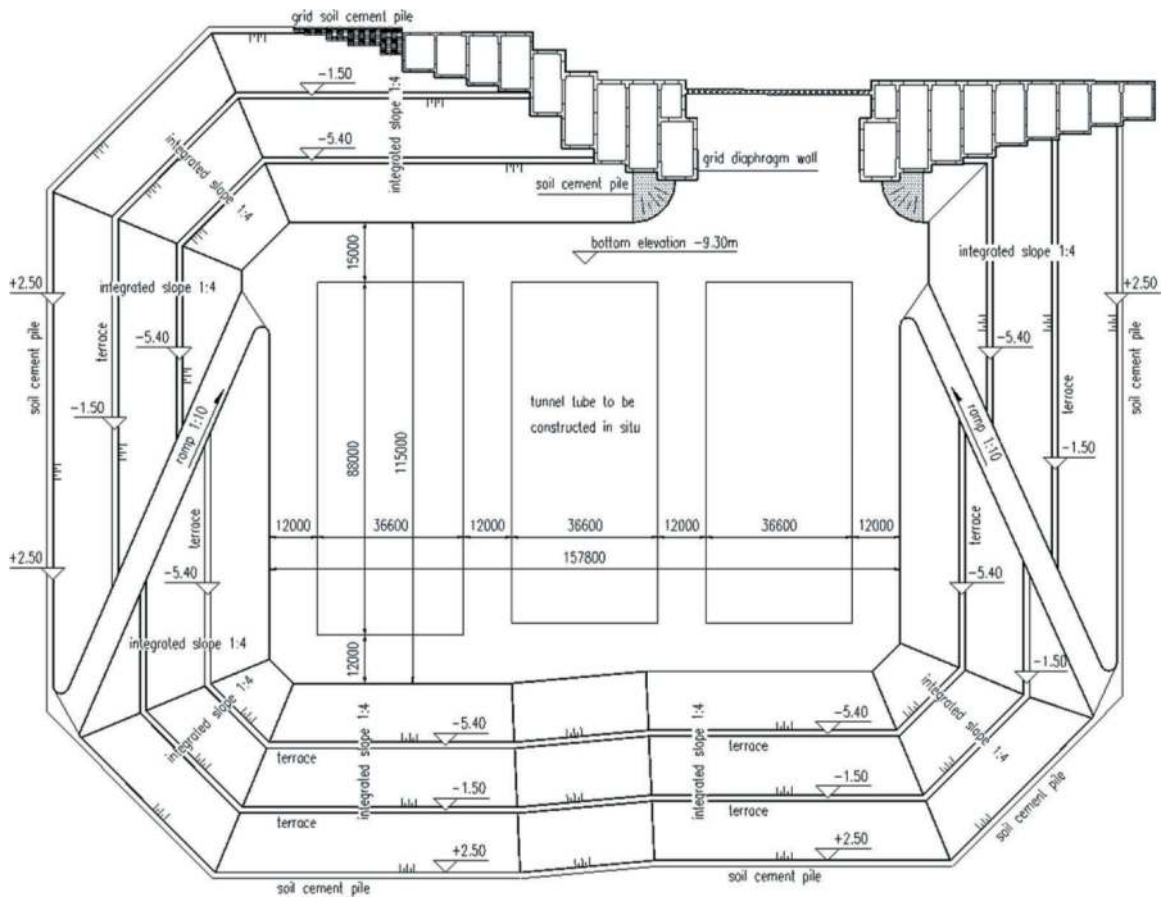

Figure 6. General layout of the dry dock.

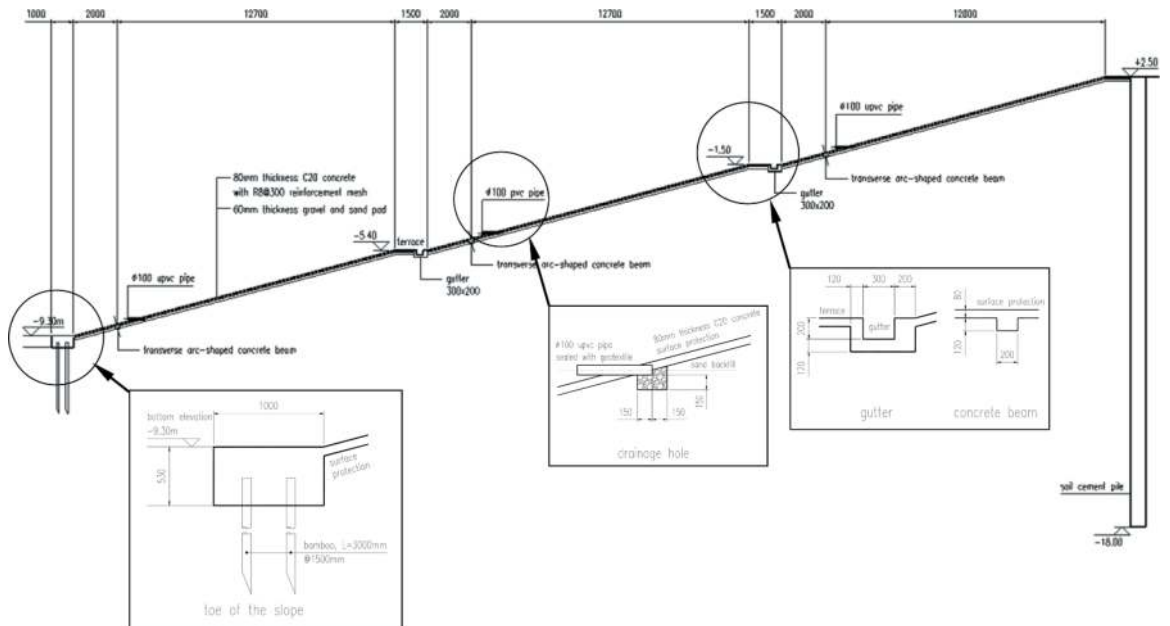

Figure 7. Profile and detail design.

on top of the slope, and the settlement of the middle of the first slope is nearly 50% of maximum settlement. With the excavation of the slope, the vertical displacement shape of the slope, from top to the bottom, turns

from settlement to upheaval gradually. Generally, the vertical displacement of the corresponding points on the slope increase with the next excavation. See Figure 8.

Figure 8. Typical vertical displacement of the slope.

During the whole period, all the points on the slope show horizontal displacements towards the excavation direction. The maximum displacement occurs on top of the slope, and the displacements of the other points are within 60% of maximum displacement. For the points on the first terrace, the displacement is generally less than the points in the two adjacent slopes. Generally, the horizontal displacements of the corresponding points on the slope increase with the next excavation. See Figure 9.

The whole displacement of the slope turns stable usually about 30 days after the completion of the final excavation.

Figure 9. Typical horizontal displacement of the slope.

4.2 Deformation relationship on top of the slope

At the beginning of excavation, the vertical displacement on top of the slope behaves with great settlement. After the completion of the first excavation and the construction of the concrete protection surface, the settlement keeps stable with performance of local upheaval. Then the settlement increases with second slope excavation, and tends to slow down again with the curing of the concrete protection surface, and so as the third excavation. After the whole slope is completed, the settlement slows down and keeps stable gradually. The maximum settlement is about 0.6% of the excavation depth. See Figure 10, symbols A ~ D represent different profile positions.

Daily vertical displacement increment shows settlement and upheaval alternately, and it can be

Figure 10. Vertical displacement - time curve.

classified into four stages, the maximum increment occurs in the first excavation. See Figure 11.

Stage1: during the first excavation (the first 10 days), daily settlement or upheaval increment varies between +1.0 mm ~ -5.8 mm.

Stage2: during the second and third excavation (the following 10 days), daily settlement or upheaval increment slows down, varies between +1.5 mm ~ -3.0 mm.

Stage3: middle period after the whole slope is completed (next 10 days), daily settlement or upheaval increment varies between +2.5 mm ~ -3.0 mm.

Stage4: at the end, increment varies between +2.0 mm ~ -2.0 mm and keeps stable.

At the beginning of excavation, the top of the slope behaves with great horizontal displacement. After the completion of the first excavation and the construction of the concrete protection surface, the displacement slows down. Then horizontal displacement increases with second slope excavation, and tends to slow down again with the curing of the concrete protection surface, and so as the third excavation. After the whole slope is completed, the displacement slows down and keeps stable gradually. The maximum horizontal displacement is about 0.72% of the excavation depth. See Figure 12.

Figure 11. Daily vertical displacement increment.

Daily horizontal displacement increment can be also classified into four stages, the maximum increment occurs in the first excavation. See Figure 13.

Figure 12. Horizontal displacement – time curve.

Figure 13. Daily horizontal displacement increment.

Stage1: during the first excavation (the first 10 days), daily displacement increment varies between +6.0 mm ~ -3.6 mm.

Stage2: during the second and third excavation (the following 10 days), daily displacement increment varies between +4.0 mm ~ -3.0 mm.

Stage3: middle period after the whole slope is completed (next 10 days), daily displacement increment varies between +4.5 mm ~ -3.0 mm.

Stage4: at the end, increment varies between +2.0 mm ~ -2.0 mm and keeps stable.

The ratio of the settlement to horizontal displacement on top of the slope for different sections is shown in Figure 14. The relationship can be found as:

At the beginning, the ratio is in disorder. After the slope is completely excavated, about 30 days after the whole slope is completed, the ratio turns stable gradually and at last reaches a certain value about 0.7 ~ 0.9.

4.3 Empirical formula for slope deformation

The deformation of the slope is mainly the results of release of the load during excavation and the consolidation of the soils. Both the release of the load and the consolidation of the soils tie up with the time, so in other words, the deformation of the slope ties up with the time, and the behaviour of the slope can be illustrate with time. The adverse points where the maximum displacement usually occurs on top of the slope. Once any empirical formula can be set up, the maximum displacement and settlement can be predicted.

Figure 14. Daily ratio of settlement to horizontal displacement.

Based on the monitoring data, the behaviours of the points on top of the slope change with the excavation of the slope in different stages. In the first 30 days during excavation of the slope, the settlement and horizontal displacement develop greatly, 79 ~ 90% of the total settlement and 46 ~ 66% of the total horizontal displacement occur in this period. In the next following 30 days, the settlement and horizontal displacement slow down gradually but still go up, mainly about 4 ~ 17% of the total settlement and 31 ~ 44% of the total horizontal displacement. And then the whole settlement and horizontal displacement keep in stable, only about 5 ~ 7% of the total settlement and 2 ~ 10% of the total horizontal displacement occur, see Figure 15 and 16.

Based on the characteristic of the settlement on top of the slope, the corresponding formula can be set up in three stages. Stage 1, the first 30days, the settlement can be expressed in polynomial function of time; Stage 2, the next 30 days, the settlement can be expressed in Ln function of time; Stage 3, the following days, the settlement can be expressed in linear function of time.

Figure 15. Settlement distribution in different period.

Empirical formula for the settlement on top of the slope can be expressed as:

Figure 16. Horizontal displacement distribution in different period.

$$V_d = \begin{cases} \alpha_1 t^4 + \alpha_2 t^3 + \alpha_3 t^2 + \alpha_4 t + \alpha_5 & 0 \leq t \leq 30 \\ \beta_1 \ln(t) + \beta_2 & 30 \leq t \leq 60 \\ \gamma_1 t + \gamma_2 & t \geq 60 \end{cases} \quad (1)$$

Where V_d is the settlement on top of the slope (mm), t is time (day); $\alpha_1 \sim \alpha_4$, β_1 , β_2 , γ_1 and γ_2 are the coefficients, which mainly depend on the process of excavation, the protection of the slope constructed in time or not and the characteristics of the soil on site.

Figure 17. Comparison of settlement obtained by empirical formula and monitor data on site.

Based on the characteristic of the horizontal displacement, the corresponding formula can be set up in three stages. Stage 1, the first 30 days, the deformation can be expressed in Ln function of time; Stage 2, the next 30 days, the deformation can be expressed in power function of time; Stage 3, the following days, the deformation can be expressed in linear function of time.

Empirical formula for the horizontal displacement on top of the slope can be expressed as:

$$H_d = \begin{cases} \omega_1 \ln(t) + \omega_2 & 0 \leq t \leq 30 \\ \psi(t)^v & 30 \leq t \leq 60 \\ \xi_1 t + \xi_2 & t \geq 60 \end{cases} \quad (2)$$

Where H_d is the horizontal displacement on top of the slope (mm), t is time (day); $\omega_1 \sim \omega_2$, ψ , v , ξ_1 and ξ_2 are the coefficients, which mainly depend on the process of excavation, the protection of the slope constructed in time or not and the characteristics of the soil on site.

Figure 18. Comparison of horizontal displacement obtained by empirical formula and monitor data on site.

5 DEFORMATION ANALYSIS BY PLAXIS

5.1 Deformation analysis by PLAXIS

In calculation, Mohr-coulomb material model, drained material type for the soil, plane strain and 15-Node elements model were used. Based on slope gradient as 4.0, four different types of slopes were considered as slope without any protections (type A), slope with surface protections (type B), slope with waterproof curtain (type C) and slope both with surface protections and the waterproof curtain (type D).

All the calculations were carried out following with the excavation steps of the slope. The results of type A and D are as shown in Figure 19 and 20.

5.2 Comparison of calculation with the data measured

All the points on the slope calculated in different conditions combined with the data monitored on site are shown in Table 3, Table 4 and depicted in Figure 21.

From the calculation results, points of view could be obtained as followed:

- The vertical deformation shape of the slope, from top to the bottom, turns from settlement to upheaval gradually and all the points on the slope show horizontal displacements towards excavation direction, which show accordance with the data monitored on site. Combined with the four deformed slope surface and the monitored slope surface, the turning point of the vertical deformation shape is the point about one third of the second slope.

Figure 19. Horizontal and vertical displacement for the slope without any protections(type A).

Top of slope	-61.6	-34.74	-33.78	-107.1	-99.72

- Comparing with the deformed slope surface without any protections and with surface protections calculated above, the two curves show almost the same shape, though the latter one shows partial prevention to the toe of the slope from upheaval. That means the surface protections have little contributions to reduce the deformation of the slope during excavation, so its function is mainly to prevent the erosion of the slope surface.
- Comparing with the deformed slope surface without waterproof curtain and with waterproof curtain, distinct difference can be found as:
For the slope without waterproof curtain, the maximum horizontal displacement occurs near the slope surface in the middle part of the second slope, while for the slope with waterproof curtain, the maximum horizontal displacement occurs inside the soil layers near the middle part of the waterproof curtain. The above two maximum horizontal displacement values are almost the same, but the whole deformed shape of the soil layers is different. The horizontal displacement on the slope surface for the slope with waterproof curtain is much lesser than the slope without waterproof curtain. That means the soil cement pile around the dry dock, can not only act effectively as waterproof curtain, but also can provide great contribution to minimize the surface horizontal displacement and enhance the stability of the slope.
For the vertical displacement, the whole deformed shape is also different for these two conditions. Through the ground water monitor outside the dry dock, the ground water keeps stable during the whole period of excavation, so the soil cement pile waterproof curtains can be proved available. Because of the dewatering inside the dry dock, for the slope with waterproof curtain, the consolidation of the upper part of the soil causes more settlement.
- The calculations results of the two slopes with waterproof curtains and the monitored data show almost the same deform shape, while the value of the former is a little bigger than the data monitored on site. The following aspects may explain the above phenomenon. First of all, due to the complex stratified soils, the distribution of the soil used in calculation may not represent the actual stratified soil on site. Secondly, the calculation results mainly depends on the physical and mechanical properties of the soil, the shear strength indexes of the soils obtained in indoor experiments usually will be different via different experiment instruments and methods, especially for these soft clay. Thirdly, in construction, the surcharge acting on top of the slope is a mobile load while in calculation it can only be simulated on top of the slope all the time, so the load in calculation may be magnified. Then the last, the process and speed of construction such as the surface protection and drainage system to be

Figure 21. Total deformation of the slope surface in different conditions.

constructed in time or not will also have influences on the deformation of the slope.

6 CONCLUSIONS

In this paper, the study mainly deals with comprehensive analysis and evaluation on the stability and deformation of the slope, based on the background of dry dock slope in Haihe Tunnels, and some preliminary conclusions can be obtained as followed.

- Based on limit equilibrium, the Swedish slice method and Simplified Bishop method were used to determine the final appropriate slope gradient as 1:4.0. And on this basis, general design and detail design of the slope were carried out. In the practice of the project, the whole design was proved successful.
- With excavation of the slope, the vertical displacement shape of the slope, from top to the bottom, turns from settlement to upheaval gradually. The maximum settlement occurs on top of

the slope, about 0.6% of the excavation depth. All the points on the slope show horizontal displacements towards excavation direction. The maximum displacement occurs on top of the slope, about 0.72% of the excavation depth. The ratio of the final settlement to the horizontal displacement on top of the slope is within 0.7 ~ 0.9.

- Based on the monitoring data, slope behavior changes with the excavation of the slope in different stages. Empirical formula as polynomial function, Ln function, linear function and power function with respect to time can be set to express the deformation of the slope.
- In practice, the detail structural design of the slope and all the protection measures used are proved available and effective. The soil cement pile around the dry dock can not only act effectively as waterproof curtain, but also can provide great contribution to control the surface deformation of the slope and enhance the whole stability of the slope.
- The successful implementation of the project provides a useful reference for any other analogous projects. All the preliminary conclusions mentioned above are just based on the study on stability and deformation of dry dock slope in Haihe Tunnel, whether these conclusions are reasonable and reliable should be tested and adapted in more practices, such as the parameters in the empirical formula and the analysis methods and the deformation relationships.

Research on online intelligent prediction of service status of immersed tunnel based on artificial intelligence

Hao Ding & Peng Cao*

National Engineering Research Center of Road Tunnel, Ltd., China

China Merchants Chongqing Communications Technology Research & Design Institute Co., Ltd., China

ABSTRACT: Due to the complexity of the construction process of immersed tube tunnels and the dynamic nature of the operating environment, the key parameters of immersed tube tunnels after service are difficult to know and measure; However, using traditional forward numerical simulation methods can only analyze the service conditions for determining parameters. Aiming at the prominent technical bottleneck of online evaluation of service status of immersed tunnels, this paper constructs a 3D refined model for immersed tunnel element joints, and establishes a large database of service status under massive working condition analysis; The BP neural network method was introduced to establish an intelligent prediction model for predicting the displacement changes of the full section waterstop and shear key of the element joints; Driven by on-site monitoring data, the reliability of the intelligent prediction model was verified, and high-precision prediction of the displacement changes of the element joint water stop and shear key was achieved. The above methods have achieved full coverage of key characterization indicators for the service status of immersed tube tunnels, providing a solution for online evaluation and early warning of service safety of immersed tube tunnels. They have important engineering significance for optimizing the operation and maintenance management methods of immersed tube tunnels and improving operation and maintenance efficiency.

Keywords: immersed tunnel, Service status, Intelligent prediction, Artificial intelligence, neural network

1 INTRODUCTION

The evaluation of service status is an important prerequisite for safe operation and maintenance of an immersed tunnel. During online evaluation and early warning of tunnel structures, the key step is to construct appropriate models by scientifically and effectively processing monitored data [1]. However, due to the complexity in the operating environment and structure of immersed tunnels as well as the lagging development of sound monitoring systems in the tunnel field, existing monitoring data is insufficient to support the safety assessment of in-service structures [2-3].

Scholars at home and abroad have performed extensive research in the field of the service status of immersed tunnels. Xu Xiangchun, et al. combined different types of data from multiple sensors and obtained the comprehensive evaluation value of immersed tunnels by the fuzzy analytic hierarchy process [4]; Shao Junjiang compared and analyzed the settlement records and actual damage data of 10 immersed tunnels and provided the allowable settlement control standards for immersed tunnels [5]; Gong Hao and Huang Minghua separately used

finite element software to conduct static and dynamic analysis for different immersed tunnels and carried out exploratory research for the sound monitoring system of immersed tunnels [6-7]. The existing data mostly provides parameter references for analysis of defect causes or construction of numerical simulation, but has not been fully utilized in structural safety assessment and early warning [8-12]. In recent years, the development of artificial neural networks in the field of geotechnical engineering opened up more research avenues for processing and analysis of monitored data, mainly focusing on predicting surrounding rock or settlement deformation of the tunnel to guide design and construction [13-18]. Some research results have also been obtained on deformation prediction during tunnel service. Meho Saša Kovačević, et al. [19] adopted the neural model with particle swarm optimization to predict the long-term deformation behavior of soft rock tunnels; Liu, et al. [20] established an intelligent decision-making neural network model for tunnel monitoring systems based on historical databases and association rules. Chen Jianzhong, et al. [21] constructed an ARIMA system to predict future

*Corresponding author: caopeng1@cmhk.com

time series of SHM data and proposed a three-level dynamic warning scheme.

Currently, researchers usually adopt numerical simulation or model testing to study the deformation characteristics and warning standards of immersed tunnels and their research results provide significant support for the design stage of immersed tunnels. However, the load, boundary conditions and geological parameters of simulation models or model tests only represent typical working conditions and cannot cover or restore the actual service status of immersed tunnels. Therefore, these research results cannot effectively support the structural safety evaluation of immersed tunnels during service. In summary, the research on deformation prediction and safety evaluation during the service period of immersed tunnels is still in its infancy.

Therefore, this paper proposes a new research solution: a three-dimensional refined model is established for element joints at key parts of the immersed tunnel to fully reflect the working characteristics of the waterstop and shear key at the element joints and obtain the mechanical response at different positions of the element joint through massive calculation of working conditions, so as to form a large database of the service status of immersed tunnels; since it is difficult to obtain the monitored data for the waterstop and shear key of element joints, a BP neural network algorithm is introduced on the basis of a large numerical simulation database to establish an intelligent prediction model for deducing the displacement changes in the full-section waterstop and shear key of element joints; then, the data monitored on the site is substituted into the intelligent prediction model of the joint components of the immersed tunnel to verify the reliability of the intelligent prediction model through the analysis of the data deduction results and finally achieve high-precision prediction of the displacement changes in the waterstop and shear key of the element joint.

2 TECHNICAL BOTTLENECKS IN STRUCTURAL SAFETY EVALUATION OF IMMERSSED TUNNEL DURING SERVICE PERIOD

Common defects of immersed tunnels during the service include deformation, water leakage, crack and joint dislocation. The quantitative description of these indicators by reasonable evaluation methods forms the basis for evaluating the service status of immersed tunnel. Moreover, accurate evaluation of the service status plays an important role in technically supporting the maintenance and management decisions for the immersed tunnel. At present, there are three main weight classification methods applied in safety evaluation of structural service status: subjective weighting method, objective weighting method and combined subjective-objective weighting method. For the subjective weighting method,

the experts assign corresponding weights to different indicators based on experience and judgment and then perform the weighted average for the indicators based on the weights to obtain overall evaluation results. This method is susceptible to subjective factors of experts, but still has certain application value in the absence of data and models. The objective weighting method mainly relies on source data but underestimates the knowledge and experience of experts, such as common neural network method, principal component analysis method, etc. The combined subjective-objective weighting method simultaneously considers the impact of subjective and objective factors on the rationality of weights and integrates two methods through relevant theories.

The precondition for reliable structural safety evaluation during the service period of an immersed tunnel is that the source data must be accurate. Currently, researchers mainly obtain evaluation source data through the following two channels:

- (1) Structural soundness monitoring data during the service period of the immersed tunnel: this data can directly reflect the service status of the immersed tunnel and the preferred solution is to use this data to evaluate the safety status of the structure. The safety evaluation object for the service status of immersed tunnels is the overall safety state of the structure. It requires multiple types, wide ranges and large quantities of monitoring data. However, the current monitoring data available during the service of the immersed tunnel far falls short of the requirements for safety evaluation.
- (2) Numerical or physical model test data: Due to the limitations of on-site monitoring data, researchers usually adopt the means of numerical simulation or physical model test to obtain structural deformation and stress data of immersed tunnels under typical working conditions. However, the service life of the immersed tunnel involves massive calculation or simulation of working conditions. Traditional numerical or model test methods cannot simulate the structural service status of immersed tunnels at the very moment because it is unable to obtain critical data, such as accurate foundation parameters, stress state of immersed tunnel upon completion and prestressed state of the segment joints. It is impossible to obtain the same numerical simulation or test model as current service status of the immersed tunnel. In addition, the external environment of the immersed tunnel is constantly changing. Even if we barely obtain a simulation or experimental model similar to the service status of the immersed tunnel at this moment, different states will occur along with the changes of external environmental factors, e.g. loads and movements from settlements, temperature variations, etc. Accordingly, it is necessary to modify the parameters for

numerical simulation calculations or model tests again. Therefore, this method can only represent the service status of the immersed tunnel under typical working conditions, but it is unfeasible and unachievable to perform structural safety evaluation during the service period of the immersed tube tunnels.

3 INTELLIGENT EVALUATION MODEL FOR SERVICE STATUS OF IMMERSSED TUNNEL

3.1 Overall idea

The overall idea of the research method proposed in this paper is as follows:

Try best to consider the boundary parameters and geological parameters, which can be obtained under actual service conditions, based on the service characteristics and evaluation requirements of the immersed tunnels, and then establish a three-dimensional refined numerical simulation model for element joints at key parts of the immersed tunnel.

Take deformation postures (compressive deformation, horizontal dislocation, vertical dislocation, vertical bending, horizontal bending and torsion) of the immersed tunnel, changes in foundation parameters, changes in overlying loads and other factors as variables, and propose a massive calculation condition under multi-factor coupling to ensure that the calculation condition is sufficient to cover the changes in the state of the immersed tunnel under external environmental effects and establish a numerical simulation database in advance.

Then, adopt a neural network model to establish a mapping relationship between actual monitoring data and simulation database, match and screen target working conditions of simulation data and actual monitoring data on the basis of actual service monitoring data of the immersed tunnel, complete the self-learning process of numerical simulation database, and input a small amount of monitoring data to output the deformation, stress and other data of key monitoring points required for structural evaluation during service in order to meet the needs of structural safety evaluation and early warning data, establish an intelligent evaluation model for immersed tunnel structure based on multi-source data and achieve online evaluation and early warning of immersed tunnel structures.

3.2 Overall idea

The specific implementation process is as follows:

(1) Building of a refined numerical model

Considering that the element joint is an important control part for the service status of the immersed tunnel, a three-dimensional refined

numerical model is established for the element joint. The important structures at the joints mainly include waterstops and shear keys.

(2) Setting of calculation conditions

The sudden sedimentation caused by typhoons, mud brought by ocean currents and siltation during flood season may lead to uneven settlement along the longitudinal and transverse directions of the immersed tube. As deformation modes may exist in general element joints of the immersed tunnel, 6 typical deformation modes (compression deformation, horizontal dislocation, vertical dislocation, vertical bending, horizontal bending and torsional deformation) are selected as deformation factors and all possible deformation zones in the joints are taken into consideration to determine the deformation level.

(3) Data extraction and output

Based on the three-dimensional refined simulation calculation results of the immersed tunnel, the deformation data of joint structures and key parts of the immersed tunnel under massive working conditions are extracted and mainly divided into the output information of the element joint structure and that of the shear key and waterstop, including deformation of joint structure and that of shear key and waterstop.

(4) Establishment of a simulation database

The results of all working conditions are summarized and sorted to form a numerical simulation database. The distribution of monitoring points in the service status database of the immersed tunnel is shown in Figures 1-4. The database mainly consists of two parts. The first part is the monitoring data that can be obtained daily for the immersed tunnel, including tensional displacement monitoring and dislocation displacement data. The second part is the data difficult to monitor/detect, including longitudinal displacement data of waterstop at the roof, side wall and floor of joint components, as well as dislocation displacement data of the side wall, middle wall and floor.

(5) Building of an artificial neural network model

To establish an artificial network model based on the established simulation database is mainly to utilize the displacement at typical positions of immersed tunnel joints (specific selection can be determined based on the actual monitoring position) to predict the displacement and stress variation of shear keys and waterstops at different monitoring points of the element joints; and to find the optimal fitting for the nonlinear relationship between these data and ultimately build an artificial neural network algorithm model.

(6) Training and verification of intelligent inference model

80% data in the established simulation database of immersed tunnel element joint is randomly selected as the training set and the remaining 20% as the test set. The training set is used to train and

Figure 1. Monitoring point of tensional displacement.

Figure 2. Monitoring point of dislocation displacement.

Figure 3. Monitoring point of waterstop displacement.

Figure 4. Monitoring point of shear key displacement.

select the optimal neural network model and then the data of the test set is entered into the neural network model to compare the difference between the deformation data output from the model and the data in the database. Meanwhile, the on-site monitoring data is entered into the neural network model to analyze the differences between the model data results and the monitored data and verify the reliability and accuracy of the established deduction model, to ensure the engineering practicality of the intelligent deduction model.

3.3 Overall idea

3.3.1 Data standardization

Due to the differences in the input training data, the deformation of each shear key and waterstop is different under each service condition and the displacement is different as well. So, in order to facilitate model training, these data should be normalized before training so as to normalize the input and output data between 0 and 1. The specific normalization method is shown in the following equation. As 0 may exist in the data, the normalization processing is adopted to output 0 as 1 at default. Finally, the predicted data is

normalized back to its original form to verify the accuracy of the predicted results.

$$X = \{x_n\} = \frac{x_n - x_{\min}}{x_{\max} - x_{\min}} \quad (1)$$

3.3.2 Adjustment of network model parameters

Parameter adjustment is the most crucial step for whole model training. The network parameters in this study mainly include training frequency (maxe-pochs), learning rate (learnrate), error final (errorfinal), hidden unit number (hidden unit number), etc. Each of these parameters may affect the training effect of the model.

3.3.3 Evaluation of network model

The BP neural network can be used to achieve regression analysis of the research data. Finally, the mean square error (MSE), root mean square error (RMSE) and coefficient of determination (R2) are selected as evaluation indicators for the model training results.

MSE, known as mean square error, refers to the expected value of the square of the difference between the estimated value of a parameter and its true value. It reflects the degree of deviation between the true value and the predicted value. So, the smaller the MSE, the better the model quality and the more accurate the prediction. Its mathematical expression is as follows:

$$MSE = \frac{1}{n} \sum_{i=1}^m \omega_i (y_i - \hat{y}_i)^2 \quad (2)$$

Where, n is the number of samples, represents the true values on the test set and is the predicted value on the test.

R², called the coefficient of determination, refers to the goodness of fit of the model. It is the degree to which the regression line fits the observed values. Its value is between 0 and 1. The closer the R² value is to 1, the better the fitting degree of the straight line to the observation value is; otherwise, the smaller the R² value is. Its mathematical expression is as follows:

$$R^2 = \frac{\sum_{i=1}^n (\hat{y}_i - \bar{y}_i)^2}{\sum_{i=1}^n (y_i - \bar{y}_i)^2} \quad (3)$$

Where, n is the number of samples, y_i is the true value on the test set and y_i is the predicted value on the test set.

4 EXAMPLE ANALYSIS

4.1 Refined modeling

With the element joint of a reinforced concrete immersed tunnel as the research object, a three-

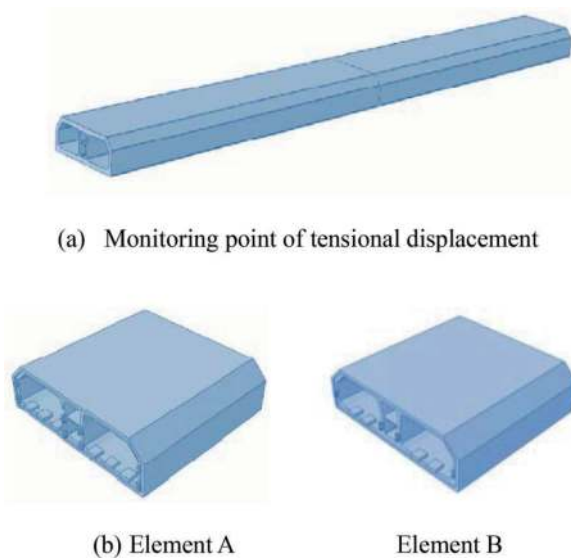

Figure 5. Schematic diagram of immersion joint.

dimensional refined model is established for the element joint structure of the immersed tunnel. The ABAQUS software is adopted to establish a FEM analysis model for two element joints of the immersed tunnel. The solid elements are used to simulate the tunnel structure, including roof, floor, side wall and middle partition wall. All cross-sectional dimensions of the numerical model are based on the middle section of actual tunnel structure. The longitudinal length of the model is consistent with the actual tunnel section. Moreover, the elements at the element joints are refined. As shown in Figure 5, Type A represents the end face of the element joint with GINA installed and Type B represents the end face of the element joint without GINA.

4.2 Calculation conditions

For different deformation modes, the gradual process from conventional small deformation to large deformation under extreme load is considered when the

calculation conditions are formulated. For example, the compression of GINA waterstop gradually increases from 100mm to 180mm and the dislocation deformation of horizontal shear keys gradually increases from 0mm to 15mm. For each element joint, in case the deformation mode, deformation range and operating environment mentioned above are taken into consideration, it is necessary to calculate about 300 simulated conditions, some of which are shown in Table 1.

4.3 Data extraction and simulation database establishment

Based on the 3D refined simulation model calculation results of the immersed tunnel, the deformation data of key positions and parts of the immersed tunnel structure is extracted under massive working conditions, including deformation of element structure and that of shear key and waterstop. a basic database is provided for the subsequent use of neural network methods for deformation prediction and cross fusion with site data.

4.4 Intelligent deduction of service status data for immersed tunnel

80% data in the intelligent simulation database of immersed tunnel joint components is randomly selected as the training set and the remaining 20% as the test set. The data of the training set is entered into the neural network model for parameter training. The fitting training results of the waterstop are shown Figure 6. It can be seen from the figure that the output prediction of the model for waterstop is relatively accurate through debugging. The average R2 is as high as 99.3% and meets the requirements for model accuracy and the error is less than 0.01mm. So, the model can effectively and accurately predict the waterstop. When the model is used to predict the output of the shear key, the average R2 is 97.02%. Compared with the Model III, the prediction accuracy of this model is further improved. For the shear key, the prediction accuracy of the displacement is greater

Table 1. Simulated calculation conditions for deformation of element joint.

Factor	Compression	Horizontal dislocation	Vertical dislocation	Vertical bending	Horizontal bending	Torsion
Unit	mm	mm	mm	rad	rad	rad
1	100	2	8	0.006	0.002	0.002
2	100	12	14	0.002	0.012	0.003
3	100	0	0	0	0	0
4	100	10	2	0.002	0.01	0.002
5	100	16	6	0	0.002	0.004
6	100	14	4	0.008	0	0
7	100	8	12	0.01	0.008	0.003
8	100	4	16	0.012	0.004	0.001
9	100	6	10	0.004	0.006	0.001
10	110	12	16	0.004	0	0.004
...

than 95% in the XY direction and the mean square error is less than 0.01mm. It can be seen from the prediction results that the intelligent deduction model for joint components of the immersed tunnel can accurately predict the output data and meet the accuracy requirements of the model.

Figure 6. Diagram for monitoring points of output information (deformation of waterstop).

4.5 Intelligent deduction of service status data for immersed tunnel

(1) Verification of test data

The above neural network model is trained based on the training set in the intelligent simulation database of immersed tunnel joints and the constructed model is validated and analyzed with the test data. The test data is entered into the model to compare its deduction results with the displacement results in the intelligent simulation of immersed tunnel joint components, as shown in Figure 7.

Figure 7. Comparison of simulated and inferred values.

It can be seen from the figure that the trend of simulation results and model deduction results is relatively consistent. The error difference between two results is small with an average error of 0.02mm. The model results are more accurate.

In order to effectively distinguish the stability and accuracy of the model, this study calculates the R2 and root mean square error of the feedforward neural

network and support vector machine based on the same training set, and the results are shown in Table 2.

Table 2. Title of the table.

Algorithm model	R ² (%)	RMSE
BP neural network	95.3	0.03
Support vector machine	89.6	0.16
Feedforward neural network	90.5	0.11

It can be seen from the table that, compared to the other two algorithm models, the R2 of the BP neural network is greater than that of the support vector machine and feedforward neural network model, and its root mean square error (RMSE) is smaller than the other two algorithms. It means that the intelligent inference model established for immersed tunnel joint components with the BP neural network has high accuracy and its error is relatively smaller than similar inference algorithms.

(2) Verification of site monitoring data

The accuracy and stability of the model are clarified through self-inspection of the model and comparison with other relevant models. In order to further apply the model to practical works, the intelligent deduction model is experimentally verified by measuring the dislocation displacement at 6 monitoring points on the site.

It can be seen that the intelligent deduction model for the joint components of the immersed tunnel has a small gap between the actual application process and the monitored data. The error results are less than 0.01mm in different directions and the error is smaller than 0.1mm in Y direction. It means that the intelligent deduction model can be used to more accurately calculate the displacement changes at various parts of the immersed tunnel.

5 CONCLUSIONS

This paper has summarized technical bottlenecks in structural safety evaluation during the service of immersed tunnels. It can be believed that the key issue in achieving reliable structural safety evaluation during the service of the immersed tunnel is to accurately obtain the source data required for evaluation. The source data must have three key characteristics: trueness, extensiveness and real-time.

- (1) In response to the technical bottleneck in structural safety evaluation during the service of immersed tunnels, this article proposes an intelligent evaluation method for the service status of immersed tunnels based on the neural network and systematically elaborates on the overall idea and specific implementation steps of this method.
- (2) Based on a certain immersed tunnel, the example analysis is performed for the intelligent evaluation method for the service status of

immersed tunnel based on the neural network, including 3D fine modeling, data extraction and output, establishment of simulation database, establishment of artificial neural network model, and verification and analysis of online monitoring data.

- (3) The displacement and stress data of the water-stop and shear key at the element joint of a certain immersed tunnel has been predicted based on the established artificial neural network model, and the accuracy of the model prediction is not less than 95%. Moreover, the reliability of the established neural network model has been verified to provide data support for safety evaluation of the immersed tunnel structure.
- (4) The artificial neural network method has laid the technical foundation for efficient and high-precision prediction of changes in element structure. Later, the fusion of actual monitoring data and numerical simulation database can be established to form a service status database of immersed tunnel structures based on multi-source data so as to achieve online evaluation and early warning of immersed tunnel structures.

Weibin Chen
CCCC Fourth Harbor Engineering Co. Ltd

ABSTRACT: Immersed road/rail tunnels (IMT) have a long history, some 120 years. During the period various evolutions have taken place, and each region had their own particular designs and methodologies, e.g. tubular steel tunnels in the U.S.A., rectangular concrete in the Netherlands (Europe) and rectangular steel shell in Japan. These developments and its contributions to the world IMT technology will be addressed in the first part of this paper. The second part addresses the great impact from China on world IMT industry with its fast developments in the new century. The paper which will focus mainly on the new innovations of immersed tunnel with relate to the design theory, construction methodologies, new material, equipment, et al. In all these developments, how sustainable ideas are in-cooperated will be highlighted such as energy saving, carbon reduction and green construction.

Keywords: Immersed tunnels, innovations, world wide, coverage, key developments, design and construction

1 INTRODUCTION

This paper discusses the key developments of world's IMT design and construction solutions. And it is divided into two parts, 1st part addresses the world IMT developments except China; and the 2nd part addresses the impact from China on world IMT industry with its fast developments in the new century.

2 IMT HISTORY IN THE WORLD

The first immersed tunnel ever, was built across the Detroit River. The tunnel consisted of 2 steel tubes, each accommodating 1 railway. The tunnel was operated in 1910, and has been the base for the design and construction of most of the USA IMT's.

It has taken many years before the first immersed tunnel in Europe was realized. The first was the Maas tunnel in Rotterdam, Netherlands.

Later, in the 1970's in the Netherlands scheduled several immersed tunnels, amongst which an immersed metro tunnel under de maas which extended onshore (still as immersed elements).

2.1 *Detroit river tunnel (Wilson S.K. 1911)*

2.1.1 *Introduction*

In the late 1800's the initiative for a tunnel between the United States and Canada was considered. The link would replace the ferries that provided the services between Detroit and Windsor. The plans were delayed several times, and only once it was clear that electrification of the railway traffic had become possible, i.e. it would replace steam locomotives.

The selection for an immersed tunnel was made due to the significant difficulties for the generally used compressed air and shields.

A relevant feature of this new method of immersed tunnel construction is the small labor cost, as compared with the compressed air and shield method. On the other hand, the aggregate cost of the materials will generally be larger, but not enough to overbalance the labor cost; the result is a stronger and more durable construction, certainly a desirable quality in a subaqueous tunnel.

At Detroit this method effected a saving of about \$2 000 000 over a shield-driven tunnel with compressed air, and this should be added the capitalized

*Corresponding author: a.doorduyn@TEC-tunnel.com

saving in annual cost of operation on account of the tunnel being placed some 15 ft. higher.

2.1.2 Tunnel design

The selection for a steel immersed tunnel was made, with 2 tubes, 1 tube for a rail line. The steel tubes were stiffened with diaphragms. The connection of the steel plates and the diaphragms were made using the techniques common at the shipping production.

The plates for the tubes were riveted together with lap-joints and attached to the steel diaphragm by an angle-iron, running entirely around the tube, riveted to the diaphragm and to the tube plate, the diaphragms being spaced so as to come at the center of the plate between the lap-joints.

Figure 1. Tube during erection at shipyard.

When an entire section of tubes was erected and securely bolted, and before riveting was started, the tubes were checked for alignment and grade, and any necessary change was made by moving the diaphragms.

Figure 2. Completed tube at shipyard.

2.1.3 Sinking of the tubes

In advance of the sinking of a section of tubes, and before placing the grillage for the temporary end support, it was necessary to determine the condition of the

trench as to depth and width, this was done by divers. The actual excavation was done by the derrick scow.

At intervals, marking the joints between the different sections of tubes, a steel grillage of I-beams was placed at the required level, under which concrete was deposited until the beams were engaged. These grillages formed temporary supports until the

Figure 3. Grillage (left) & the tremie installing the concrete below the steel grillage (right).

foundation concrete could be deposited. A plan of the grillage is shown by Figure 3.

For sinking, the ends of the tubes were fitted with water-tight bulkheads. Each of these bulkheads was equipped with a 14-in. gate-valve, which could be opened from the outside. The sections were sunk by opening valves and permitting the tubes to fill with water. The time required for submerging a section of tubes was approximately 2 hours.

Four air cylinders, or buoys, were used for floating and ballasting the tubes to correct position, two being placed over each tube and connected to the diaphragms.

After a section of the tubes was in proper position in the bottom of the trench and sufficiently anchored by concrete, the air cylinders were detached by a diver, brought to the surface, and held in readiness for use on the next section. One set of cylinders was used for all the sections.

Figure 4. Tunnel element prepared for immersion.

Figure 5. Immersion in progress.

Figure 8. Model of the maas tunnel element with the towers at both ends, the sand jet system and buoyancy cylinders.

Figure 6. Method of placing concrete by Tremie to ballast the tunnel element in the permanent situation.

2.2 Maas tunnel (H. Dekking, 1937-1941, Erwin Schnitter, 1941, H. van Tongeren, 1978)

For the Maastunnel it was decided to make a monolithic reinforced concrete tunnel with an external waterproofing steel shell accommodating 2 x 2 road traffic lanes and specific bicycle traffic and pedestrian tubes, as shown below.

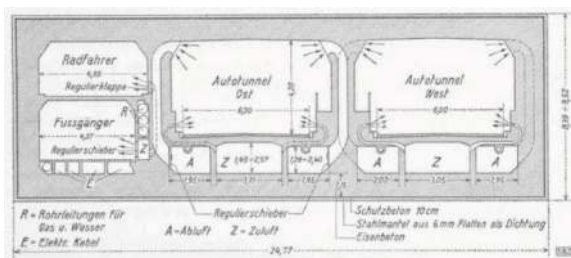

Figure 7. Cross section of maastunnel.

The Maas tunnel is the first rectangular tunnel. This was possible due to the development of a system that could fill the space between the trench bottom and the tunnel element with sand, e.g. by using a Sand-jetting system.

Figure 9. The sand-jet concept by Christiani & Nielsen.

The maas tunnel elements were placed on a pre-installed concrete support beam. The beams were provided with supports on both sides with horizontal jacks to fine tune the alignment of the tunnel element. In addition, also vertical jacks were installed in the tunnel element walls to fine tune the vertical position of the tunnel element.

Figure 10. Element on beam (left) and support beam (right).

This picture shows the floating tunnel element with the end-frame (left) needed for the positioning of the element as well as for the completion of the immersion joint. In addition, the sand-jet frame is shown with the travel frame.

Figure 11. Tunnel element with tower & sand jet system.

For the connection of the immersion joints half Larssen XI planks were arranged at the ends of the tunnel sections and firmly anchored in the concrete of the side walls. Next the space of the roof slab is provided with a diving bell that covers the whole length. See below Figure.

Figure 12. Immersion joint completion with diving bell.

2.3 Deas island (Carson Kerr, 1959)

In 1959, the first use of a rubber profile to realize watertightness at the immersion joint was done at the George Massey tunnel in Vancouver, Canada.

Figure 13. Combination of gasket with inflatable tube.

A special inflatable rubber seal was developed to speed up joining of the elements and finish from the inside.

Figure 14. Immersion joint inflatable rubber seal.

2.4 Rotterdam metro tunnel (G. Plantema, 1968, H. van Tongeren, 1978)

The Rotterdam metro tunnel is partly located inshore (for a significant length) and a limited length across the river. For the inshore part, the tunnel elements are placed on specially designed adjustable piles and adjusting beams. The immersion joints between the tunnel elements adopted a new design, using so-called Gina and Omega gaskets for the watertightness. Gina appeared common since then.

Figure 15. Details immersion joint with the gaskets.

2.5 Later developments

2.5.1 Øresund tunnel (R. Spreng, et. al, 2000)

Figure 16. The first industrial tunnel element production facility with 2 production lines.

2.5.2 Sandwich structure elements (Akifumi Kojima, et al, 1995) (R. Ojima et al, 1996)

The sandwich structures (mostly in Japan) can be open sandwich with steel plates at the out-side with stiffeners and studs for a proper connection to the concrete. Furthermore, at the inner-side conventional reinforcement is used.

Figure 17. Example of sandwich immersed tunnel options.

Figure 18. Example of open sandwich (left) full sandwich (right).

The second option is the full sandwich where the in- and out-side of the walls are of steel plates. Between the plates, diaphragms are installed in longitudinal and in transverse direction, thus realising boxes of typical 10m³, that are filled with highly fluid concrete.

Figure 19. Casting of full sandwich immersed tunnel element in floating position.

2.5.3 Japanese closure elements (Kazunari Umeyama & Haruo Shibuyama, 1995) (M. Shimoishi, et. Al, 2001)

The V-block method was newly developed for the closure joint. The method was developed to achieve safe, rapid and economic construction.

Figure 20. V-Block (left) and closure element (right).

2.5.4 Japanese joint - bellow (Kazunari Umeyama & Haruo Shibuyama, 1995) (Hideo Kimure, et. Al., 2003)

Immersed tunnels in Japan are subject to significant earthquakes. One of the solutions are the bellows joints that are made from steel and has a high allowable deformation. The reference paper shows the development of bellows joint adopted as the flexible joint for the immersed tunnel elements in lieu of conventional seismic joints.

Figure 21. Bellow joint.

2.5.5 Japanese joint – crown seal (Shuji Eguchi. Et. al, 2005)

Another innovated joint with large deformation capacity to withstand earthquakes and uneven settlement of tunnel elements that may occur in the future between the land section and the seabed section or earthquakes, may causing displacement at the submerged box joint. As a result of various studies were conducted of a new type of joint that can follow such displacements, a new crown seal type joint was developed is the Crown Seal.

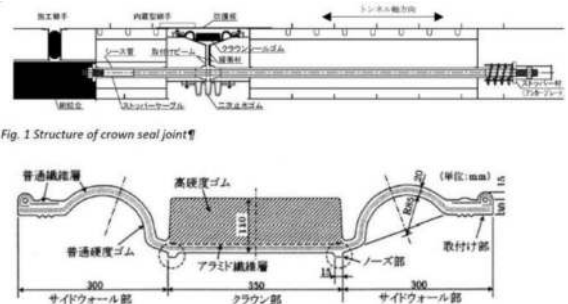

Figure 22. Crown seal & restraining bars.

3 NEW DEVELOPMENTS IN CHINA

The first immersed tunnel in China originates from 1972 in HK and 1993 in mainland. In this century, China has demonstrated strong development momentum which contribute to the world IMT industry. Till now, more than 22 IMTs have been realized and about 10 are under construction. Due to page limits, only typical examples are selected with key developments from the aspects of design, construction, material, equipment, et al. In all these new developments, how sustainable ideas are incorporated will be highlighted.

Undoubtedly, the immersed tunnel of the Hong Kong Zhuhai Macao Bridge (HZMB) is the most important milestone project in the history of China's IMT development. Its successful implementation has transformed China from a small IMT country to one of the world's leading countries and has also driven the great development of China's IMTs and the continuous emergence of innovative technologies in recent 5-10 years.

3.1 Innovation in design and construction

3.1.1 "Semi-rigid" concept in longitudinal behavior
HZMB project brought new "semi-rigid" theory with respect to the longitudinal behavior of reinforced concrete immersed tunnels, in which generally two basic structural forms are distinguished, e.g., the rigid tunnel (one element behaves as one rigid body) and the flexible tunnel (one element subdivided in various segments that allow flexible behaviour in segment joints).

HZMB immersed tunnel took segmented element. However, it changed the temporary use of the longitudinal post tensioning cables for transport and immersion phase into permanent for operational phase, still allowing opening of the segment joint in case the bending moment capacity provided by the pre-stressing is exceeded. special design of local debonding of the post tension cables at the segment joints was applied to provide the segment joint with a certain rotation capacity.

Figure 23. Principle of de-bonding of post tension cables (Hans de Wit, et al., 2018).

The semi rigid method combines the advantages of the flexible (segmental) and rigid (monolithic) tunnel concept. Especially in offshore tunnel projects that

involve challenging transport and immersion conditions and resulting in a significant amount of post tensioning, the semi rigid concept is very interesting. But leaving the post tensioning in place will make the tunnel more cost effective (all cutting work can be omitted) and movements in tunnel segment joints will be reduced significantly, or avoided, which is beneficial to the water tightness performance of the tunnel.

The Piet Hein tunnel in the Netherlands was the first segmental tunnel in which the post tensioning was kept in place, using some basic ideas of the semi rigid concept. The Chinese engineers really brought this idea to the next level and turned it into a real innovation in which the segment joint detailed design allows some rotation when the bending moment capacity of the post tensioning is exceeded and that will cap the forces in the joint. At the same time the segment joint detailed design is using the normal force (of which post tensioning is a significant part) to increase the shear capacity of the segment joint (Hans de Wit, et al., 2018)

3.1.2 Closure joint

An exceptional innovation of HZMB project was the successful installation of the world's first steel "sandwich" closure joint, using the world's largest single arm floating crane with a lifting capacity of 12,000 ton. The length of the bottom structure was 9.5 m and that of the roof was 12 m with total weight of about 6000tons.

Figure 24. Closure joint installation of HZMB (Su Quanke, et al., 2022).

Following the HZMB project, two other large sea crossings in China, the Dalian Bay Crossing and the Shenzhen-Zhongshan Link, have adopted similar concept of convenient offshore installation with high accuracy, further optimizing the design and construction of its closure joint.

Dalian Bay subsea tunnel has 18 elements of 180m each. The closure joint with segment-jacking method mainly consists of an external sleeve, jacking segment, water stop structure, jacking device, locking structure, and post pouring strip structure. It connects the 18th element with C&C section.

The closure joint of Shen-Zhong Link immersed tunnel adopts the overall prefabrication and underwater pushing out construction method consisting of an expansion section,

a push-out section, and a post welding section. The push-out section is hidden within the expansion section, and by the hydraulic and jack push-out system, it is pushed out and connected with the previous immersed tunnel element. The post welding section is welded inside the tunnel; A deviation correction jack system is used to control the position of the push-out section.

Figure 25. Closure joint by segment jacking of Dalian Bay crossing (Ren Dongsheng, 2022).

Figure 26. Closure joint of Shen-Zhong Link (DENG Bin, et al, 2023).

3.1.3 Steel sandwich structure

Shen-Zhong Link is another world-class project composed of “bridge, island, tunnel and underground interchange” after the HZMB Project in China. In order to deal with the structural stress and reduce the engineering risk regarding the complex construction condition, max 24.0m span of one traffic tube and extra thicker soil cover (partly larger than 10m) on top of the tunnel, the steel-concrete sandwich structure is applied. This is the world’s first bi-directional 8-lane immersed tunnel built with steel-concrete sandwich structure. Mechanism of this structure, technologies for intelligent manufacturing of Steel Shell, mixture and intelligent pouring of high strength self-compacting concrete had been detailed studied and realized successfully.

3.1.4 Full sectional casting for monolithic element

Very sound concrete quality had been realized by fully sectional casting method in the three segmented immersed tunnel projects: HZMB, Oresund Link and

Figure 27. First steel sandwich element casting construction (Picture by Ying Li in 2019).

Busan-Gorge Link. It avoided cold joints by traditional staged casting method. In order to increase the overall performance of the structure, control the development of structural cracks, and enhance the waterproof performance of the structure, Chinese engineers further had developed this technology for monolithic immersed tunnels.

Xiangyang- Hanjiang Tunnel in Hubei province has 120.5 m and 86.5 m long elements which are divided into 5 and 4 segments along the longitudinal direction, respectively. All segments adopt a sequential full sectional casting process one by one without a post pouring belt between segments. The control of concrete cracks was studied through numerical and physical model tests.

Figure 28. Full-section casting and prefabrication with integral hydraulic formwork of Xiangyang- Hanjiang Tunnel (WANG Yong, et al.2022).

In Chebei-XinJiao East Road immersed tunnel Guangzhou, one element is divided into 6 segments with the length range from 14.5 to 16m, with 1.6m post-pouring band which is different from Xiangyang- Hanjiang Tunnel. But one segment uses full sectional casting as well. the formwork is designed with an external truss structure and a no-tie-rod system to ensure the precast quality of the segments. It is similar to HZMB project. This technology has been promoted and applied in subsequent projects such as the Ruyifang Tunnel.

Figure 29. Full-section casted elements with post-pouring band in between (source: CCCC4th Harbor Engineering Co. Ltd).

Figure 30. Full-section casting formwork of Chebei-Xinjiao West Road tunnel (source: CCCC4th Harbor Engineering Co. Ltd).

3.2 New equipment

A lot of new equipment had been developed in IMT industry in China, here only two examples are picked up.

3.2.1 Intelligent trolley system

Factory production of IMT elements is becoming attractive for long tunnels after Oresund Link and HZMB projects. Intelligent trolley system was developed in China to move the heavy elements more efficiently and safely with self-adapting jacking for fast transporting in the factory. For example below Figure shows a system made of 200 trolleys for Shen-zhong Link project. Each trolley can bear 800tons. It can intelligently control and manage of synchronous forward, lifting, and automatic deviation correction for 200 trolleys.

Figure 31. Intelligent trolley system for Shen-zhong Link project.

3.2.2 Integrated equipment for transport and installation

In response to adverse meteorological conditions such as busy and complex waterways, deep water, and complex wind, wave, and currents in the route of floating transportation of tunnel element, in order to improve the accuracy and efficiency of construction, Shenzhen-Zhongshan Link has developed the first specialized operation vessel that integrates the functions of floating transportation, positioning, sinking, and installation of immersed elements. The ship has a length of 190.4m, a width of 75.0m, and a molded depth of 14.7 meters. When carrying element, the speed can reach 5 knots. The hull is equipped with a side thrust engine, which has DP power positioning, tracking, and deviation correction functions.

Figure 32. Transport & installation integrated vessel for Shenzhen-Zhongshan Link (Chen Hong, at el. 2022).

3.3 Improvements on materials

3.3.1 Machine-made sand

Based on the Dalian Bay subsea tunnel project in cold area, concrete made from machine-made sand is firstly used in large immersed tunnel pre-fabrication. After numerous mixture tests, a concrete mixture suitable for cold areas had been found, which can meet the design requirements of immersed concrete in terms of working performance, strength, hydration heat, shrinkage, early crack resistance, and durability. This application provided a good reference for future projects where shortage of nature sand is a problem.

3.3.2 Self-compacting concrete

The steel shell sandwich structure is a global challenge in achieving concrete filling density in closed compartments. The self-compacting concrete for the closure joint of the immersed tunnel of HZMB is a successful start. The Shen-zhong link project adopts a super large-scale steel shell sandwich structure and has undergone hundreds of separate compartments model pouring tests. Based on research on the mixture, long-term performance, quality control,

and construction quality inspection, a self-compacting concrete with high robustness, good flowability, filling performance, and anti-segregation performance has been developed. Reasonable processes and structures have been proposed for self-compacting concrete pouring.

3.4 Sustainability considerations

Sustainability has been paid more and more attention in the new century in China, the same in the world. For every new development or innovation, sustainability is always one of the important factors to check.

The development trend of IMTs in China since the new century: simplified construction, intelligence, industrialization, more durable and environment friendly, energy-saving and low-carbon. Taking the HZMB and the Shenzhen-Zhongshan Link as examples, the design has begun to pay attention to the full life cycle consideration, and increasingly focuses on the maintenance free, easy to maintain, or easy to replace issues of the structure during the operational stage. The factory prefabrication has improved the quality and durability of the structure, greatly reducing the cost of future maintenance.

The trench excavation is often considered the most environmentally affected process, and both projects use specialized equipment such as dredgers and siltation cleaning vessels to maximize accuracy and reduce environmental disturbance caused by underwater construction. All types of offshore construction strictly control environmental pollution and its impact on aquatic animals and plants. Especially for the protection of local white dolphins. Minimize offshore construction time and processes as much as possible, and reduce the pollution of the marine environment caused by repeated shuttling of ships. For example, both projects have adopted innovative and fast steel cylinder technology for artificial island formation.

Shared utilization of resources is another characteristic. The prefabrication yard for immersed tubes is a very high part of the cost. The re-use of dry docks or prefabrication yards has become a trend, such as the re-use of prefabrication factory of the HZMB for the tunnel of Shenzhen-Zhongshan Link, and the re-use of dry dock and formworks from the Chebei-XinJiao East Road Tunnel for the Huizhan West Tunnel in Guangzhou, etc.

4 CONCLUSIONS

It is fascinating how immersed tunnel construction has developed of the past century. It is our good fortune that the construction methods of the first immersion tunnels have been documented and still accessible to us. Archives are accessible and provide the design documents and patents of several IMT's.

Where patents provide technical information, they also provide restrictions and may restrict progress

when new designs need to be developed. An example of an important design that was not restricted due to a patent was the GINA gasket as developed in Rotterdam, the Netherlands and has freely been used all over the world.

Ultimately, however, always new designs are developed. Next to longer, wider, and at deeper location, immersed tunnels are developed in new countries and at more remote locations that are outside the main (economic) parts of countries, and IMT technologies are constantly innovating towards a more efficient, high quality, and cost-effective direction.

Structural optimization design of seamless expansion joint based on finite element analysis

Wei Jiang, Shuangjiao Zhang, Yinghui Wang, Rui Bao & Jinhuan Shan
School of Highway, Chang'an University, Xi'an, China

ABSTRACT: The expansion joint structure is usually installed at discontinuous positions in bridge and immersed tube tunnel projects, serving as a transitional structure while also having the ability to accommodate deformation. To address issues such as stress-induced damage and bonding interface cracking that occurred during the use of expansion joints in immersed tube tunnel, this study conducted a detailed finite element numerical simulation analysis of seamless expansion joints. Firstly, the sources of stress in the seamless expansion joints of the immersed tube tunnel were analyzed clearly. The structural model of the seamless expansion joints was built. Secondly, combined with material variations at different structural locations, stress concentration in the seamless expansion joints under two extreme conditions was analyzed. Finally, the structure of the seamless expansion joint was changed. The impacts of design factors such as chamfer, angle steel component, and layered bonding interfaces on structural stress were analyzed, thus determining an optimized structural design scheme for seamless expansion joints. The results indicated that stress concentration occurred particularly at interfaces A and C of the seamless expansion joint structure. The increase of chamfer structure in the design effectively alleviated stress concentration, reducing maximum principal stress by 52%. Simulation results suggested that the optimal position for the angle steel component was 40 mm from the base point, with an optimal height of 40 mm. For the bonding interface, the layered design was proposed, with a recommended thickness of 50 mm for the lower layer. All three structural optimization designs effectively mitigated stress concentration, improving the crushing failure of the ballast concrete corners and the bonding failure between the expansion joint filling materials and road pavement materials. The relevant research results can provide a reference basis for the design of seamless expansion joint structures.

1 INTRODUCTION

Bridges and the pipe joints of immersed tube tunnels experience multidirectional repetitive deformations (Chen et al., 2022). To accommodate these deformations, expansion joints are installed at discontinuous locations within bridges and immersed tube tunnels (Marques et al., 2006). As an integral component of bridge and tunnel engineering, the quality of expansion joints directly impacts the quality and safety of these projects (Lu et al., 2021a; Qian et al., 2000). If the selection of filling materials or the structural design is not reasonable, expansion joints will be prone to defects (Wang et al., 2020; Lee et al., 2019). Seamless expansion joints are a type of expansion joint that use viscoelastic materials as sealing materials, relying on the deformable properties of the filling materials to accommodate deformations in different directions of the expansion joint structure (Xiao, 2016a). Asphalt-

based seamless expansion joint materials are typically special asphalt mixtures with excellent deformability. Seamless expansion joints offer advantages such as smoothness, comfort, and noise reduction (Xie et al., 2013). Consequently, they are widely used in small and medium-sized bridges with expansion requirements less than 60mm (Bramel et al., 2000).

However, it has been observed during usage that seamless expansion joints can experience defects like high-temperature rutting, low-temperature cracking, and bond interface delamination (Ren et al., 2021; Li et al., 2021). Asphalt-based sealing materials exhibit significant temperature dependence, becoming soft at high temperatures in summer, making them prone to rutting and extrusion under loads. In contrast, they become stiff and brittle in cold temperatures in winter, leading to reduced deformability and susceptibility to low-temperature cracking and debonding (Mo et al., 2013). Cracks in

seamless expansion joints can progress to material delamination, negatively impacting road smoothness and driving comfort (Marques et al., 2009). Among these, high-temperature rutting and bond interface delamination are relatively common occurrences (Mogawer et al., 2004). In addition to the performance of sealing materials (Liu et al., 2016), the structural design of seamless expansion joints also has a significant impact on the incidence of defects (Partl et al., 2011; Park et al., 2010). Structural optimization and research on sealing material properties are crucial steps in improving the quality and widespread application of seamless expansion joints.

In previous research, scholars mainly focused on filling materials for seamless expansion joints (Jiang et al., 2023), especially the performance of the binders (Lu et al., 2021b). Min prepared rubber modified asphalt seamless expansion joint what binder using different proportions of recycled rubber powder. The study found that when used the content of recycled rubber powder was 30%, the prepared seamless expansion joint mixture exhibited excellent mechanical properties, with higher high-temperature performance compared to BJ200 mixtures, while their low-temperature performance was similar (Min et al., 2022). Teltayev's research found that using polymer-modified asphalt and measures like adding polyphosphoric acid could effectively improve the low-temperature crack resistance of seamless expansion joint materials (Teltayev et al., 2019). Polyurethane materials have gradually been introduced as an alternative to traditional asphalt-based sealing materials in seamless expansion joints (Meng et al., 2017). Polyurethane flexible expansion joints are considered an optimal solution for small displacement expansion joints in bridge engineering (Kovach et al., 2022), likely due to the robust strength and elasticity of polyurethane materials (Shen et al., 2022). Gallai and colleagues developed a novel polyurethane material. The filling materials that made from this material exhibited superior lifespan and deformability (Gallai, 2016, 2014; Gallai et al., 2018). Therefore, measures such as optimizing material properties (Cao et al., 2023), optimizing mixture composition (Lu et al., 2022), and developing new materials (Funabashi et al., 2021) can enhance the performance of seamless expansion joints, effectively addressing issues of high-temperature rutting and low-temperature cracking (Mo et al., 2012).

The structure of seamless expansion joints in immersed tube tunnels undergoes longitudinal deformation and nonuniform settlement due to some factors such as temperature and vehicle loads. Tensile forces generated by pavement material shrinkage, horizontal forces from vehicle acceleration and deceleration, and vertical pressures from vehicles can lead to stress concentration in certain parts of the seamless expansion joint (Lu et al., 2023). Therefore, research and optimization of seamless expansion joint structures are necessary (Park et al., 2011; Reid et al., 1998). Jiang et al. conducted finite element simulations of longitudinal displacement induced by

temperature. The author found that increasing the width of seamless expansion joints could effectively reduce stress at the bonding interface (Jiang et al., 2020). The bonding interface between the expansion joint filling material and the road pavement material is one of the weak points in the structure (Xiao, 2016b), Xiao studied the main factors influencing interface tensile stress, shear stress, and vertical displacement of the APJ interface. The author found that measures such as changing the properties of the expansion joint filling material, the roughness of the interface, and pavement layer thickness effectively mitigate interface damage behaviors (Xiao, 2016c). Lu et al. used finite element simulation to study the influence of cross over joint steel plates with rectangular and arc-shaped sections on the internal stress of seamless expansion joints, concluding that optimizing the cross-seam steel plate's section shape effectively improves the mechanical performance of seamless expansion joints (Lu et al., 2023). Moor found that adding steel support components to seamless expansion joints can extend their service life (Moor et al., 2016). It indicates that altering the structure of seamless expansion joints can address some of the issues encountered during their use (Ghafoori et al., 2015).

While the above research has investigated the structure and stress of seamless expansion joints, the focus has primarily been on those used in bridge engineering. Currently, there is a limited amount of research on seamless expansion joint structures in immersed tube tunnel engineering. Therefore, leveraging immersed tube tunnel engineering of the Shenzhen-Zhongshan Bridge and employing finite element simulation analysis, this paper, from the perspective of internal stress, combines the condition of seamless expansion joint defects to conduct structural optimization. First, utilizing the Abaqus finite element analysis program, a finite element structural model for the seamless expansion joint in the immersed tube tunnel is constructed. Subsequently, according to the finite element simulation calculations of the original structure, the stress responses within the seamless expansion joint structure are analyzed. Stress concentration phenomena are studied, and the most critical load positions are identified under different limit states. Finally, based on the observed stress concentration within the structure, some structural optimized designs for the seamless expansion joints are proposed, and the optimization rates are determined through finite element simulation calculations.

2 ESTABLISHMENT OF SEAMLESS EXPANSION JOINT STRUCTURAL MODEL

2.1 *Stress sources of seamless expansion joint*

During the operation of immersed tube tunnels, multiple sources of stress act on seamless expansion joints, primarily caused by traffic loads, segment

nonuniform settlement, and temperature variations. The combined stress from multiple sources leads to multidirectional deformation in seamless expansion joints, especially in stress concentration areas, where rapid deformation occurs. It will result in defects such as cracking or bonding interface delamination in seamless expansion joints.

Traffic loads result in compressive, tensile, and shear stresses at seamless expansion joint structures. When the vehicle wheel is positioned above the seamless expansion joint, the load is transmitted downward from the surface of the joint, causing compression deformation in the seamless expansion joint. At this point, the uppermost part of the seamless expansion joint material experiences maximum compressive stress, the lowest part experiences maximum tensile stress, and shear stress develops between the seamless expansion joint filling materials and the road pavement materials. When the vehicle wheel is positioned on the road surface either behind or in front of the seamless expansion joint, minor downward deformation occurs in the road surface, potentially leading to high shear stress between the seamless expansion joint and the road pavement material, as shown in Figure 1.

Figure 1. Schematic of stress changes caused by traffic loads.

Influenced by the uneven settling of the foundation cushion and the siltation above the immersed tunnel segments, nonuniform settlement may occur between segments in the immersed tube tunnel. It results in height differences on both sides of the seamless expansion joint. This leads to vertical shear stresses within the seamless expansion joint, as illustrated in Figure 2.

Figure 2. Schematic of stress changes caused by nonuniform settlement.

With temperature variations, the lower ballast concrete and upper road pavement materials undergo longitudinal shrinkage or expansion deformations, causing changes in the spacing between segments. Seamless expansion joints will be stretched or compressed, resulting in longitudinal tensile or compressive stresses within the structure, as shown in Figure 3. The greater the temperature gradient, the more significant the deformation, and consequently, the greater the longitudinal stress within the seamless expansion joint.

Figure 3. Schematic of stress changes caused by temperature variations.

2.2 Original structure of seamless expansion joint

The original structure of seamless expansion joints is depicted in Figure 4(a), primarily comprising ballast concrete, road pavement materials, seamless expansion joint materials, and cross-joint plates. Considering the influence of contact area and boundary conditions, the longitudinal length of the finite element model is set at

(a) Original structure of seamless expansion joint

(b) Abaqus model of seamless expansion joint

Figure 4. The structure of seamless expansion joint.

2500mm, with a height of 910mm (Bao, 2021). The finite element model of seamless expansion joints was established by the software ABAQUS 2021, using a four-node bilinear plane stress quadrilateral element (CPS4R). Figure 4(b) shows the finite element model of seamless expansion joints.

Due to variations in material properties and construction times at different sections, the interface between the expansion joint filling material and other components is considered a structural weak point. Park et al. noted that cracks in seamless expansion joints typically occur first at the contact points with the cross over joint steel plates and bridge pavement layers. Based on the current usage of seamless expansion joints, detachment and cracking at the interface are common issues (Park et al., 2011). These detachment and cracking issues often result from excessive local stresses. Therefore, the surfaces, sides, and bottoms of the expansion joint filling material were selected for study. Figure 5 illustrates the schematic of the internal interfaces within the seamless expansion joint structure. Among these, interface A refers to the interface between the cross over a joint steel plate and ballast concrete, interface B refers to the interface between the bottom of the expansion joint filling material and the ballast concrete, interface C pertains to the interface between the expansion joint filling material and the tunnel road pavement material, and interface D represents the upper surface of the expansion joint filling material in contact with the load, with appropriate contact points selected as needed.

Figure 5. Interface schematic of seamless expansion joint.

2.3 Parameters of structural model

Based on the material composition of seamless expansion joints in the reference Shenzhen-Zhongshan Tunnel, this study utilized C30 cement concrete for the ballast concrete, SMA-13 asphalt

mixture for the road pavement material, Q235A steel plate for the cross over joint plate, and elastic concrete for the seamless expansion joint filling material. Table 1 presents the parameters of the materials used in various parts of the seamless expansion joint.

The bonding state between seamless expansion joint filling materials and cross over joint steel plates and ballast concrete is not in a fully bonded state. The coefficient of interlayer friction was selected as 0.35. The model was loaded using the standard axle load BZZ-100, with a contact pressure of 0.7 MPa between the tire and the road surface. The applied load was simplified as a rectangular load with dimensions of 192 mm in length and 184mm in width.

Based on the study of the positions of the most unfavorable load for the seamless expansion joint structure, this paper set the load in four different locations. (Load-1) The load was located in the middle of the expansion joint structure; (Load-2) The load's centerline was directly above the left edge of the cross-joint plate; (Load-3) The load was positioned to the left of the expansion joint material, with the left edge of the load coinciding with the left edge of the expansion joint material; (Load-4) The load's centerline was positioned above the bonding interface between the expansion joint material and the road pavement material. Figure 6 shows the schematic diagram of load locations.

Figure 6. Schematic of load locations.

3 MECHANICAL ANALYSIS OF SEAMLESS EXPANSION JOINT STRUCTURES

3.1 Stress in nonuniform settlement condition

The siltation above the immersed tunnel and nonuniform settlement between pipe sections can result in vertical relative displacement in seamless expansion

Table 1. Material parameters of the seamless expansion joint structural model.

Components	Materials	Elastic Modulus/ (MPa)	Poisson's Ratio	Thickness/ (mm)	Density/ (kg/m ³)
Road Pavement Material	Asphalt Mixture	1400	0.30	110	2600
Ballast Concrete	Cement Concrete	30000	0.25	800	2100
Cross Over Joint Plate	Galvanized Steel Sheet	206000	0.28	4	7850
Expansion Joint Filling Material	Elastic Concrete	800	0.40	110	2200
Anchor Bolt	Angle Steel	206000	0.28	4	7850

joints. According to the design data of the Shenzhen-Zhongshan Tunnel, a maximum relative displacement of up to 10 mm vertically between pipe sections has occurred. One side of the seamless expansion joint structure was fixed, while the other side experiences a 10 mm settlement. The structural maximum principal stress, structural maximum shear stress, and maximum principal stress and shear stress at interface A of the seamless expansion joint structure have been calculated when subjected to different load positions.

Figure 7. Stress changes in seamless expansion joint structure under different load application positions in nonuniform settlement condition.

Figure 7 presents the stress in seamless expansion joint structure under different load application positions in nonuniform settlement conditions. Under conditions of maximum nonuniform settlement, the maximum principal stress and maximum shear stress in the seamless expansion joint structure and interface A varied with different load positions. When the load was applied at Load-2 and Load-3 positions, the maximum principal stress in the seamless expansion joint structure was the highest, followed by the Load-4 position. When the load was applied at the Load-1 position, the maximum principal stress in the seamless expansion joint structure was the lowest, but the maximum shear stress was the highest. The maximum

shear stress and maximum principal stress at interface A were ranked from highest to lowest as Load-1, Load-2, Load-3, and Load-4, indicating that Load-1 is the most unfavorable load position for interface A. The maximum principal stress at interface A was 64%, 55%, 52%, and 49% of the maximum principal stress in the structure, respectively, showing that stress concentration at interface A was more pronounced when Load-1 was applied. The reason may be Load-1 is closest to the corner of the ballast concrete.

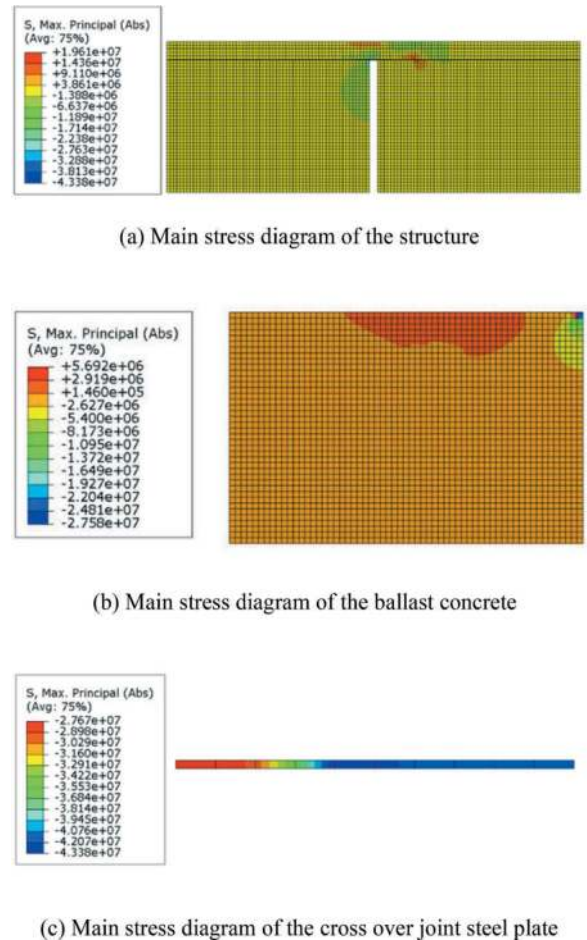

Figure 8. Main stress diagram of seamless expansion joint in nonuniform settlement condition.

Figure 8 shows the stress distribution in the seamless expansion joint structure when the load is at the Load-1 position. When there was a 10 mm vertical displacement between pipe sections, the maximum principal stress in the seamless expansion joint was 43 MPa, occurring at the cross-joint steel plate. Stress concentration was observed on the upper surface of the ballast concrete just below the cross-joint steel plate (interface A), with a maximum compressive stress of 28 MPa at the corner of the ballast concrete. Prolonged loading may lead to localized stress concentration, potentially causing crushing failure at the corner of the ballast concrete. This phenomenon may be attributed to the gap between the segments of the submerged tunnel

below the Load-1 position, where stress cannot propagate downward, resulting in significant stress concentration at interface A.

3.2 Stress in longitudinal tension condition

Changes in temperature and the longitudinal effects of traffic loads can lead to longitudinal stretching or compression of the seamless expansion joint structure. Temperature variations cause different degrees of deformation in various parts of the seamless expansion joint, resulting in changes in its length. During the driving process, horizontal forces are resulted between traffic loads and the road surface, which have a certain impact on the dimensions of the seamless expansion joint. According to the design data of the Shenzhen-Zhongshan Tunnel, the seamless expansion joint structure was designed to undergo a 25 mm longitudinal stretching. When subjected to loads at different positions, the maximum principal stress, maximum shear stress, and maximum principal stress and shear stress at interface C of the seamless expansion joint structure have been calculated.

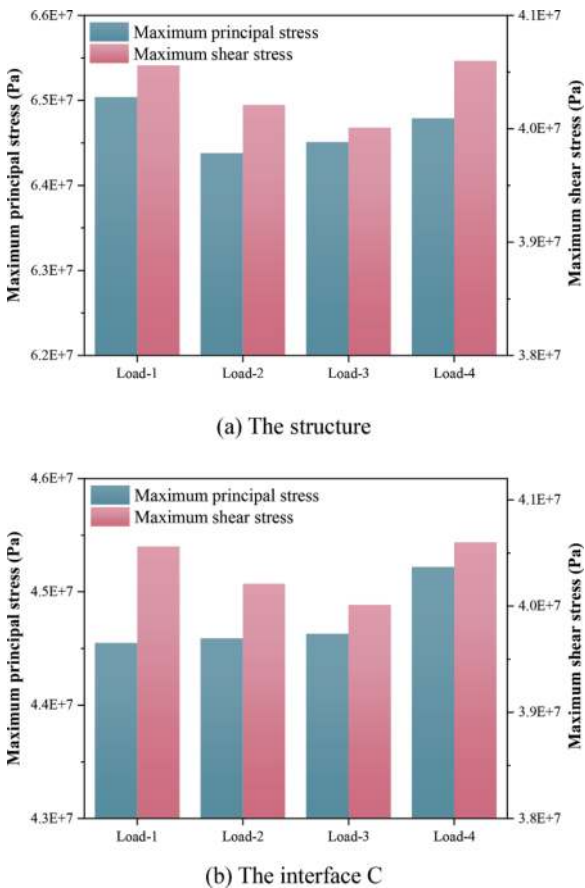

Figure 9. Stress changes in the seamless expansion joint structure under different load application positions in longitudinal tension condition.

Figure 9 shows that the stress in the seamless expansion joint structure under different load application positions in longitudinal tension conditions.

Under conditions of longitudinal stretching, the maximum principal stress of the seamless expansion joint structure was in descending order, which is Load-1, Load-4, Load-3, and Load-2. The maximum principal stress at interface C was ranked as Load-4, Load-3, Load-2, and Load-1. The maximum principal stress at interface C was 68%, 69%, 69%, and 70% of the maximum principal stress in the structure, respectively. It indicates that the stress concentration at interface C is relatively more pronounced when the load is at Load-4. The maximum shear stress at interface C was ranked in descending order as Load-4, Load-1, Load-2, and Load-3, indicating that Load-4 is the least favorable load position for interface C. Although both Load-3 and Load-4 edges coincide with interface C, Load-4 is farther from the edge of the ballast concrete than Load-3. Consequently, the load at Load-3 causes greater vertical deformation of the ballast concrete, leading to a decrease in relative displacement between the road pavement material and the expansion joint material, resulting in higher shear stress at interface C for Load-4.

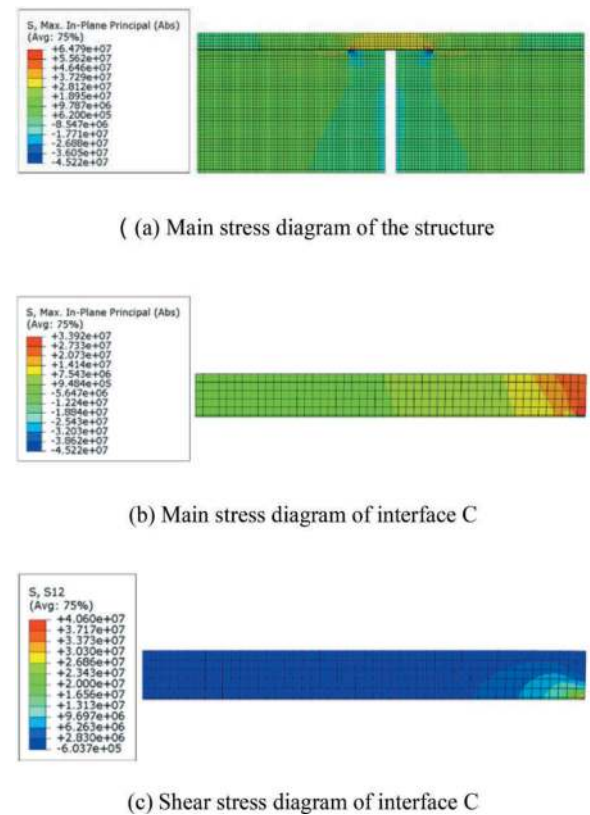

Figure 10. Stress diagram of seamless expansion joint in longitudinal tension condition.

Figure 10 depicts the strain condition of the seamless expansion joint structure when the load is applied at position Load-4. When there was maximum longitudinal stretching between pipe sections, the maximum shear stress in the seamless expansion joint was 41 MPa, occurring at the bonding interface between the seamless expansion joint material and the paving

material, namely, interface C exhibits stress concentration. This result may be due to the differences between the road pavement material and the expansion joint material. The road pavement material undergoes vertical deformation under load. Due to the bonding between the road pavement material and the expansion joint material, interface C experiences higher stress to accommodate the deformation of the road pavement material. It also explains why the seamless expansion joint is highly prone to delamination and cracking at the bonding interface.

4 OPTIMIZATION DESIGN OF SEAMLESS EXPANSION JOINT STRUCTURE

4.1 Optimization design of the ballast concrete section

To mitigate stress concentration at the corners of the ballast concrete, chamfer structures are introduced at the edges of the ballast concrete, simultaneously filled with elastic composite material. Figure 11 depicts the optimized design of the ballast concrete section and the contact points a_1 and a_2 , which are the vertices of the ballast concrete. The finite element simulations were performed on the expanded joint structure with added chamfer structures (Optimized Structure 1) under maximum differential settlement conditions. The load was at the position of the most unfavorable load. The stress of the seamless expansion joint structure under extreme conditions has been calculated and analyzed.

Figure 11. Schematic diagram of optimized design for the ballast concrete part.

Figure 12 presents stress results for the overall structure, interface A and the two contact points. The Optimized Structure 1 features chamfer structures added to the seamless expansion joint. It is evident that under maximum settlement conditions, the maximum principal stress in the Optimized Structure 1 shows little change compared to the original structure. However, the maximum principal stress at interface A decreased from 28 MPa to 13 MPa, a reduction of 52% compared to the original structure. The principal stresses at the corners of the ballast concrete were reduced by 72% and 57%, respectively. The addition of chamfer structures

significantly reduced the maximum shear stress in the seamless expansion joint structure, decreasing it from 9 MPa to 4 MPa, a reduction of 56% compared to the original structure. Shear stresses at contact points a_1 and a_2 were reduced by 75% and 85%, respectively, compared to the original structure. This reduction is likely due to the stress-buffering effect of the filling material at the chamfer locations. Adding chamfer structures in seamless expansion joints can reduce the principal and shear stresses in

(a) The structure

(b) The interface A

(c) The contact Points

Figure 12. Stress changes in the seamless expansion joint after increasing chamfer in nonuniform settlement condition.

the ballast concrete, effectively improving stress concentration at the corners. Therefore, in conditions with significant vertical deformation of the seamless expansion joint structure, the recommended structural optimization approach is to add chamfers.

4.2 Optimization design of the expansion joint filling material section

To improve the stress concentration, at the bonding interface between the expansion joint filling material and the road pavement material, an attempt was made to introduce the angle steel components within the seamless expansion joint to reduce stress at the bonding interface. Figure 13 provides a schematic representation of the optimized design for a portion of the seamless expansion joint. The distance between the bonding interface and the cross over joint steel plate was 150 mm. The optimal position of the angle steel component was determined through finite element analysis. The thickness of the angle steel component matched that of the cross over joint steel plate. The height of the angle steel component was determined through finite element analysis. Finite element simulations were conducted on the seamless expansion joint structure with added angle steel components (Optimized Structure 2) under maximum longitudinal stretching conditions. The load was applied at the most critical position to analyze stress responses under extreme conditions. The lowest point on the bonding interface was selected as contact point c_1 .

Figure 13. Schematic diagram of optimized design for the expansion joint filling material part.

4.2.1 Position of the angle steel component

When determining the horizontal position of the angle steel component, the height of the angle steel component was selected as 40 mm. The contact point c_1 was considered as the base point. The distance between the angle steel component and the base point was 10 mm, 20 mm, 30 mm, 40 mm, 50 mm, 60 mm, and 70 mm. Figure 14 and Figure 15 show the simulation results.

Figure 14 illustrates the schematic of the shear stress on interface C, comparing the shear stress in the original structure to those in the structures with adding the angle steel components. It is evident that without the angle steel components, the shear stress values on interface C were consistently higher than in the optimized structures. Contact point c_1 represented the location of maximum shear stress on interface C, making the stress value at contact point c_1 the crucial

Figure 14. Shear stress diagram of interface C when the angle steel component is at different horizontal positions.

Figure 15. Stress changes of interface C when the angle steel component is at different horizontal positions.

parameter for determining the optimal placement of the angle steel component. Figure 15 shows the maximum principal stress and maximum shear stress on interface C. The maximum principal stress and maximum shear stress at interface C of the original structure reached 45 MPa and 41 MPa, respectively. As for the optimized structure, the position of the angle steel component varied, resulting in differences in the maximum principal stress and maximum shear stress on interface C. However, these values were overall lower than in the original structure. As the distance between the angle steel component and the base point increased, the maximum principal stress on interface C initially rose and then stabilized. The maximum principal stress reached a stable state when the distance was 40 mm. The maximum shear stress on interface C decreased with increasing distance from the angle steel component to the reference point. And as the distance increased, the decreasing trend gradually stabilized. When the distance between the angle steel component and interface C was 40 mm, the decreasing trend reached a stable state, with a decrease rate of about 72%. Therefore, the recommended distance between the angle steel component and the reference point is 40 mm.

4.2.2 Height of the angle steel component

Based on the previous finite element analysis results, the distance between the angle steel component and the reference point was set to 40 mm. The height of the angle steel component was 10 mm, 20 mm, 30 mm, 40 mm, and 50 mm, respectively. Figure 16 and Figure 17 show the finite element simulation results.

Figure 16. Shear stress diagram of interface C when the angle steel component is of different heights.

Figure 17. Stress changes of interface C when the angle steel component is of different heights.

Figure 16 provides the schematic of the shear stress on interface C for different heights of the angle steel components. From the figure, it can be observed that the height of the angle steel component has a relatively minor impact on the principal stress on interface C. However, when the height of the angle steel component was 40mm, the stress of interface C was slightly lower than the stress at other heights. Figure 17 illustrates the maximum principal stress and maximum shear stress on interface C for different heights of the angle steel components. The relationship between the maximum principal stress and maximum shear stress on interface C and the height of the angle steel component is not significant. Following the trend of increasing maximum principal stress on interface C, the order of the angle steel component heights was 40 mm,

20 mm, 50 mm, 30 mm, and 10 mm. Following the trend of increasing maximum shear stress on interface C, the order of the angle steel component heights was 40 mm, 10 mm, 50 mm, 30 mm, and 20 mm. It indicates that when the height of the angle steel component is 40 mm, the values of maximum principal stress and maximum shear stress on interface C are lowest, resulting in the most optimal design effect. Therefore, a height of 40 mm for the angle steel component can be recommended. The optimization design involving the addition of the angle steel components not only significantly reduces the shear stress in the seamless expansion joint structure but also, to some extent, diminishes the principal stress in the same structure. Therefore, it is suggested to adopt this optimization design under heavy traffic load conditions.

4.3 Optimization design of the road pavement section

To mitigate the stress concentration at the bonding interface between the seamless expansion joint filling material and road pavement material and to reduce the relative deformation between these materials, an approach involving stepped layering in the road pavement section is adopted. Considering the relatively small road thickness, a two-stage cutting method was employed. During construction, cutting can be carried out separately, followed by the pouring of the expansion joint material together. Figure 18 depicts the optimized design for the road pavement section. For the seamless expansion joint structure with adding a stepped layered design (Optimized Structure 3), the finite element simulation was performed in the maximum longitudinal stretching state. The load was applied at the position of the most unfavorable load to analyze stress responses under extreme conditions. Figure 19 presents the finite element simulation results.

Figure 18. Schematic diagram of optimized design for the road pavement part.

Figure 19 displays the simulation results for the maximum principal stress and maximum shear stress of the overall structure and interface C. The Optimized Structure 3 represented the seamless expansion joint structure by adding a stepped layered design. When the longitudinal tensile deformation reaches its maximum state, the maximum principal stress in the Optimized Structure 3 increased from 41 MPa to 70 MPa, and the maximum principal stress on interface C increased from 45 MPa to 49 MPa. Compared to the original structure, these values increased by 8% and 9%,

respectively. This result could be attributed to the higher stress transfer efficiency within the expansion joint filling materials compared to the road pavement materials. After optimizing the road pavement section, the maximum shear stress in the seamless expansion joint structure significantly decreased. The maximum shear stress in the structure reduced from 41 MPa to 33 MPa, and the maximum shear stress on interface C decreased from 41 MPa to 12 MPa. Compared to the seamless expansion joint before optimization, these values decreased by 19% and 71%, respectively. The reason may be that the stepped layered design can reduce the relative deformation between the expansion joint material and road pavement material. Due to there being no joint in the upper part of the road pavement material section, the shear stress is shared by both the expansion joint filling material and part of the interface. It indicates that adding a stepped layered design to seamless expansion joints can reduce shear stress occurring at the bonding interface and effectively improve stress concentration at the bonding interface. Although the stepped layering design can effectively fall shear stress at the bonding interface, it may increase the principal stress of the structure to some extent. Therefore, incorporating the structural optimization method with the stepped layering design can be adopted under light traffic load conditions.

(a) The structure

(b) The interface C

Figure 19. Stress changes in the seamless expansion joint after increasing layered design in longitudinal tension condition.

4.4 Comparison of different optimization designs

Figure 20 illustrates the optimization rates of different seamless expansion joint structural stress compared to the original structural stress. It can be seen that all three optimization structures significantly improve the shear stress in the structure and interfaces. The Optimized Structure 1 had a minor adverse impact on the principal stress of the structure, but the maximum principal stress in the Optimized Structure 1 occurred at the cross over joint steel plate, and the stress values were within the allowable stress range. Therefore, the Optimized Structure 1 exhibits good optimization results. The Optimized Structure 2 reduced the principal stress in the structure and interfaces to some extent but involved relatively complex construction processes. Hence, it can be recommended for use on road surfaces with heavy traffic loads. The Optimized Structure 3 harmed the principal stress in the seamless expansion joint structure and interfaces. However, this structure significantly improved the phenomenon of shear stress concentration at the bonding interface of the seamless expansion joint. Therefore, it can be suggested for use under conditions of light traffic loads.

Figure 20. Optimization rate of different optimize structures.

5 CONCLUSIONS

- (1) Finite element analysis indicated that under non-uniform settlement conditions, the seamless expansion joint structure was prone to stress concentration at interface A, between the cross over joint steel plate and the ballast concrete, with the middle position of the expansion joint structure representing the position of the most unfavourable load. In the longitudinal deformational state, the seamless expansion joint structure was susceptible to stress concentration at interface C, between the expansion joint filling material and the road pavement material, with the position where the load's centerline coincides with the bonding interface being the position of the most unfavourable load.

- (2) The structural design of adding chamfer to the ballast concrete section resulted in a 52% reduction in maximum principal stress and a 56% reduction in maximum shear stress between the cross over joint steel plate and ballast concrete, effectively improving stress concentration. This design optimization can be recommended for use in conditions where vertical deformation of the seamless expansion joint structure is significant.
- (3) Finite element simulation results indicated that the optimal position for adding the angle steel component was 40 mm from the base point, with an optimal height of 40 mm. After adding the angle steel components to the expansion joint material, the maximum principal stress and maximum shear stress between the expansion joint material and road pavement material decreased by 2% and 72%, respectively, effectively improving stress concentration at the bonding interface. This optimization can be recommended for conditions with significant longitudinal stretching deformation and heavy traffic loads.
- (4) Adopting a stepped layering design in the road pavement section with a recommended lower layer thickness of 50 mm resulted in a 9% increase in maximum principal stress and a 71% decrease in maximum shear stress between the expansion joint filling material and road pavement material compared to original structure. This result significantly reduced shear stress at the bonding interface. However, the addition of a stepped layering design had an adverse effect on the principal stress of the seamless expansion joint structure. Therefore, it can be recommended for use under conditions with significant longitudinal stretching deformation and light traffic loads.

Analysis and research on seismic effects of immersed tunnel joints of Shenzhen-Zhongshan Link

Zhi Li*, Zheng Jie Chen & Hong Chen

Shanghai Tunnel Engineering & Rail Transit Design and Research Institute, Shanghai, China

ABSTRACT: The immersed tunnel of Shenzhen-Zhongshan Link is the first to adopt the steel shell concrete structure in China, and the immersed tunnel section is ultra-wide, ultra-long and ultra-deep with complicated stress on the element joints under seismic effects. A refined three-dimensional model was established for the elements (Element 2 to Element 5) with significant changes in shallow stratum by the nonlinear time-history analysis method. The model included foundation soil, backfill materials, immersed tunnel structure, GINA gasket, horizontal shear key, vertical shear key, etc. Under the horizontal & transverse seismic and horizontal & longitudinal seismic effects in earthquake fortification and rare working conditions, the unevenness of foundation stiffness and the stress characteristics of GINA gaskets and shear keys are mainly considered. The compression of element joints opening, shear forces of shear keys, and interlayer displacement angles of elements were calculated to verify the safety, water tightness, and overall deformation performance of the element joints under seismic conditions, providing a reference for engineering design.

Keywords: Immersed tunnels, Element joints, Seismic effects, Time-history analysis

1 INTRODUCTION

Immersed tunnels have become an important means of crossing rivers, harbors, and sea due to their unique advantages. Immersed tunnels are generally shallower in depth, more susceptible to seismic effects. Meanwhile, the immersed tunnel is formed by multiple elements and requires very high performance of the sealing, and stress behavior. During the earthquake, the immersed tunnels buried in soil layers are generally less likely to experience collapse like structural damage, but the elements are prone to significant deformation due to their low stiffness, which poses a safety hazard to the normal operation of immersed tunnels. Therefore, the study on the stress deformation at the element joint under earthquake action is of great significance for its seismic safety evaluation.

Today, there has been some research on the overall dynamic response of immersed tunnels under earthquake action and the seismic performance analysis of local refined structures. The nonlinear seismic performance of immersed tunnel structures under deep water were calculated and analysed by establishing a beam and spring model (Anastasopoulos, 2007); an analytical model for the seismic response of the immersed tunnel in Tianjin Haihe River was established, and calculated the stiffness of the steel tension cables, horizontal shear keys, vertical shear keys, and GINA

gaskets in the direction of corresponding degrees of freedom, and then conducted the nonlinear spring simulation through superimposed the above equivalent stiffness (Zhang et al., 2011); The dynamic calculation method of the interaction between soil and structure in the immersed tunnel of Hong Kong-Zhuhai-Macao Bridge, and the seismic response analysis method for ultra long immersed tunnels under non-uniform seismic effects were elaborated (Yu et al., 2012); a 3D dynamic time history analysis model of the soil-waterstop-immersed tunnel system were established based on the immersed tunnel of Hong Kong-Zhuhai-Macao Bridge, in which the waterstop was simulated by elastic rubber material (Qiu et al., 2019).

In this paper, 3D time history analysis method was adopted to accurately simulate the stratum fluctuation changes, treated soil and backfill materials that have a great impact on earthquake response. Spring unit was used to simulate GINA gasket, vertical shear key and horizontal shear key respectively to analyze the stress deformation characteristics of element joints under seismic fortification and rare working conditions, providing references for engineering design.

2 PROJECT OVERVIEW

Shenzhen-Zhongshan Link Project is located in the core area of the middle reaches of the Pearl River,

*Corresponding author: li.zhi@stedi.com.cn

about 30km from Humen Bridge in the north and 38km from Hong Kong-Zhuhai-Macao Bridge in the south. The immersed tunnel of Shenzhen-Zhongshan Link starts from the East Artificial Island at Shenzhen side, runs westward through Dachanwan Channel, Airport Branch Channel, Fanshi Waterway, and ends at the boundary milestone of the bridge and tunnel on the West Artificial Island. The total length of the tunnel is 6845m, of which the immersed tunnel section is 5035m long. The immersed tunnel adopts the monolithic rigid element scheme. The maximum longitudinal slope of the tunnel is 2.98%, the minimum longitudinal slope is 0.4%, and the lowest design elevation of the road surface is -33.786m. The immersed section is divided into 32 elements, with a standard element length of 165m. Five 123.8m long elements are arranged on the side of the east artificial island due to the widening of the cross section, and one 123.8m long section is arranged on the west artificial island. The profile of immersed tunnel is shown in Figure 1, and the cross section of steel shell concrete immersed element is shown in Figure 2.

Figure 1. Profile of the immersed tunnel.

Figure 2. Cross section of the immersed element.

3 TIME-HISTORY ANALYSIS METHOD

The time-history analysis method was applied for this seismic analysis. The “time-history analysis method” is a kind of structural dynamic calculation method which integrates the basic motion equation of structure into the seismic acceleration record and obtains the seismic effect of structure in the whole time history. Since the 1960s, it has gradually developed into one of the general structural analysis methods because of its clear concept and its ability to reflect the influence of the three parameters of ground motion (amplitude, frequency content and ground motion duration) on the structure. The time-history analysis method can be used for a variety of complex analysis cases.

The main analysis steps of finite element time-history analysis method of soil-underground structure were as follows: The appropriate finite element model was established according to the characteristics of the analysis object and model. The appropriate seismic wave was selected when the influence of the three

elements of ground motion (amplitude, frequency content, and ground motion duration) on the calculation results should be taken into account. The dynamic time history response of the whole structure model was obtained by applying the ground motion as a load to the finite element model in the way of time history.

4 MODELLING

Based on the analysis of the design drawings and research report of Site Design Ground Motion Parameters, the refined finite element model of soil-structure interaction was considered for the elements (Element 2 to Element 5) of the west slope section. The calculation section were about 660m long, which included the climbing slope section, and the buried depth of the immersed tunnel in this section was shallow. The spatial layout and structural stress were of typical significance.

4.1 Stratum and backfill

The main stratum within this calculation section were divided into 5 layers: silt, silty clay, silty sand - medium sand, fully weathered rock and medium weathered rock. According to geological exploration report and the soil shear wave velocity, ②₂₃ silt, ③₅ fine sand, ③₆ medium sand and ③₈ gravel sand layers were integrated into silt - medium sand layer. The local small layer was simplified considering the complexity of modelling, as shown in Figure 3. The foundation of Element 2 to Element 5 was considered to be reinforced with deep cement mixing (DCM) piles, with a depth of reinforcement reaching the top of layer ④ of fully decomposed granite. The backfill and foundation reinforcement condition refers to Figures 3-4. The stratum calculation parameters were obtained from the research report of Design Ground Motion Parameters of Shenzhen-Zhongshan Link and one-dimensional ground motion response analysis, as shown in Table 1.

Figure 3. Geological profile of immersed tunnel.

Figure 4. Backfilling and foundation reinforcement of the anti-collision section of west artificial island.

Table 1. Soil layer calculation parameters.

Soil layer	Unit weight (kN/m ³)	Dynamic poisson's ratio	Dynamic modulus of elasticity (kN/m ²)
Silt	16.1	0.49	27402
Silty clay	17.1	0.49	56224
Fine~medium sand	18.6	0.49	199520
Completely weathered	25.0	0.49	1439028
Moderately weathered	25.0	0.49	2286524
Lock backfill	24.0	0.49	801024
Block stone	24.0	0.49	450576
DCM reinforcement for silt	20.0	0.49	69601
DCM reinforcement for silty clay	20.0	0.49	142810
DCM reinforcement for fine~medium sand	20.0	0.49	506783

4.2 Modelling

4.1.1 Model establishment

In the modeling, the shell element was used to simulate elements, the spring element was used to simulate element joints, and the hexahedral and pentahedral solid elements were used to simulate soil. Three element joints were considered in the model.

Modelling length direction: From Element 2 to Element 5, the length was $4 \times 165\text{m} = 660\text{m}$; modeling depth direction: From the bottom of Element 5 to the top of Element 2, the elevation ranged from -31.743 to -9.171, with a total of 22.572m, the modeling depth was 50m, and the foundation was medium-weathered rock; modeling width direction: The width of the immersed tunnel structure(B) was 46m, and the expansion range of both sides was 3B respectively, with a total width of $7B = 7 \times 46 = 322\text{m}$.

In the depth direction, the unit depth the was about 1~1.5m. In the width direction, the unit length was about 3m~4m. In the length direction, unit length was about 5m~10m. The number of model units was 296 948, and the number of nodes was 290 191.

Figure 5. Overall model diagram.

Figure 6. Model cross-section.

4.1.2 GINA gasket simulation

Trelleborg's GINA gasket was used, and different types of GINA gaskets were used for different water depths. The basic material of GINA gasket is natural rubber, which is a highly nonlinear elastomer. The equivalent particle - spring model method was used in the calculation. The compression of GINA gasket opening was less than 30mm, and the deformation of GINA was considered to be in the elastic deformation range. Considering that the calculation volume of 3D overall nonlinear time history analysis would be too large, the linear spring unit was adopted for the calculation to simulate GINA gasket, and the initial stiffness under initial compression of the force-compression curve was taken as the calculation stiffness, as shown in Table 2. The simulation of GINA gasket for the model is shown in Figure 8. Stiffness conversion was carried out according to unit length in the calculation.

Table 2. Sheet of GINA stiffness values.

Element Joints	Element 6~Element 5	Element 5~Element 4	Element 4~Element 3
GINA body hardness	62	62	62
Average pressure on GINA gasket at construction stage (kN/m)	939.1	822.8	702.4
Initial deformation (mm)	140.6	134	127.1
Initial stiffness (kN/m/m)	6679	6140	5526

4.1.3 Shear key simulation

There were 2 sets of horizontal concrete shear keys (bottom) and 4 sets of vertical steel shear keys (side and middle walls) between the elements. 2 sets of vertical steel shear keys were arranged on the middle and side walls respectively. The steel shear keys on the side wall were connected with the transverse partition inside the steel shell by high-strength bolts, and the steel shear keys on the middle wall were welded directly with the end panel of the steel shell. The bottom slab was provided with 2 sets of horizontal concrete shear keys located in the ballast concrete of the bottom slab of traffic tubes.

Figure 7. GINA gasket + shear key diagram.

For the element joints in Shenzhen-Zhongshan Link, the recommended stiffness value of the vertical steel shear keys of the 2 sets of side walls was $1.3 \times 10^5 \text{ kN/m}$, that of the 2 sets of vertical steel shear keys of the middle wall was $1.9 \times 10^5 \text{ kN/m}$, and that of the 4 sets of horizontal concrete shear keys was $5 \times 10^6 \text{ kN/m}$. The shear key simulation in the model was simulated with 8 separate springs, as shown in Figure 7.

4.1.4 Boundary conditions

In the eigenvalue analysis, the 4 sides of the model used vertical constraints, and the bottom adopted fixed constraints. In the dynamic time history analysis, the 4 sides of the model adopted vertical constraints, the bottom adopted vertical constraints and mass elements, and the calculated damping used Rayleigh damping. Through the eigenvalue analysis, the two periods with the highest mass participation were obtained. The characteristic periods of horizontal lateral seismic effects were 0.972s and 0.832s, and the characteristic periods of horizontal longitudinal seismic effects were 0.89s and 0.82s, respectively. The empirical critical damping ratio was 0.05.

5 SEISMIC LOADS AND WORKING CONDITIONS FOR ANALYSIS

According to the Site Seismic Safety Evaluation Report, the seismic response of the immersed tunnel was analyzed by selecting the seismic acceleration of the man-made ground motion of bedrock with the probability of exceeding 10% (fortification earthquake) and 4% (rare earthquake) in 100 years. The time history of seismic acceleration of the site bedrock is shown in Figure 9. The entire seismic wave calculation time could be 35s. The control frequency was considered around 5~10Hz, and the integral time step was between 0.005s and 0.01s. Considering the size of the model and the calculation time, the 3D fine analysis was calculated according to the integral step size of 0.01s. Seismic analysis under fortification earthquake and rare earthquake was carried out respectively, as shown in Table 3.

6 ANALYSIS OF CALCULATION RESULTS

This calculation mainly took into account the compression of element joint opening under horizontal and longitudinal seismic effects, the stress of horizontal shear keys and the interlay displacement angle between elements under horizontal and transverse seismic effects.

(a) 10% acceleration for 100-year probability of exceedance

(b) 4% acceleration for 100-year probability of exceedance

Figure 8. Seismic acceleration time history of site bedrock.

Table 3. Calculated working conditions for seismic analysis.

Calculated working conditions	Seismic wave input direction	seismic effects level	Standard	Amplitude modulation of surface peak acceleration
1	Horizontal and longitudinal	Fortification earthquake	10% for 100 years	160 gal
2		Rare earthquake	4% for 100 years	210 gal
3	Horizontal and transverse	Fortification earthquake	10% for 100 years	160 gal
4		Rare earthquake	4% for 100 years	210 gal

6.1 Horizontal and longitudinal seismic effects

The compression deformation of element joint opening under horizontal and longitudinal seismic effects of fortification and rare earthquakes are shown in Figures 9-12.

When the horizontal and longitudinal seismic input was applied, the longitudinal deformation of the element joint was relatively large, while

Figure 9. Envelope value of element displacement under fortification earthquake.

Figure 10. Time history curve of compression of element joint opening under fortification earthquake.

Figure 11. Envelope value of element displacement under rare earthquake.

Figure 12. Time history curve of compression of element opening under rare earthquake.

the shearing force of the horizontal and vertical shear keys was relatively small. The main focus was on the deformation of the element joint. According to calculations, the maximum compression and opening of the element occurred at the joint between Element 3 and Element 2, where the elements are shallowest and most significantly affected by seismic effects. Under fortification working conditions, the maximum compression amount was 5.6mm and the maximum tension amount was 5.7mm; under rare working conditions, the maximum compression amount was 10.6mm and the maximum tension amount was 10.4mm. According to the design of reinforcement plan, DCM reinforcement was used for both the ranges from Element 5 to Element 2 and backfilling area, which played good role in controlling the deformation at the element joints. Under horizontal and longitudinal seismic effects, the deformation of the element joint met the water tightness requirements.

6.2 Horizontal and transverse seismic effects

The internal force of the horizontal shear key and interlayer displacement difference of the elements under horizontal and transverse seismic effects are shown in Figures 13-16.

Figure 13. Envelope value of internal force of horizontal shear key under fortification earthquake.

Figure 14. Interlayer displacement difference of elements under fortification earthquake.

Figure 15. Envelope value of internal force of horizontal shear key under rare earthquake.

Figure 16. Interlayer displacement difference of elements under rare earthquake.

When inputting horizontal seismic effects, the internal force of the horizontal shear key was relatively large, while the deformation of the element joint and the shearing force of the vertical shear key were relatively small. The main focus was on the horizontal shear key and the interlayer displacement difference of elements. According to the calculations, the maximum internal force of the horizontal shear key under fortification working conditions was 1571kN, and the maximum internal force of the horizontal shear key under rare working conditions was 4417kN. With the consideration of partial coefficient of horizontal seismic effects, the design value should be less than the limit requirement of 34MK for a single shear key. The calculation of the interlayer displacement angle of the elements is shown in Table 4. And the interlayer displacement angle of the elements met the requirements under both fortification and rare working conditions.

Table 4. Horizontal seismic interlayer displacement angle.

Working condition	Horizontal relative displacement DX (mm)	Floor height (mm)	Inter-layer displacement angles	Limit value of interlayer displacement angle
Fortification	3.35	9100	1/2716	1/550, compliance
Rare	8.40	9100	1/1083	1/250, compliance

7 CONCLUSIONS

By establishing a refined 3D dynamic time history analysis numerical model for the immersed tunnel of Shenzhen-Zhongshan Link, the focus was on analyzing the compression of element openings under horizontal and longitudinal seismic effects, internal force of horizontal shear keys under horizontal and transverse seismic effects, and interlayer displacement difference of elements.

- (1) Under the action of horizontal and longitudinal seismic effects, the longitudinal deformation of element joint was relatively large, while the internal forces of horizontal and vertical shear keys were relatively small; when the horizontal and transverse seismic input was applied, the internal force of the horizontal shear key was relatively large, while the deformation of the element joint and the internal force of the vertical shear key were relatively small.
- (2) Under horizontal and longitudinal seismic effects, the deformation of the element joint met the waterproofing requirements. The maximum compression and opening of the element occurred at the joint of Element 3 and Element 2, where the elements are shallowest and most significantly affected by the seismic effects. The DCM reinforcement in the area from Element 5 to Element 2 had played a good role in controlling the deformation of the element joints.
- (3) Under horizontal seismic effects, the horizontal shear key met the design requirements. The interlayer displacement angle of the elements met the specification requirements.

The analysis results provides references for seismic design of similar immersed tunnel structures.

Seismic resilience assessment for longitudinal response of immersed tunnels

Xinxi Li*

Department of Geotechnical Engineering, Tongji University, Shanghai, China

Haitao Yu

State Key Laboratory of Disaster Reduction in Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: Seismic resilience assessment is an important means to evaluate the seismic performance of structures, but the seismic resilience assessment for longitudinal response of immersed tunnels has not been reported yet. Based on the multi-scale model, this paper proposes a longitudinal resilience assessment framework for immersed tunnels. The macroscopic spring-beam model is used to describe the dynamic nonlinear characteristics and the interaction between structure and stratum. And the microscopic refinement model is used to capture the dynamic laws of the relative deformation of joints. Fragility curves are developed at different limit states by nonlinear incremental dynamic analysis procedure with appropriate ground motion, intensity measure and damage measure. The seismic resilience assessment method was modeled by the estimation of restoration functions and the resilience index. Taking an immersed tunnel as an application example, parametric analyses are performed to investigate the influence of the peak ground acceleration and soil-structure relative stiffness ratio. The results show that the residual functionality and seismic resilience decrease significantly with the increase of the peak ground acceleration. And the seismic resilience index increases with the increasing soil-structure relative stiffness ratio. The proposed method can provide reference and basis for seismic risk assessment of immersed tunnel.

1 INTRODUCTION

The damage of tunnels under earthquakes will have an impact on urban traffic, energy, municipal and other aspects. Seismic resilience can be described as the ability to withstand, respond and rapidly recover from hazards. It is a crucial means to evaluate the seismic performance of structures by considering the degree of functional loss and the post-earthquake repair process. Therefore, it is of paramount importance to evaluate the seismic resilience of tunnels.

The conceptual framework of seismic resilience was proposed by Bruneau et al. (2003), and its theory and design have gradually become a research hotspot and applied to buildings, bridges, transportation network and other fields (Alipour & Shafei, 2016; Anwar et al., 2020). At present, the research on the seismic resilience of underground structures mainly focuses on the improvement of structural resistance and self-centring

structure, such as the installation of supports at the end of middle columns to increase their deformation capacity (Ma et al., 2018). Chen & Zhou (2019) realized the self-centring of the structure by installing energy dissipation devices between the bottom of the column and the beam so that the damage of the structure under earthquake was significantly reduced. Huang et al. (2022) put forward the seismic resilience assessment process for cross-sectional tunnels in soft soil areas, and explored the influence laws of soil conditions, tunnel burial depth, construction quality and other factors. However, the above research is limited to the cross-sectional seismic resilience study of underground structure. Considering that joints are the weak point of tunnel structures, it is necessary to evaluate the longitudinal seismic resilience of tunnel.

This paper establishes the evaluation method and process of longitudinal seismic resilience of immersed tunnels. Taking the characteristics and joints of immersed tunnels into consideration, fragility curves

*Corresponding author: 2010049@tongji.edu.cn

are calculated and the seismic resilience assessment framework are modelled by the estimation of restoration functions and the resilience index. Taking an immersed tunnel as an application example, parametric analyses are performed to investigate the influence of the peak ground acceleration and soil-structure relative stiffness ratio.

2 SEISMIC RESILIENCE FRAMEWORK FOR IMMERSSED TUNNELS

2.1 Numerical model of immersed tunnel

As shown in Figure 1, the longitudinal dynamic response analysis of immersed tunnel based on beam-spring model is established. The tunnel is simulated as beam element and the soil-structure interaction is modelled as spring and damping elements. The spring stiffnesses of longitudinal, transverse and vertical formation springs can be expressed by Eq. (1)-(2) (John & Zahrah, 1987). The damping between tunnel and soil can be expressed by Eq. (3)-(4). Non-linear hyper-elastic springs is introduced to simulate the actual non-linear force-deformation behavior of the Gina gasket. And bilinear models are used to describe the structural forms and bearing mechanics of shear keys. Each node and the adjacent end of segmental element is rigid connect, forming a combination of the microscopic refinement model of joints and the macroscopic beam model. The continuity equation is satisfied between the macro and micro models, as shown in Eq. (5) (Zhang et al., 2021).

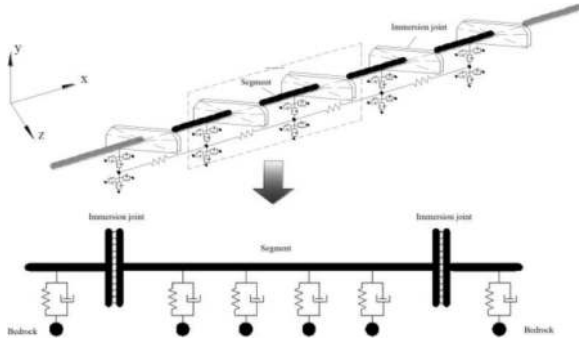

Figure 1. Multi-scale model of immersed tunnel.

$$k_x = k_y = \frac{16\pi G(1-\nu)d}{3-4\nu} \frac{d}{L} \quad (1)$$

$$k_z = \frac{2\pi G d}{1-\nu L} \quad (2)$$

$$C_x = \rho V_s \pi d \quad (3)$$

$$C_y = C_z = \rho V_s d + \rho V_{La} d \quad (4)$$

$$\begin{cases} x'_{O_1} = x'_{S_i} = 0 \\ y'_{O_1} = \sum_{i=1}^j y'_{S_i}/j \\ z'_{O_1} = \sum_{i=1}^j z'_{S_i}/j \end{cases} \quad (5)$$

Where, L is the wavelength of the incident wave (m); d is the width of the tunnel (m); G is the shear modulus of soil, $G = \rho V_s^2$, ρ is the soil density (kg/m^3), V_s is the shear wave velocity (m/s); ν is the Poisson's ratio; V_{La} is the Lysmer wave velocity, $V_{La} = \frac{3.4}{\pi(1-\nu)} V_s$; O_1 is the end of beam element; S_i is the node of the joint; x'_{O_1} , y'_{O_1} , z'_{O_1} are the coordinates of O_1 , respectively; x'_{S_i} , y'_{S_i} , z'_{S_i} are the coordinates of S_i , respectively; j is the number of joint spring elements.

2.2 Fragility curves

The seismic vulnerability can be assessed based on fragility curves, that is, the exceeding probability of structural damage measures (DM) exceeding a certain limit state under a given ground motion intensity measures (IM), which can be calculated by Eq. (6) (Liu et al., 2017).

$$\begin{aligned} P(LS_i | IM = im) &= P(DM > dmi | IM = im) \\ &= 1 - P(DM < dmi | IM = im) \\ &= 1 - \Phi\left(\frac{\ln dmi - \mu_{\ln DM | IM = im}}{\sigma_{\ln DM | IM = im}}\right) \end{aligned} \quad (6)$$

Where, the limit state LS_i is quantified by DM and expressed as dmi . Eq. (6) calculates the probability of DM exceeding dmi , when $IM = im$. $\mu_{\ln DM | IM = im}$ and $\sigma_{\ln DM | IM = im}$ are the mean and the standard deviation of $\ln(DM)$, respectively. And Φ is the standard cumulative normal distribution function.

The limit state represents the maximum expected damage degree of the structure under a specific ground motion intensity, and it can be divided into four types, namely no damage, minor damage, moderate damage and extensive damage. Table 1 shows the definitions of each limit state using the ratio of the bending moment (M) and moment capacity (MRd).

Table 1. Definitions of each damage state.

Limit state	M/M_{Rd}
no damage (LS_0)	1
minor damage (LS_1)	1.5
moderate damage (LS_2)	2.5
extensive damage (LS_3)	3.5

2.3 Restoration models and resilience analysis

A reasonable restoration model should be established for seismic resilience assessment, as shown in Figure 2, where $Q(t)$ is the functionality function changing over time. t_0 is the time when the earthquake occurs, and t_1 is the time when the repair is completed. The functionality function between t_0 and t_1 is the resilience curve. Once the form of the resilience curve is determined, the seismic resilience of the tunnel can be quantitatively evaluated. However, the resilience curve needs to consider the influence of many factors, and is closely related to the damage of the component, repair cost, repair priority and other factors, so it is difficult to get a unified form. At present, classical restoration models include linear functions (Bruneau & Reinhorn, 2007), trigonometric functions (Bocchini & Frangopol, 2012), and exponential functions (Cimellaro et al., 2010; Dong & Frangopol, 2015).

Figure 2. Assessing model of seismic resilience (Bruneau & Reinhorn, 2007).

The resilience index R is given in Eq. (7) to quantitatively evaluate the longitudinal seismic resilience of the immersed tunnel.

$$R = \frac{\int_{t_0}^{t_1} Q(t) dt}{t_1 - t_0} \quad (7)$$

3 APPLICATION

3.1 Parameters of the numerical modelling

This research is based on the real project of an immersed tunnel. As shown in Figure 3, the immersed tunnel is composed of 7 concrete elements with a standard length of 108 m. The tunnel structure was modelled as beam elements supported by interaction springs and dashpots, with the cross-section 43 m in width and 9.55 m in height. Concrete Damaged Plasticity model is used to simulate the material of the tube, in which the density is 2500kg/m³, the elastic modulus is 3.15×10^4 MPa, Poisson's ratio is 0.2, the initial compressive yield stress is 14.3MPa, the ultimate compressive yield stress is 29.6MPa,

and the tensile failure stress is 2.5MPa. Non-linear hyper-elastic springs are introduced to simulate the Gina gaskets and bilinear models are used to describe the two load-deformation stages of vertical shear keys and horizontal shear keys, as shown in Figure 4.

Figure 3. Finite element model.

(a) Gina gasket

(b) Shear keys

Figure 4. Force-displacement relationship of immersion joint.

The layered soil is equivalent to a homogeneous soil layer with equivalent shear velocity, with a soil density of 2000kg/m^3 , shear velocity of 180m/s , and Poisson's ratio of 0.3 . The nonlinear characteristics of soil layer are treated by equivalent linearization and calculated by Shake91, a one-dimensional soil layer seismic response analysis program. The curve of shear modulus ratio and damping ratio change with shear strain is shown in Figure 5. Finally, the stiffness and damping of soil spring are calculated by Eq. (1)-(4) according to the equivalent shear modulus.

Figure 5. Shear modulus ratio and damping ratio.

In this study, the peak ground acceleration (PGA) is adopted as the IM and the peak relative extension of immersion joints is selected as DM. Based on incremental dynamic analysis (IDA), fragility curves of the four limit states are shown in Figure 6.

Figure 6. Seismic fragility curves.

3.2 Resilience assessment

Functionality function $Q(t)$ is estimated using the method proposed by FEMA (2020), as shown in Figure 7. The resilience curve is obtained based on the best fitting of ATC-13 data, and $Q(t)'$ is defined

as the average function of the tunnel in the recovery process, as shown in Eq. (8). According to the definition, the functionality function $Q(t)$ under the given IM can be derived, and then the resilience index R can be obtained from Eq. (7).

Figure 7. Tunnel restoration curves (FEMA, 2020).

$$Q(t)' = \sum_{i=1}^3 Q[LS_i|t]P[LS_i|IM] \quad (8)$$

Where, $Q[LS_i|t]$ represents the functionality of the tunnel being in LS_i at time t , which can be obtained from Figure 7. $P[LS_i|IM]$ represents the probability of occurrence of LS_i for a given IM, as defined in the following equations

$$P[LS_i|IM] = P[DM > LS_{i-1}|IM] - P[DM > LS_i|IM], i = 1, 2, 3 \quad (9)$$

Where, $P[DM > LS_{i-1}|IM]$ and $P[DM > LS_i|IM]$ are the exceeding probabilities of the DM exceeding LS_{i-1} and LS_i at a given IM, respectively.

3.3 Parametric analysis

3.3.1 Effect of PGA

The resilience curves for immersed tunnel with different PGAs is presented in Figure 8. It can be known from the figure that the residual function $Q(t=0)$ of the tunnel after the earthquake decreases with the increase of ground motion intensity. And the slopes of the resilience curves change significantly during the 3-5 days of the recovery process. According to Figure 7, the recovery time of minor damage and moderate damage is 3 days and 7 days respectively, that is, after 7 days, the tunnel function is expected to recover 100% in cases of minor and moderate damage, and the resilience curve is only determined by the recovery function of extensive damage. Figure 9 shows the resilience index of

immersed tunnel decreases with the increase of ground motion intensity. Especially when PGA is greater than 0.25g, the resilience index decreases significantly.

Figure 8. Resilience curves of the recovery of functionality with time for immersed tunnel with different PGAs.

Figure 9. Resilience index of immersed tunnel.

3.3.2 Effect of the soil-structure relative stiffness ratio

The soil-structure relative stiffness ratio F is defined as (Wang, 1993)

$$F = \frac{G}{24} \left(\frac{d^2 H}{EI_B} + \frac{dH^2}{EI_H} \right) \quad (10)$$

Where, G is the shear modulus of soil; d and H are the width and height of the tunnel, respectively; E is the elastic modulus of the tunnel; I_B is the inertia moment of the top and bottom plate; and I_H is the inertia moment of the side wall.

The soil-structure relative stiffness ranges from 0.0006 to 0.03 in the analysis and the resilience index is shown in Figure 10. It can be seen from the

figure that with the increase of the soil-structure relative stiffness ratio, the t resilience index gradually increases, that is, the greater the relative stiffness ratio, the higher the tunnel resilience.

Figure 10. Resilience index with different soil-structure relative stiffness ratios.

4 CONCLUSIONS

This paper established an evaluation method for the longitudinal seismic resilience of immerse tunnel. Based on the longitudinal dynamic response analysis model of multi-scale immerse tunnel, the seismic fragility curve is established. Combined with the recovery model proposed by FEMA, the seismic resilience of tunnel is quantitatively evaluated. Parametric analyses were performed to investigate the influence of PGA and the soil-structure relative stiffness ratio. It is shown that the residual function of the tunnel after earthquake significantly decreases with the increase of PGA. And the seismic resilience increases with increasing soil-structure relative stiffness ratio.

It is worth noting that this paper aims to establish a framework for evaluating the longitudinal seismic resilience of immersed tunnels, but there are still unavoidable limitations. The restoration models need to consider the influence of various factors, which is closely related to the damage situation of the component, repair cost, repair priority and other factors, involving social, technical and economic factors, etc. The model adopted in this paper is a simplified model proposed by FEMA based on the data of California, so a more reasonable functional function recovery model needs to be developed in the subsequent research to consider the tunnel construction, maintenance costs and related uncertainties accurately and quantify them.

Void detection method and its application for steel shell-concrete interface of immersed tube tunnel

Songhui Li & Yan Zhang*

State Key Laboratory of Simulation and Regulation of Water Cycle in River Basin, China Institute of Water Resources and Hydropower Research, Beijing, China

Shaokong Feng

School of Naval Architecture, Ocean and Civil Engineering, Shanghai Jiaotong University, Shanghai

ABSTRACT: In the manufacturing process of sandwich-structured immersed tunnel (SSIT), the self-compacting concrete cannot be vibrated. Therefore, the bonding surface between the steel plate and concrete is susceptible to void defects, and the overall safety of the tunnel will be adversely affected. In this study, we performed void detection on large-scale steel shell-concrete SSITs using the impact imaging method and proposed some void defect control methods. First, the relationship between impulse response and each of the void area and void depth was derived theoretically. Next, a full-size model of a steel shell-concrete SSIT was established. According to the waveform characteristics of shock response measured by the test, an impact response strength index was proposed as a quantitative criterion for void detection. The relationship between the normalized impact response strength and the height of cavitation was fitted, and the quantitative criterion of sinking tube cavitation was put forward. The accuracy rate of test data was up to 87.5%. Using this method, 32 tubes in the Shenzhen - Zhongshan bridge were inspected, and by summarizing the void law, suggestions to improve the casting process were proposed, such as adjusting the casting speed. Meanwhile, the void probability decreased significantly. The proposed method provides an important basis for high - quality construction in SSIT projects.

1 INTRODUCTION

Immersed tube tunnels are widely used in large underwater tunnelling projects, and have two main structural forms, namely reinforced concrete immersed tubes and steel shell - concrete immersed tubes (Grantz,1997 and Lin et al., 2017). Reinforced concrete immersed tubes have a reinforced concrete structure as the core component of the immersed tube, complex prefabrication and casting processes, and stringent constraints for prefabrication sites (Deng et al., 2002 and Yu et al., 2000). The walls, ceiling slab, and base slab of the shell - concrete immersed tube are assembled in sections using steel components, self - compacting concrete being poured into the interior of the steel compartment after assembly. This structural form is also known as sandwich - structured immersed tunnel (SSIT) (Kimura et al.,

2002, Akimoto et al., 2002 and Bowerman et al., 2002). The steel shell of an SSIT serves as the main component for bending and shear resistance and as a waterproof layer. The concrete serves as the ballast and bears the pressure (Liu et al., 2021). The overall structure has several advantages, such as a high carrying capacity, small section size, good waterproof performance, no temperature control crack prevention problems, and construction convenience (Nie, 2019). Among which, the largest being the under - construction SSITs in the world is the Shenzhen - Zhongshan bridge in China (Luttikholt et al., 2022).

The SSIT is cast with self - compacting concrete through the reserved pouring holes and ventholes. Because the self - compacting concrete casting cannot be subjected to vibration, void defects can occur during the casting process and cannot be directly observed. The voids can reduce the carrying

*Corresponding author: zhangyan@iwhr.com

capacity of the structure and lead to local buckling, affecting the overall safety and long - term service life of the structure (Nie, 2019 and Guo et al., 2019). The detection of steel shell - concrete voids has many challenges. First, the thickness of steel plate, as a load - bearing component of the SSIT, is generally more than 14 mm (to meet force requirements), while that of the steel plate even reaches 40 mm at the local position of the ultra-wide tube section. Therefore, void detection must be performed through the thick steel plate to reach the void-defect area and carry details of the defects back to the surface of the steel plate. Second, there are longitudinal and transverse bulkheads, stiffening ribs, and other components in the steel-shell structure that make the structure very complicated. Third, the results of SSIT model tests have shown that with a 14 - mm thick steel shell, local void depths of 10 mm or more are unacceptable in a steel-shell-concrete compartment of size $3.5 \times 3 \times 1.5$ m, and void depths of more than 5 mm had to be avoided in the structural design (Guo et al., 2019). Consequently, the complex form of the thick steel-plate cover, dense distribution of ribs, millimetre-scale detection accuracy, and high detection efficiency requirements are problems that need to be addressed (Liu et al., 2022 and Mizuno et al., 2013).

Researchers have tried to address the high precision and efficiency detection requirements of steel shell - concrete void detection using ultrasonic, infrared thermal imaging, impact elastic wave, acoustic, neutron, and impact imaging methods (Mizuno et al., 2013, Yanagihara et al., 2013, Nishioka et al., 2008, Mitsuo et al., 2008, Chen et al., 2020, Mandal et al., 2012 and Meng et al., 2013). Among them, impact acoustics and impact imaging methods are the only methods that can simultaneously distinguish the type, as well as the area and depth of a void defect. However, some experimental studies conducted in Japan (Nishioka et al., 2008 and Mitsuo et al., 2008) show that when the impact acoustics method is used, the small gap that forms between the steel plate and concrete due to hardening-induced shrinkage may be misidentified as a void defect. In addition, the impact acoustics method demonstrates low efficiency (approximately 30 s/point), and in practical engineering applications, its detection accuracy is generally only 60%–70%. The impact imaging method originates from seismic imaging in petroleum exploration. In this method, an elastic wave field is generated on the surface of the structural component mechanically, e.g., using a steel hammer or a steel ball. The health of the structural component is determined based on the analysis of the reflected waveforms. The application and the effectiveness of this method for void detection in steel shell-concrete SSITs have not been reported.

The aim of this study is to investigate void detection using the impact imaging method and propose methods of void defect control for steel shell-

concrete SSITs, and hoping to realize the quantitative detection of millimetre void of thick steel shell-concrete interface. First, the relationship between impulse response and the void volume is derived theoretically. Next, a full-size model of a steel shell-concrete SSIT is established. Finally, the accuracy of the impact imaging detection method is analysed.

2 THEORY

The impact imaging method uses a phase-controlled array to collect the elastic wavefield on the surface of a medium to reflect an image of its internal structure on its surface, before analyzing the spatial distribution characteristics of the full wavefield through inverse mapping.

The normalized free vibration waveform is integrated with respect to time to obtain the impact response strength function, as follows:

$$I(k) = \Delta t \times \sum_{i=1}^k (x(i-1) + x(i))/2 \quad (1)$$

where $I(k)$ is the impact response strength function; Δt is the time interval; k is the number of sample data points obtained during the free vibration test; $x(i)$ is the value of the i -th sampling point; i is the number of the sampling point, where $i = 1, 2, 3, \dots, k$.

After the void area at the detection point is obtained through integration, the calculated value is corrected using the actual void area. Once obtaining the corrected void area, the relationship between the impact response strength and the void index of the thick steel shell-concrete can be established.

The void area within a detection area of a thick steel shell-concrete structure is expressed as:

$$\begin{aligned} A_c &= \iint \psi(x, y) dx dy \\ &= \Psi(x_1, y_1) \Delta s + \Psi(x_2, y_2) \Delta s + \dots + \Psi(x_3, y_3) \Delta s \\ &= A_{c1} + A_{c2} + \dots + A_{cn} \end{aligned} \quad (2)$$

$$\psi(x, y) = \begin{cases} 0, & d < 5mm \\ 1, & d > 5mm \end{cases} \quad (3)$$

where A_c represents the void area in the detection area of a thick steel shell-concrete structure; $\Psi(x, y)$ is the discriminant function of the void area at different detection points; x_n and y_n represent the coordinates of the n -th detection point; Δs is line spacing of the detection grid; A_{ci} is the void area at the i -th detection point; d_i is the void depth at the i -th detection point, which is related to the impact response strength and can be expressed as:

$$d_i = -ae^{-bl_i} + c \quad (4)$$

where I_i is the impact response strength at the i -th detection point; a , b and c are constants. Thus, the void volume is the multiplication of the void area and depth.

The positive correction factor between the calculated and actual void area is expressed as:

$$\alpha = A_m/A_c \quad (5)$$

where A_m represents the measured void area, and A_c is the calculated void area. Therefore, the corrected void area is

$$A'_c = \bar{\alpha}A_c \quad (6)$$

where A'_c is the corrected void area, and $\bar{\alpha}$ is the average correction factor calculated based on sampled void defect data.

3 FULL-SCALE MODEL EXPERIMENT

3.1 Model establishment

The SSIT comprises a fully enclosed steel shell structure filled with self-compacting concrete. Several transverse and longitudinal partitions are arranged between the inner and outer plates of the steel shell to integrate them into a single force-bearing frame, thereby increasing the overall shear bearing capacity of the SSIT. Furthermore, the entire shell is partitioned into multiple independent compartments, which facilitates the pouring of self-compacting concrete. The full-scale model of an SSIT section and the layout of one compartment are shown in Figure 1. To strengthen the effective bonding and synergistic force between the steel shell and concrete, steel studs and longitudinal T-stiffeners are installed in the top-slab compartments, as shown in Figure 2(b), and multiple longitudinal stiffeners and transverse flat ribs are installed in the bottom-slab compartments, as shown in Figure 2(c). Each compartment is designed with a pouring hole and air vents, as shown in Figure 3.

The full-scale model of the steel shell–concrete SSIT section used in this study is 9.6 m long, 55.4 m wide, and 10.6 m high. The steel shell comprises 14 mm/44 mm steel plates welded together, with the entire shell structure weighing approximately 740 t. Additionally, approximately

Figure 1. Full-scale model and compartment partitioning of steel shell SSIT section.

Figure 2. Stiffener components.

Figure 3. Full-scale model of typical compartment.

1500 m³ of self-compacting concrete was used to independently cast 105 compartments.

3.2 Material properties and concrete mix proportion

The material parameters and mix proportions of the self-compacting concrete are shown in Tables 1 and 2, respectively.

3.3 Detection method

In the present study, the full-scale model was manufactured, transported, and poured using actual construction

Table 1. Material parameters.

Cement	Fly ash	Slag powder	Fine aggregate	Coarse aggregate	Coarse aggregate	Water	Plasticizer
P II42.5	Grade I	S95	Grit	(5–10 mm)	(10–20 mm)	Tap water	Polycarboxylate superplasticizers

methods and processed under typical operating conditions of a steel shell–concrete SSIT. Therefore, the void defects formed naturally during the pouring process without any human intervention. Void detection was performed during the initial setting period of concrete in the poured compartments.

3.3.1 Data acquisition equipment

The detection system used in the present experiment is shown in Figure 4. Elastic wave excitation was performed manually using a steel hammer; the excitation frequency ranged from tens to thousands of Hertz. The testing equipment included a medium-high frequency vertical geophone (100 Hz) with a sensitivity of $0.28 \pm 5\%$ (V/cm/s), and a US-made high-resolution GEODE seismograph. During data acquisition, the impact strength must remain as consistent as possible. The impact magnitude should be recorded and normalized to eliminate the human factor.

Figure 4. Schematic diagram of testing equipment.

3.3.2 Data acquisition

In the present void detection experiment, each compartment of the full-scale model was regarded as a data acquisition unit. The data acquisition process is as follows:

(1) Testing-grid layout: during detection, the elastic wave excitation and data acquisition devices should be applied strictly along the designed grid lines. In each tested compartment, the detection grid lines were arranged along the direction of the T-stiffeners. For a typical compartment measuring $2.8 \text{ m} \times 3.5 \text{ m} \times 1.5 \text{ m}$, the grid line spacing was set to 10 cm, except the areas adjacent to the T-stiffeners, where a denser spacing of 5 cm was used, as shown in Figure 5(b). Therefore, in areas adjacent to the T-stiffeners, a uniform $5 \text{ cm} \times 10 \text{ cm}$ grid was used, whereas in the remaining areas, a uniform spacing of $10 \text{ cm} \times 10 \text{ cm}$ was used.

(2) Elastic wave excitation and data acquisition: A small hammer was used to hit the steel top-plate of the compartment, generating an elastic wave field in the detection area. A vertical geophone was placed 10 cm away from the excitation location to record the waveform data. A single-point method of data acquisition was adopted along the detection lines, with an acquisition interval of $20.83 \mu\text{s}$ and a total of 8,192 sampling points. After the stress wave propagation and reflection signal were recorded by the vertical detector, the data acquisition system was shifted to the next detection point while maintaining a constant distance between the excitation and receiving points. In addition, the striking direction and strength were maintained constant. The process above was repeated along the entire grid line, as shown in Figure 5(d).

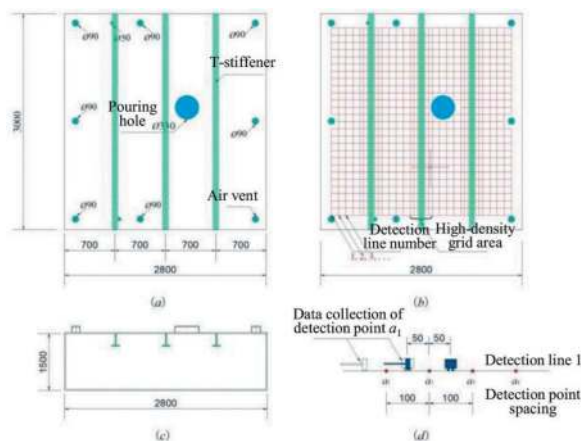

Figure 5. Detection point layout on compartment surface (units: mm).

3.4 Void characteristics

3.4.1 Measurement of void index

After the initial concrete setting period, the steel shell plates of 10 randomly selected compartments were partially cut open to verify the condition of the poured concrete at those locations. The positions of the selected compartments in the full-scale model are shown in Figure 6. In each compartment, we randomly selected six square grid units ($30 \text{ cm} \times 30 \text{ cm}$) to cut open the steel shell. Each grid unit contained 15 to 21 detection points. The void area can be obtained by calculating the number of grid units along the

measuring line, and the void depth can be read using a Vernier caliper and a measuring frame.

Figure 6. Layout of open compartments in full-scale section model.

3.4.2 Void defect characteristics

A typical compartment was selected to determine the condition of the poured concrete. The cutting locations of the steel shell and their corresponding numbers are shown in Figure 7.

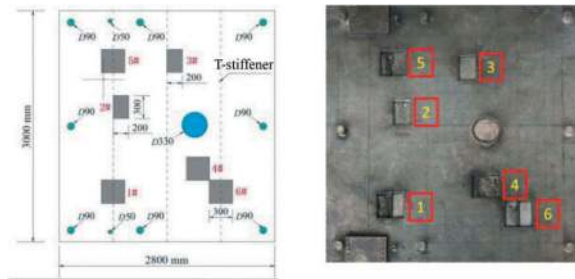

Figure 7. Distribution and numbering of steel shell opening locations in typical compartment.

4 DATA ANALYSIS

4.1 Impact response strength index

The impact response strength I defined in Equation (1) can be used as a potential discriminant parameter for detecting voids in steel shell – concrete structures via the elastic wave method. In actual signal processing, I can be calculated by integrating the absolute value of the normalized impulse response signal during the acquisition period t . The original signal is composed of a set of discrete equidistant sampling points. Therefore, the integral of the waveform signal can be approximated as the sum of the product of all previous sampling values and the sampling time, as follows:

$$\begin{aligned}
 I &= \int |x(t)| dt \\
 &= \int_0^t |I_1 \sin(\omega_1 t + \varphi_1) + \dots + I_n \sin(\omega_n t + \varphi_n)| dt \\
 &\approx \sum_{i=1}^{i=s} |F_i| * \Delta t,
 \end{aligned} \tag{7}$$

where F is the waveform amplitude, Δt the sampling time interval, i the number of sampling points at time t , and $s = 1, 2, \dots, n$.

4.2 Correlation between impact response strength and void depth

The impact response strength index I_i of the detection points at open-shell locations and the corresponding void depths d were analyzed statistically to determine the relationship between the response intensity and void depth; the resulting best-fit curve is shown in Figure 8. The best-fit curve was expressed in Equation (8) with a correlation coefficient (R) of 0.916 and a coefficient of determination R^2 of 0.839.

$$d = -25.58e^{-0.08I_i} + 23.1 \tag{8}$$

Based on the fitting curve, we propose a quantitative criterion for the non-destructive testing of void defects in steel shell–concrete SSITs, as shown in Table 3. Different colors (blue, yellow, orange, and red) signifying different void depths were used to represent the bonding condition between the steel plate and concrete.

Figure 8. Comparison between detection results and measured data at open-shell locations.

4.2 Verification of testing criterion

The void detection was performed again on another 5 model compartments. The steel shell cover of each compartment was cut open in six randomly selected locations for verification. Figure 9 shows the comparison between the detected and actual conditions at six typical open-shell locations. It is evident that the detection results were generally consistent with the actual condition of the concrete surface. The detection results at all 30 open-shell locations were analyzed statistically to determine their accuracy in reflecting the actual condition of the concrete

Table 3. Normalized impact response strength index.

Normalized impact response strength (A)	Color code		Bonding condition	Description
$A \leq 2.3$		blue	Dense	Steel plate and concrete are closely bonded
$2.3 < A \leq 3.3$		yellow	2–3 mm	Steel plate and concrete are not bonded; concrete has a honeycomb-pitted surface; the void depth is 2–3 mm
$3.3 < A \leq 5.0$		orange	3–5 mm	Steel plate and concrete are not bonded; void depth is 3–5 mm
$A > 5.0$		red	5 mm or more	Steel plate and concrete are not bonded; suspected void depth is ≥ 5 mm

Figure 9. Comparison between normalized impact response strength values and actual condition of concrete surface.

surface. It was discovered that the coincidence rate between the detection results and the actual surface condition was 87.5%.

5 CONCLUSION

The aim of this study was to investigate void detection using the impact imaging method and propose methods of void defect control for steel shell-concrete SSITs. The main conclusions are as follows:

- (1) By extracting the impact response energy and waveform processing, the impact imaging

method could quantitatively calculate the void area and classify the voids based on a specific depth range.

- (2) The void location, area, and depth were determined as metrics to describe the void severity in thick steel shell - concrete immersed tube tunnels, and using four levels for the void depth - namely, 0 - 3, 3 - 5, and > 5 mm - the bonding state of the steel plate and the concrete could be described.
- (3) The relationship between impact response strength I and void depth d was established statistically through full-scale model experiments, based on which the quantitative void detection criterion was proposed. The void detection accuracy using the impact imaging method was shown to reach 87.5% through experimental verification.

ABSTRACT: In order to meet the transportation and installation requirements of tunnel elements in nearshore shallow water environments and overcome the economic problems of prefabrication factories and the installation site of tunnel elements, shallow draft semi-submersible barges are employed for the long-distance transportation and installation of tunnel elements. For offshore installation operations of tunnel elements dominated by waves, the operating limit is typically expressed by allowable sea state parameters, such as the significant wave height (H_s) and spectral peak period (T_p). However, due to their particularity, in-depth research is required to accurately determine the large scale and shallow draft parameters of shallow draft semi-submersible barges. Moreover, the allowable sea conditions need to be evaluated during the planning phase of long-distance transportation and installation. Multiple sources of uncertainties (e.g., weather forecasts, wave spectrum models, and numerical models) must also be considered in the allowable sea conditions to provide safety margins. Based on the response spectrum and failure probability analysis of the operating conditions, this study establishes an adaptability analysis method for tunnel element transportation and installation using a shallow draft semi-submersible barge and evaluates the impact of wind sea and swell sea on its propagation under different directions and propagation directions in the Guangdong–Hong Kong–Macao Greater Bay Area. We also investigate the adaptability of long-distance transportation and installation using a shallow draft semi-submersible barge and assess the construction operation limits of the transportation and installation for tunnel elements. A case study using a semi-submersible barge to transport and install tunnel elements was selected to address these uncertainties in the allowable construction sea conditions, and to subsequently analyse the adaptability and superiority of tunnel element transportation and installation using a shallow draft semi-submersible barge.

Keywords: tunnel element, operational limit, shallow draft semi-submersible barge, response spectrum, failure probability

1 INTRODUCTION

Immersed tube tunnels and shield tunnelling are important types of river crossing channels. The immersed tunnelling method has the advantages of less land occupation, a lower navigation impact, and a fast construction speed compared to shield tunnelling. However, the former also requires a greater amount of construction technology and accurate construction monitoring systems. With the continuous maturity of its construction technology, the construction scale of immersed tunnelling is constantly growing and the construction conditions are becoming more complex. Furthermore, immersed tunnels are typically constructed using dry dock or factory

prefabrication. Prefabrication is followed by wet towing or the specialized floating construction of towing ships for floating transportation. However, urban traffic congestion, narrow urban spaces, and the high cost of axis dry docking act as key bottlenecks affecting the construction cycle and cost of immersed tube tunnels. Thus, employing off-site dry docking or factories for prefabrication and long-distance floating transportation to the installation site has become a preferred construction method (Hu, Xie et al. 2015, Quanke, Yongling et al. 2022). Despite this, due to the complex sea conditions and higher requirements for the crack control of tunnel elements, long-distance floating transportation can pose potential risks during construction and have

*Corresponding author: linmeihong@qq.com

a huge impact on the safety of tunnel construction. Therefore, the risk assessment and control of risk factors for immersed tunnel construction are of great significance (Busby and Marshall 2000).

Sudden disastrous weather is an important risk factor during floating transportation (Dong, Li et al. 2023). By analysing the motion behaviour of the tunnel element and installation ship system under different wave, current, and ballast system load combinations, the weather window for the tunnel element can be determined. This consequently ensures that the tunnel element can be safely and accurately transported to the installation site for installation (Huang, Zhang et al. 2016). Thus, in-depth research is required to select the response measures for tunnel element movements under long-term regular and irregular wave actions. This with aid in improving the predictions of the accurate and safe handling of tunnel elements under adverse weather conditions (Song, Zhang et al. 2018).

Despite the current availability of numerous advanced software (e.g., ANSYS AQWA, and OrcaFlex) for the time-domain response analysis of a three-dimensional floating body motion, establishing accurate numerical simulations to predict its six-degree of freedom motion is still highly challenging. Time-domain methods can be inefficient due to their long calculation time and the large number of calculation conditions implemented for long construction windows. Although frequency domain and spectral analyses methods have been applied to the motion analysis of large floating structures, there is relatively little research on the motion of tunnel elements transported by transport vessels (Li, Haver et al. 2021). Combining frequency domain analysis methods with spectral analysis can potentially be used to predict the motion response of tunnel elements.

In this study, based on the frequency domain calculation of three-dimensional potential flow theory and the wave spectrum analysis method, we establish a calculation approach for the motion response spectrum of a semi-submersible barge during transportation. The spectral energy distribution of the shallow draft semi-submersible barge under different wave directions is subsequently analysed, and the boundary conditions of the semi-submersible barge construction are obtained using a probability-based approach. The time series data is then employed to analyse the operability for construction window of the semi-submersible barge.

2 METHODOLOGY FOR THE ASSESSMENT OF OPERATIONAL LIMITS

For the motion response prediction of a semi-submersible barge during offshore construction, it is usually assumed that the semi-submersible barge generally moves in a rigid body under the action of wind, waves, and currents. Current dynamic analysis methods and software used to simulate small

amplitude waves on floating bodies are relatively mature, and the calculation results based on commercial software such as ANSYS AQWA have a high accuracy for semi-submersible barge construction analysis. The motion response of a semi-submersible barge is calculated based on three-dimensional potential flow frequency domain theory. ANSYS AQWA solves a set of linear algebraic equations to obtain the harmonic response of a semi-submersible barge to regular waves. These response characteristics are commonly referred to as response amplitude operators (RAO) and are proportional to the wave amplitude. The linear frequency domain motion equations of hydrodynamic interaction structures with frequency correlation coefficients can be expressed as follows:

$$[-\omega^2(M_s + M_a) - i\omega C + K_{hys}] [X_j] = [F_j], \quad (1)$$

where ω is the frequency; M_s is the float body mass matrix; C is the damping matrix; K_{hys} is the hydrodynamic stiffness matrix; X_j is the motion response; and F_j is the external force. Equation (1) can be expressed as $[X_j] = H [F_j]$, and $H = \{-\omega^2(M_s + M_a) - i\omega C + K_{hys}\}^{-1}$.

We determined the $RAO(\omega)$ of the incident waves at different angles acting on the semi-submersible barge through commercial hydrodynamic analysis software such as ANSYS AQWA. The motion response of the semi-submersible barge was then calculated as follows:

$$S_{res}(\omega) = S(\omega)RAO^2, \quad (2)$$

where RAO is the amplitude response operator of the barge motion calculated in equation (1); $S_{res}(\omega)$ is the motion response spectrum; and $S(\omega)$ is the irregular wave spectrum. In offshore seas, the irregular wave spectrum is generally a mixed wave composed of wind waves and swells. The combination of wind waves and swells can be described using a bimodal spectrum, as in equation (3):

$$S(\omega) = S_{wind}(\omega) + S_{swell}(\omega), \quad (3)$$

where $S_{wind}(\omega)$ is the wind-wave spectrum; and $S_{swell}(\omega)$ is the swell wave spectrum.

In addition, the actual sea waves are usually multi-directional and irregular, and the wave energy spectrum function is a function of the wave direction and frequency. The length width ratio of the plane dimensions of semi submerged barges and other construction ships often exceeds 2. Thus, the motion response peak frequency of semi submerged barges in the length and width directions can be different. The different directions and frequency distribution characteristics of irregular wave energy spectra complicate the motion response analysis of semi-submersible barges. During the construction process,

the length direction of semi-submersible barges usually maintains a small angle with the spectral direction to avoid significant rolling motion. However, the characteristics of multi-directional irregular waves may increase the roll. Therefore, it is necessary to analyse the motion response characteristics of semi-submersible barges under the action of multi-directional irregular waves. The directional spectrum of multi-directional irregular waves can be expressed as:

$$S(\omega, \theta) = S(\omega)G(\omega, \theta), \quad (4)$$

where $S(\omega, \theta)$ is the multidirectional wave spectrum; and $G(\omega, \theta)$ is the directional distribution function of ocean waves, with

$$\int_{\theta_{min}}^{\theta_{max}} G(\omega, \theta) d\theta = 1, \quad (5)$$

where $[\theta_{min}, \theta_{max}]$ is the directional distribution range of the multi-directional wave spectrum. Considering equations (4) and (5), equation (3) becomes:

$$S(\omega, \theta) = S_{wind}(\omega)G_{wind}(\omega, \theta) + S_{swell}(\omega)G_{swell}(\omega, \theta). \quad (6)$$

The influence of frequency can generally be ignored, and the wind wave spectrum can thus be expressed as:

$$G(\theta) = \frac{\Gamma(1 + \frac{n}{2})}{\sqrt{\pi}\Gamma(\frac{1}{2} + \frac{n}{2})} \cos^n(\theta - \theta_p), \quad (7)$$

Where Γ is the Gamma function, θ_p is the main wave direction. Finally,

$$S_{res}(\omega, \theta) = S(\omega, \theta)RAO^2(\omega, \theta). \quad (8)$$

For semi-submersible barge construction operations within a limited duration, the barge movement within 3 hours can be used as the basic parameter for its operation, and multiple 3-hour windows can be analysed as the analysis conditions for continuous operations. By further assuming that the global maximum is statistically independent and identically distributed, the distribution of $N_{3h}=10800/T_z$ can be expressed as follows:

$$F(x_j) = \left\{ 1 - \exp\left\{-\frac{1}{2}\left(\frac{x_j}{\sigma_j}\right)^2\right\}\right\}^{N_{3h}}. \quad (9)$$

In order to determine the appropriate extreme sea state, we assume that the probability of the maximum value exceeding the limit $x_{j,lim}$ within 3 hours is less than the selected target failure probability q_{3h} hours. To meet this requirement, the following equation should be met:

$$P[x_{j,3h} > x_{j,lim}] = 1 - \left\{ 1 - \exp\left\{-\frac{1}{2}\left(\frac{x_{j,lim}}{\sigma_j}\right)^2\right\}\right\}^{N_{3h}} \leq q_{3h} \quad (10)$$

By calculating the motion response index using equation (10), the boundary wave parameters with the limiting conditions can be determined.

3 FLOATING TRANSPORTATION PARAMETERS AND PROCESS

3.1 Main scale parameters of the semi-submersible barge

Figure 1 presents the hull shapes of the semi-submersible barge employed in the case study. Table 1 reports the corresponding characteristics. The ship is mainly used for the transportation of large tunnel elements for nearshore tunnel construction. It is also used as a dock to repair ships, as a prefabricated platform for large caissons, for the towing and transportation of large offshore components, and the dispatch and transportation of engineering ships.

The semi-submersible barge selected for the case study is employed as a transportation platform for large tunnel elements. The barge is connected to the dock and a wheel rail type trolley is used to roll and transport the tunnel element from the dock to the loading area of the deck and place it on the support pier. The semi-submersible barge is towed to the diving area by a tugboat to dive. The immersed tunnel element floats and is pulled away from the semi-submersible barge. The semi-submersible barge then begins to float and enters the next working cycle.

The semi-submersible barge has core advantages such as a high cargo capacity, universality, and intelligence, and a strong ballast capacity. Moreover, it has an excellent “wide, flat, and shallow” draft performance. The ship can significantly reduce the amount of channel dredging, avoid the construction of large dry docks, and effectively reduce the construction costs of immersed tube tunnels.

Figure 1. Hull shape of the semi-submersible barge in the case study.

Table 1. Key parameters for the semi-submersible barge.

Parameter (unit)	Value
Length (m)	164
Moulded breadth (m)	65
Moulded depth (m)	10.2
Operational draft (m)	6.0
Displacement (kg)	5E7
Design load capacity (kg)	4.5E7

3.2 Floating transportation process

The loading, transportation, unloading, and floating in the foundation trench require strict hydrological and meteorological constraints. The selection of the construction window is a complex process related to the overall project schedule, project risks, and equipment costs. It thus requires comprehensive argumentation and analysis to ensure the safe installation of tunnel elements.

We used the tunnel construction in Tai Shan Bay of Shenzhen as an example. During the transportation process of semi-submersible barges, due to the complexity of the wind, wave, and flow parameters compared to inland rivers, and the resistance to oblique currents, the total floating resistance of semi-submersible barges is usually analysed at different upstream angles and tugboat configurations. The semi-submersible barge transports tunnel elements from Niutou Island through the Rongshutou Waterway to the Lingdingyang Waterway, and subsequently passes through the Tonggu, Shenzhen Public, and Tai Shan Bay Channel Waterways to a dedicated diving pit for the semi-submersible barge (Figure 2). Table 2 reports the angle of each transportation path and Figure 3 depicts an example of the towing system.

Figure 2. Transportation path of the semi-submersible barge of the case study.

Table 2. The angles of each transportation path in the case study.

Transportation Path	The angle between the current direction and the orientation of barge(°)
Rongshutou Channel	12, 168
Lingdingyang Channel	-11, 191
Tonggu Channel	25, 155
Shenzhen Western Channel	0, 180
Tai Shan Bay Channel	0, 180

Figure 3. Example of a towing system in the case study.

4 RESULTS

The model for the semi-submersible barge is determined by analysing the wave angles that could potentially be encountered along the entire transportation path, combined with the energy distribution of the wind, waves, and swells. In this section we analyse the construction limiting parameters and construction windows of the semi-submersible barge.

4.1 Numerical model and parameters

The model of the semi-submersible barge and tunnel elements is established using ANSYS AQWA. Frequency domain analysis is then performed and the corresponding RAO is obtained. Figure 4 presents the numerical model and Table 3 reports the corresponding calculation parameters.

Figure 4. Numerical model.

Table 3. Parameters of the barge.

Parameters (unit)	Value
Tunnel element length (m)	80
Total mass (Kg)	70435900
I_{xx} ($\text{kg}\cdot\text{m}^2$)	3.18E10
I_{yy} ($\text{kg}\cdot\text{m}^2$)	2.71E11
I_{zz} ($\text{kg}\cdot\text{m}^2$)	3.00E11

4.2 Statistical analysis of sea state parameters

The waves are affected by many islands in the Pearl River Estuary, and the wave propagation is complex. The SE, SSE, S, and SW waves are the main wave directions in this sea area. The annual maximum wave height (H_m), $H_{1/10}$, H_s and H_z are 2.58 m, 1.81m, 1.43 m, and 0.89 m, respectively, all of which occur in August.

Taking the wave data of March and August 2020 from ERA5 data set of ECMWF as an example, Figures 5 and 6 present the significant wave height (H_s) and spectral peak period (T_p) of the total sea, wind sea and swell sea of the wave data. Although these scatter plots overlap, the swells are generally steeper and have longer periods compared to windy seas. Extreme wave conditions with high H_s values are usually dominated by wind seas, and wind waves and swells tend to occur simultaneously. In addition, the two-month scatter plot clearly reveal that August is more likely to experience severe wave conditions. This is due to the influence of the typhoons Mekkhala and Higos, and indicates significant deviations in the operability of transportation operations across the two months. Based on the data from March, 26.8% of the angle differences between total sea and swell sea exceed 10° , while 8.8% of the angle differences between total sea and swell sea are greater than 30° . Moreover, based on the data from August, 16.5% of the angle differences between total sea and swell sea are greater than 10° , while 2.6% of the angle differences between total sea and swell sea that greater than 30° .

Figure 5. Scatter plot of the sea state parameters for H_s and T_p from March, 2020.

Figure 6. Scatter plot of the sea state parameters for H_s and T_p from August, 2020.

4.3 RAO Characteristics

Table 2 reports the natural periods of the barge, which range from 9 to 21 s. The size of the semi-submersible barge is observed to have a strong adaptability to the wave period of 3–9 s in the nearshore sea area (Figure 7 and Table 4). The differences in ship size induce a 1.85 times difference in the natural periods of roll and pitch, with a corresponding increase in the motion response by 4.59 times. Under the action of oblique waves, multiple peaks appear in the motion response due to its coupling effect.

4.4 Operational limit analysis

Large variations are observed in the spectral density distribution across the entire wave frequency when using JONSWAP and Torsethaugen spectra. In particular, the response spectrum peak of JONSWAP is close to 5–7 s, while when using the bimodal spectrum, the energy is concentrated around 6–8 s. When the Torsethaugen spectrum is adopted, the spectrum density of the semi-submersible barge is distributed over a wider frequency range. Moreover, the difference in heave response spectrum values between the two spectra types exceeds 1.66 times.

Figure 9 present the operational limits of several incident angles. Due to the misalignment of sea condition and barge direction, the allowable sea conditions are lower than those of the alignment conditions. For wave conditions with T_p values less than 9 s, the misalignment may result in a 30–50% reduction in the maximum allowable H_s values.

4.5 Operability analysis

The operability of floating transport operation is defined as the ratio between the length of the operable weather window and the total reference duration. We calculated the monthly construction operability based on equation 10 and using continuous 3-hour operation data of year 2020 from ERA5 data set of ECMWF.

(a) Heave

(b) Roll

(c) Pitch

Figure 7. RAOs of the barge for three wave directions (The direction is defined as the angle between the wave propagating direction and the positive X-axis measured anti-clockwise).

Table 4. Natural periods of the barge motion.

Motion	Value (s)
Heave	20.9
Roll	9.6
Pitch	17.9

Table 5 shows the corresponding parameters. Note that due to the strong seasonal variations in sea state data, independent calculations and analysis were conducted on the operability of each month. Operability calculations were performed using JONSWAP (Total sea parameters), Torsethaugen spectra (Separate sea parameters: swell wave + wind wave) and both include

(a) Heave (JONSWAP sea, Torsethaugen sea)

(b) Roll(JONSWAP sea, Torsethaugen sea)

(c) Pitch(JONSWAP sea, Torsethaugen sea)

Figure 8. Response spectra for motion, $S(\omega, \theta)$, with misaligned wind sea and swell sea (total sea: $H_s = 1.19$ m, $T_p = 6.37$ s, direction = 172.5° ; wind sea components: $H_{s1} = 1.00$ m, $T_{p1} = 5.04$ s, direction = 176° , $n_1 = 2$; swell sea component: $H_{s2} = 0.65$ m, $T_{p2} = 7.66$ s, direction = 162.5° , $n_2 = 12$).

Figure 9. Allowable sea states.

Figure 10. Operability (total sea, separate sea and total + separate sea).

Table 5. Parameters.

Parameter	Value(unit)	Failure probability
Heave	0.1m	0.0001
Roll	1°	0.0001
Pitch	0.5°	0.0001

condition (Total sea + Separate sea), respectively. Adopting both include condition for operability analysis resulted in a 10% reduction in operability during the months 05-09 and a 10% reduction in operability during the months 10-04, and the variability in the operability was higher within months (10-02). The operability in all directions during winter (10-11) was on average below 40%. This reveals that using both include condition for the analysis can account for inconsistencies in the surge direction, and the constructability analysis results are more reasonable.

5 CONCLUSIONS

In order to address the uncertainties in the operational limits caused by different sea state modelling

methods, this article adopts a case study that implements a semi-submersible barge to transport tunnel elements. We analysed the characteristic parameters and adaptability to sea conditions of semi-submersible barges, and compared the effects of the wave propagation, wave spectrum types, and directional deviation of wind and swell seas on semi-submersible barges. Following this, we calculated the construction operability. Based on the results, the following key conclusions were obtained.

- (1) The design of the semi-submersible barge size has strong adaptability to wave periods of 3–9 s in the nearshore sea area.
- (2) The direction misalignment of wind seas and swell seas can enhance the motion response, which subsequently increases the difficulty in controlling the towing system.
- (3) Due to the misalignment of the wind sea and swell sea components, the allowable sea conditions are reduced compared to the alignment conditions. For wave conditions with T_p values less than 9 s, misalignment may result in a 30–50% decrease in the maximum allowable H_s value of both containers.
- (4) Analysis based on both include condition is able to consider the inconsistencies of surge direction, which increases the reasonability of the constructability analysis results.

ABSTRACT: As a new production mode, the intelligent manufacturing has become the development direction for the future manufacturing industry. The steel shell used in the Shen-Zhong Link steel sandwich immersed tunnel is characterized by its large volume, comprising 32 pipes with a total weight of approximately 320,000 tons. To meet the project's timeline, the production rate of one pipe per month must be achieved. However, traditional process technologies face challenges in achieving high-quality and high-efficiency construction. Therefore, it is imperative to conduct research and apply intelligent manufacturing techniques to ensure the timely completion of this project. This paper presents the key technologies employed in the intelligent manufacturing of steel shells for the Shen-Zhong Link immersed tunnel. By establishing intelligent manufacturing systems and technical standards for steel shells, developing welding robots based on visual recognition, implementing intelligent coating for large steel structures, and integrating BIM-oriented system integration, the large-scale application of intelligent manufacturing for large steel structures has been successfully realized. Moreover, the application of intelligent production lines demonstrates significant advantages over traditional manual operations in terms of efficiency.

Keywords: Shen-Zhong Link steel, intelligent manufacturing, welding robots, intelligent coating

1 INTRODUCTION

In recent years, there has been a global boom in intelligent manufacturing. Germany, known for its manufacturing prowess, proposed the "Industry 4.0 strategy," while the United States put forward the "advanced manufacturing national strategy." In May 2015, China also launched the "Made in China 2025" plan, aiming to achieve the strategic goal of becoming a manufacturing powerhouse through a three-step approach. Transportation construction plays a crucial role in the manufacturing industry, and technologies such as production execution systems (MES), industrial robots, new sensors, and intelligent control systems have been partially applied in transportation construction. However, there is still a significant gap in terms of interconnection, information integration, and other aspects when compared to advanced production models as previously shown (Wu et al., 2016).

Overall, the level of automation and intelligence in transportation construction is still insufficient. The problem of "information islands" remains prominent, and there is a lack of comprehensive integration, collaboration, and innovation.

The Shenzhen-China Channel project is built on the concept of "integration of the two" and seizes the opportunity presented by the "Made in China 2025" initiative. By combining Internet technology, Building Information Modeling (BIM), and smart engineering, the project focuses on research and applications in intelligent manufacturing for steel shell concrete immersed tube tunnel steel structures. This endeavor aims to enhance manufacturing efficiency and quality, ultimately elevating the level of intelligent manufacturing in the transportation industry.

2 PROJECT OVERVIEW TRANSPORTATION TECHNOLOGY

The Shenzhen-China Passage is another world-class mega project that combines bridges, islands, tunnels, and underwater interconnections, following the Hong Kong-Zhuhai-Macao Bridge as previously shown (Song et al., 2020). The immersed tube tunnel measures 5035m in length and consists of a total of 32 immersed tubes with 1 final joint. The standard pipe section spans 165m, while the curve-widened pipe

*Corresponding author: 29888766@qq.com

section extends to 123.8m. The specific division of joints is as follows: $123.8 + 21 \times 165\text{m} + 2.2\text{m} + 5 \times 165\text{m} + 5 \times 123.8\text{m} = 5035\text{m}$. The Shenzhen-China Passage is the first steel-concrete composite immersed tube tunnel scheme in China as previously shown (Xu et al., 2015). The manufacturing of the steel shells for the immersed tube tunnel is a pivotal process within the entire project, as it plays a crucial role in overseeing the overall progress. Each individual standard steel shell pipe section measures 165m in length, 46m in width, and with a height of 10.6m. The maximum weight of a single section reaches 12,500 tons, resulting in a total steel volume of approximately 320,000 tons

3 SINKING TUBE STEEL SHELL STRUCTURE AND DIFFICULTIES

The steel shell primarily consists of internal and external panels, vertical and horizontal partitions, vertical and horizontal stiffening ribs, and welding nails. The inner and outer panels, along with the vertical and horizontal partitions, are interconnected to create a cohesive structure, forming an independent partition for concrete pouring. The longitudinal stiffening ribs are constructed using T-shaped steel and Angle steel, working in conjunction with the transverse flat ribs to enhance the panel's rigidity. Simultaneously, the longitudinal stiffening ribs and welding nails ensure a secure connection between the panel and the concrete, as depicted in Figure 1.

Figure 1. Schematic diagram of basic structure of steel shell.

Based on the structural form and construction process characteristics of Sink steel shells, they are suitable for factory assembly-line manufacturing in large shipyards. However, there are several challenges associated with the construction of Sink steel shells:

- (1) Large volume: A single standard pipe section requires approximately 10,000 tons of steel and involves a weld length of nearly 300 kilometers.
- (2) Complex structure and manufacturing process: The Sink steel shell comprises numerous independent compartments (up to 1597), with staggered horizontal and vertical partitions and

connecting parts. Additionally, there can be up to 15,000 process holes. China lacks mature construction experience in this regard.

- (3) High precision requirements pose a significant challenge in the construction of steel shells. The accuracy standards for steel shells are much higher compared to those in the shipbuilding industry and steel box girder manufacturing. Additionally, the use of Q420 high-strength medium-thick steel plates in large quantities presents difficulties in controlling welding deformation.
- (4) High anticorrosion requirements are essential due to the severe seawater corrosion at the tunnel site. To address this, a triple anticorrosive approach is employed for the pipe sections, including “reserved corrosion thickness + heavy coating + sacrificial anode block” measures. This involves applying a glass scale paint coating with a dry film thickness of 700~1000 μm . The quality of the painting construction plays a crucial role in ensuring effective corrosion protection.

4 INTELLIGENT MANUFACTURING SYSTEM CONSTRUCTION

In accordance with the project's requirements for controlling the overall construction period, the steel shell manufacturing unit for the immersed tube tunnel needs to have the capacity to produce one pipe section per month. Given the challenges involved in steel shell manufacturing, meeting high-quality construction demands using traditional technology alone is difficult. Therefore, it is essential to conduct research and implement intelligent manufacturing techniques for the steel shell of the immersed tube tunnel. This will ensure timely project completion while maintaining high-quality standards. The following sections will outline the development of an intelligent manufacturing system for the project based on the construction process flow of the steel shell and leveraging existing advanced manufacturing technologies.

4.1 Steel shell construction process

To fulfill the requirements of intelligent manufacturing for the steel shell, the 165m standard segment is divided into 11 larger segments, each measuring 15m in length along the longitudinal direction. These larger segments are further divided into 22 sub-segments based on left-right symmetry principles along the width direction, as illustrated in Figure 2. Each sub-segment is then divided into four plane blocks, namely the bottom plate, middle wall block, side wall block, and top plate, taking into account the structural characteristics. Additionally, based on the specific structural characteristics of each block, further division into several pieces is made. The primary process flow of steel shell construction is depicted in Figure 3.

Figure 2. Schematic diagram of steel shell division.

Figure 3. Main process flow chart of sinking tube steel shell structure.

4.2 Construction of intelligent manufacturing system

Taking into account the construction process of the steel shell structure and the current level of intelligent manufacturing equipment, a study is conducted on the construction processes of cutting and beveling, sheet assembly, block assembly, and subsection painting in the production of the steel shell structure. Based on the operations involved and their characteristics, these processes can be categorized into five intelligent production lines: the intelligent cutting production line, slice intelligent welding production line, block intelligent welding production line, segment intelligent painting production line, and the workshop manufacturing execution control system (MES). The research and development of the steel shell intelligent manufacturing system focuses on implementing “four lines and one system,” utilizing robots and assembly lines for intelligent production.

4.3 Function and technical index design of “four-wire one system”

Intelligent cutting production line

(1) The application of plate/profile CNC cutting production lines in the steel shell production unit has reached a relatively mature stage. However, each production line’s cutting equipment operates independently, requiring manual allocation and

statistical tracking of tasks and production volumes. This manual process significantly limits production efficiency. To address this issue, it is essential to implement intelligent networking control through network system integration technology for the original CNC cutting production lines. This transformation will enable intelligent cutting operations, as illustrated in Figure 4.

Figure 4. Frame of intelligent steel cutting production line.

(2) The main key technical indicators are as follows:

- ① Enable networking between CNC cutting machines, profile cutting lines, and the workshop MES system.
 - ② Realize real-time data acquisition and feedback of CNC cutting machine and profile cutting line;
 - ③ Can feedback processing data including cutting steel furnace batch number, cutting part number, cutting time and other information to the information management system.
- (2) sheet intelligent welding production line

Based on the analysis of the steel shell structure, it is observed that there are numerous relatively simple sheet parts. With the availability of production line conditions, these parts can undergo manual assembly, followed by 3D online scanning to automatically generate welding procedures. Once the instructions are received, robots can carry out automatic welding operations, as illustrated in Figure 5.

Figure 5. Schematic diagram of sheet body intelligent welding production line.

(3) The main technical indicators are as follows:

- ① Welding capacity: capable of performing flat fillet welding and wrap fillet welding in the range of 3.5mm to 9mm.;

- ② The system can accurately position the welding, automatically acquire workpiece information, and generate welding programs automatically.;
 - ③ Realize longitudinal and transverse diaphragm unit stiffening fillet weld intelligent welding;
 - ④ Processing capacity: the size range of the body can be processed is 1500mm-4500mm long, 1500mm-4500mm wide;
 - ⑤ Realize the production line and workshop MES system networking, with online programming function.
- (3) block intelligent welding production line
- The block intelligent welding production line is primarily utilized for the robotized automatic welding of open block structures within the deep channel. It consists of various stations, including loading, FCB panel installation, longitudinal assembly welding, block intelligent robot welding, repair, pre-outfitting, tire out, and more. The block robot welding system comprises a mobile welding gantry, beam-type walking trolley, and welding robot (including a vertical lifting system), as illustrated in Figure 6.

Figure 6. Schematic diagram of the block robot welding system.

- (4) The main technical indicators are as follows:
 - ① Able to accurately position the weld, automatically obtain the workpiece information, and automatically produce welding procedures;
 - ② It can realize intelligent welding of vertical and transverse partition board and top and bottom plate structure;
 - ③ Realize the block intelligent welding production line and MES system networking, with offline programming function;
 - ④ Welding capacity: It can meet the 5mm to 12mm foot height of flat fillet welding, vertical fillet welding, cladding fillet welding and no more than 14mm plate thickness of deep penetration welding.
 - (4) Intelligent coating production line
- The outer surface of the steel shell section (top, bottom, side) is flat with a large area and few surface outfitting parts. Utilizing robots for sanding and spraying provides significant advantages. By incorporating sandblasting and painting robots along with a remote control system, intelligent

coating of the steel shell subsection is achieved. The intelligent sandblasting and painting workshop can be seen in Figures 7 and 8.

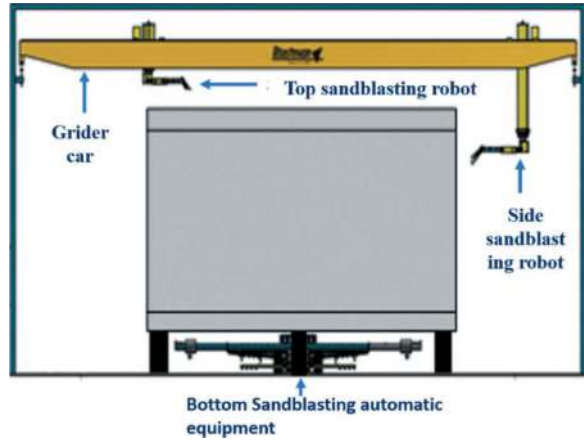

Figure 7. Schematic diagram of intelligent spraying workshop.

Figure 8. Schematic diagram of intelligent spraying workshop.

- (5) The main technical indicators are as follows:
 - ① Can realize the robot automatic sandblasting and automatic spraying.
 - ② Processing capacity: The size range of the bar segment that can be processed: (L × W × H) 15m × (23m-28m) × 10.6m;
 - ③ With offline programming, online monitoring functions, and can be optimized and upgraded during use;
 - ④ Realize intelligent painting production line and workshop MES system networking.
 - (5) Workshop manufacturing implementation control system
- Within the framework of the BIM technology management system, a workshop manufacturing execution system software is developed. This software utilizes the digital workshop integrated management system (MES) as its core and adheres to the unified standard of BIM technical data interface. Through various modules such as basic data management, intelligent engineering

planning, tire frame layout, block transportation management, quality control, equipment management, status Kanban management, etc., the software enables information control over the workshop manufacturing execution process. It further achieves data interconnection by developing a data interface with the intelligent production line and establishes seamless integration with the BIM platform. This ultimately realizes intelligent control over the workshop manufacturing execution process. The functional architecture of the digital workshop Manufacturing Execution System (MES) is depicted in Figure 9.

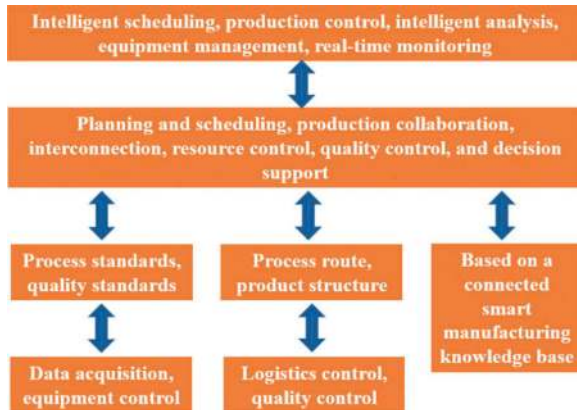

Figure 9. Digital workshop Manufacturing execution system (MES) functional structure.

(6) The main technical indicators are as follows:

- ① Deploy a wired or wireless network in the production workshop to facilitate the transmission of processing data to each production station through the network; Through the collection of equipment working status data, to
- ② achieve the monitoring of the running status of each production line, through the development of data interface, the relevant information into the special management information platform;
- ③ Realize the information management and control of the workshop manufacturing execution process, and realize the interconnection and interworking of data by opening the data interface with the intelligent production line of blanking processing, the intelligent welding line of sheet body, the intelligent production line of block body and the intelligent painting production line;
- ④ And the special management information platform to achieve seamless connection, to achieve the intelligent control of the workshop manufacturing execution process;
- ⑤ With basic data module, production management module, quality management module, resource management module, status Kanban management module, etc;
- ⑥ 3D digital production design model and drawings are completed and submitted on time, to

realize the integration and linkage of MES system and “four lines”, and to realize the integration of MES system and special management information platform system.

5 APPLICATION PRACTICE OF INTELLIGENT MANUFACTURING

Currently, intelligent manufacturing has been implemented in over ten steel shell projects. Based on the application results, the “four-wire one system” operates smoothly, and it successfully achieves the intended objectives in terms of functionality, manufacturing quality, and efficiency.

(1) The steel intelligent cutting production line is built upon the existing automatic CNC cutting equipment. By developing networking control software, layout data acquisition systems, and integrating on-site industrial computers, it can automatically receive plate and profile cutting instructions, nesting book data, as well as cutting equipment operating status information and production data feedback generated by the design system. These data are then uploaded to MES (Manufacturing Execution System). Additionally, key production process data can be fed back to the BIM system through an external network, creating an integrated program for automation, management data, Kanban visualization, and intelligent cutting production line, with modules for management, information, monitoring, early warning, analysis, reports, and Kanban.

The implementation of the production line enables the comprehensive deployment of a CNC cutting production line network control system. This addresses issues such as real-time remote monitoring of the cutting production line’s status, real-time production progress statistics, and equipment fault alarm analysis. It also introduces an innovative solution for real-time data acquisition and replication of CNC cutting equipment, laying the technical foundation for achieving the “digital twin” of an intelligent cutting production line.

Figure 10. Application of intelligent cutting.

(2) Body intelligent welding production line

The intelligent sheet welding production line incorporates advanced technologies including machine vision analysis, automatic welding path planning, and fully automated and efficient welding. It achieves workpiece identification and online programming through 3D

laser scanning adaptive programming, eliminating the need for importing a 3D model. The line laser enables real-time tracking of the weld, allowing for automatic adjustment of the welding path based on the work-piece's weld straightness deviation.

Figure 11. Application of sheet body intelligent welding in steel shell and ship products.

After conducting preliminary tests and continuous adaptability tests during the production process, the welding of stiffeners in the diaphragm body of the steel shell structure achieves 100% full coverage of 3D scanning and 100% automatic identification welding. The robot welding speed reaches 0.42m/min, enabling 2 door frames and 4 robots to weld synchronously in a single pass. The robot welding demonstrates stable quality, uniform and good weld formation, and can achieve fillet welding, significantly reducing the workload of repair and grinding. Intelligent sheet welding greatly enhances production efficiency and welding quality, providing significant advantages in improving production capacity, reducing labor costs, and minimizing manual polishing tasks.

(3) Block intelligent welding production line

The intelligent welding production line enables robot automatic recognition and welding in complex and narrow spaces composed of vertical and horizontal partitions, longitudinal ribs, and bottom plates. It supports various types of welding such as flat fillet welding, vertical fillet welding, and deep penetration welding. The objective is to facilitate the complete automation and intelligence of the entire process from panel → FCB welding → longitudinal rib assembly → longitudinal rib welding → block component assembly → block component robot intelligent welding → shipping for the sink steel shell blocks.

Figure 12. Application of block robot in product welding.

By incorporating advanced technologies and equipment such as offline programming, three-dimensional simulation, and welding robots, the block intelligent production line facilitates fully automatic collaborative work of multiple welding robots. This results in uniform weld formation, stable welding quality, and a weld inspection pass rate of up to 99.9%. As a result, the workload for grinding and repair is significantly reduced, with approximately 225 hours of grinding saved for a single standard pipe section.

In comparison to the previous manual welding production mode, the block intelligent welding production line has substantially improved the proportion of welding time and efficiency. It has also significantly reduced waste in welding materials caused by excessive welding beads and defect repairs.

(4) Intelligent coating production line

The intelligent painting production line utilizes multiple sandblasting and painting robots to achieve fully automatic collaboration in performing sandblasting and painting operations for subsections of the submerged tube steel shell. It is equipped with a central control system that enables remote monitoring of the entire painting process. The system provides functions such as fault alarms, real-time display of dynamic information on painting working conditions, and parameter data. Additionally, it includes intelligent data collection and processing capabilities. This greatly reduces the risk of physical harm to operators and lays the groundwork for the realization of unmanned painting workshop operations.

Based on the application of multiple pipe sections, the sandblasting robot achieves a sandblasting efficiency of more than 50m²/h with a single gun, while the painting robot achieves a painting efficiency of more than 150m²/h with a single gun. These figures represent a significant improvement of approximately 67% and 25% in efficiency compared to manual operations, respectively. The block intelligent production line not only enhances the quality of the process but also reduces labor requirements. It ensures a high level of roughness, uniform paint film thickness, and a high one-time pass rate. Additionally, there is no longer a need for construction work, resulting in a reduction of about 36 hours.

(5) Workshop manufacturing implementation control system

The BIM-oriented Workshop Manufacturing Execution System (MES) has a wide application scope, including the steel shell pipe section cutting workshop, sheet and block site, and intelligent painting production line. By deploying network optical fiber in the steel shell manufacturing area, it enables data processing through the network and monitors the operating status of intelligent production lines. The collected data is then connected to the MES system platform. Through the development of data interfaces within the MES system, seamless integration with design systems, product data management systems, and other information systems can be achieved internally. Externally, timely dissemination of steel shell pipe manufacturing production information to the Shenzhin-China channel BIM

Figure 13. Application of intelligent painting.

collaborative platform is facilitated, opening up the gateway for upstream and downstream data flow and resolving long-standing data “island” issues. This ultimately enables intelligent control over the entire process of steel shell manufacturing.

Figure 14. Intelligent production line integrated management and BIM collaborative platform.

Simultaneously, various research efforts are being conducted on BIM technology to ensure efficient connectivity between project planning, implementation, and operation as previously shown (Chen et al., 2020). The aim is to achieve an organic combination of the design system and production management system used by shipyards in steel shell manufacturing with the BIM system. Currently, Shenzhen-China Channel Steel Shell Manufacturing has undertaken comprehensive work related to intelligent

manufacturing and BIM information technology for steel shells. This includes the establishment of an information platform (BIM technology-oriented Workshop Manufacturing Execution System (MES), weld three-dimensional mapping, BIM models, and WBS coding) as well as infrastructure development (workshop network, site video surveillance, etc.). Additionally, the application of the Shenzhen-China BIM collaborative management platform is employed. Through the implementation of BIM and information technology, process improvements, and functional verification, the overall system operation has become stable. This has effectively enhanced the level of intelligent manufacturing for steel shells, thereby laying a solid foundation for improving the production quality of steel shells.

6 CONCLUSIONS

Through the research on intelligent manufacturing of steel shells, the application of the “intelligent manufacturing system of steel shells” has been successfully promoted. Moreover, technical standards for intelligent manufacturing of steel shell tube segments have been established. This breakthrough includes key technologies such as online programming of welding robots based on visual recognition, integration of 3D positioning of large steel structure blocks, precise positioning of weld points using lasers, intelligent painting of large steel structures, and BIM-oriented system integration. The intelligent production line demonstrates excellent production capacity and efficiency, meeting the requirements of the steel shell manufacturing schedule. The cutting, welding, and painting processes exhibit stable and reliable quality, offering significant advantages over traditional manual operations. The achievements in this field play a leading and exemplary role in the transformation and upgrading of intelligent manufacturing within the transportation manufacturing and shipbuilding industry.

Guangfeng Zhang

Guangchuan Shipbuilding International Limited Company, Guangzhou, China

ABSTRACT: The steel shell volume of the Shen-Zhong Link's steel sandwich immersed tunnel is substantial. To enhance production efficiency and quality, the steel shell manufacturing and concrete pouring are carried out in two specialized factories. Each steel shell weighs approximately 10,000 tons. After manufacturing, it undergoes a ro-ro (roll-on/roll-off) process from land to a barge, then transferred to the concrete pouring plant site. Subsequently, the steel shell is ro-ro'd from the barge to the land workshop for concrete pouring. However, conventional transportation methods pose significant technical and safety risks, leading to potential deformation of the steel shells. In this paper, we present an innovative transportation technology for immersed tunnel steel shells. This approach involves utilizing a rail-type hydraulic car and Self-Propelled Modular Transporter (SPMT) in tandem for combined transportation. By improving the transportation system, calculating and verifying transfer deformations, implementing linkage control between the two systems, and regulating transfer deformation, successful transportation and landing of super-large steel shells for immersed tunnels have been achieved. This method offers advantages such as effective control of shell deformation, flexible layout options, and cost efficiency, thereby serving as a valuable reference for similar large-scale steel structure projects.

Keywords: transportation, landing, rail type hydraulic car and Self Propelled Modular Transporter, deformation control

1 INTRODUCTION

The Shenzhen-China Corridor is a remarkable infrastructure project that connects the motorway expressway of Shenzhen in the east with Zhongshan's Saddan Island in the west. It also links up with the Zhongkai and Eastern Outer Ring Expressways. Spanning a total length of approximately 24km, the section across the sea measures around 22.4km. This project is yet another world-class engineering feat that integrates bridges, islands, tunnels, and underwater connections, following the success of the Hong Kong-Zhuhai-Macao Bridge.

One notable feature of this project is the implementation of the first steel-concrete composite immersed tube tunnel scheme in China. It is also the first time worldwide that the two-way 8-lane super span steel shell concrete immersed tube tunnel structure form has been utilized as previously shown (Song et al., 2020).

This innovative approach has established the foundation for controlling the overall project. Specifically, the immersed tube tunnel in the Shenzhen-China Passage project measures 5035m long and consists of 32 immersed tubes, including one final joint. The standard pipe length is 165m, with additional lengths for curved widening pipes measuring 123.8m. The concrete division of the pipe sections is as follows: $123.8\text{m} + 21 \times 165\text{m} + 2.2\text{m} + 5 \times 165\text{m} + 5 \times 123.8\text{m} = 5035\text{m}$. Each individual standard steel shell section has a length of 165m, width of 46m, and height of 10.6m, with a maximum weight of 12500 tons.

According to the project plan, a total of 22 ultra-large steel shell of immersed tunnel are manufactured on the platform line of the Shipyard using the Guishan Island plan. After manufacturing, these steel shell are loaded onto barges using a special transportation method known as "over barge." Subsequently, the barges tow them to Guishan Island

*Corresponding author: 29888766@qq.com

Prefabrication Yard, where the steel shell are carefully rolled off the barge and landed using the same transportation method known as “ashore.” The steel shell are then transferred to the support system in the unloading area of the precast yard for temporary storage. Once the pouring area is ready, the track trolley within the precast yard transports the pipe section by driving into the bottom of the steel shell, transferring it from the supporting system in the unloading area onto the track trolley, and finally transporting it to the pouring area for concrete pouring as previously shown (Chen et al., 2020).

Transporting the steel shell requires strict control over deformation, with a maximum allowable deformation of 20mm within the 165m × 46m wide range of the steel shell. However, the design of the Immersed Tunnel featuring two holes and one pipe corridor results in a weaker transverse structure. Conventional transportation methods used in shipyards often lead to significant deformation during the process of overloading and landing, making it difficult to meet the deformation control requirements. Therefore, it becomes necessary to study a transportation method specifically for super-large immersed tube tunnels, utilizing the existing resources of the shipyard to solve the deformation control problem during steel shell transportation and reduce operating costs.

From the manufacturing of the steel shell to the prefabrication of the immersed pipes, ensuring proper temporary storage of the steel shell in the unloading area and facilitating system conversion are crucial steps in the key lines of immersed pipe tunnel construction. The steel shell sections may remain in the unloading area for an extended period, possibly spanning tens of days. Given the local environmental factors, including prevailing typhoons and adverse sea conditions, it is essential to ensure long-term storage of the steel shell and the safety of system conversion. The design of the support system in the unloading area poses great challenges due to the existing foundation conditions, the performance requirements of the transfer track trolley equipment in the prefabrication yard, and the need for precise control of the steel shell.

2 RESEARCH ON STEEL SHELL OF IMMERSSED TUNNEL COMBINED TRANSPORTATION TECHNOLOGY

2.1 Shortcomings of existing transport overloading and landing methods

The shipyard platform line is primarily used for ship-building purposes and is equipped with self-propelled rail-type hydraulic trolleys for transporting ships on barges. To accommodate the launching of various large and small wide ships, while considering the substantial transverse structural strength of the ships, only a set of trolley tracks are positioned

at distances of $\pm 1\text{m}$ and $\pm 7\text{m}$ from the platform line. In accordance with the existing transportation method and accounting for the robust structure of the steel shell, 32 cars are evenly arranged along the track $\pm 7\text{m}$ below the steel shell (refer to Figure 1, Figure 2). Based on the average total weight of the steel shell, which is calculated to be 11,000 tons, each car carries an average load of 344 tons. This is less than 0.8 times the designed load capacity of 500 tons per car, thus meeting the load requirements for each car.

Figure 1. Layout diagram of rail type hydraulic carriage transport pipe section (Plan).

Figure 2. Layout diagram of pipe section for rail type hydraulic carriage (cross section).

The Partran software was utilized to conduct finite element calculations regarding the transportation conditions of the pipe sections. It was determined that the maximum deformation of the pipe section during transportation reached 36.5mm (refer to Figure 3), surpassing the allowable maximum deformation limit of 20mm. Therefore, it was deemed infeasible to employ the existing transportation method.

Figure 3. Deformation cloud diagram of pipe section transported by 32 rail-type hydraulic trolleys at $\pm 7\text{m}$ distance (maximum deformation 36.5mm).

2.2 Technical scheme design of combined transportation

The existing transportation equipment for horizontal berthing in the shipyard consists of track-type hydraulic cars and tire-type module cars. This includes 40 track-type hydraulic cars with a total load capacity of 20,000 tons, and 136 units of tire-type module cars with a combined load capacity of approximately 4,800 tons. The track-type hydraulic car is equipped with its own power unit and features self-lifting and self-propelling capabilities. It offers a large carrying capacity per unit area and provides cost-effective transportation. On the other hand, the wheeled module car is a hydraulic flatbed vehicle with wheels, widely used for transporting large components both domestically and internationally. While it offers stable performance and flexible usage, its unit area carrying capacity is lower compared to the track-type hydraulic car, and the cost is significantly higher.

Based on the results of finite element calculations, it was determined that the main transverse deformation occurs during the transportation of the pipe sections. This is attributed to the weak transverse structure resulting from the design of two holes and one pipe gallery for the pipe sections. For a pipe section with a width of 46m, the rail hydraulic trolley is only arranged at a distance of $\pm 7\text{m}$, causing overhangs on both sides and leading to transverse deformation of the pipe section.

The effective solution to this problem involves increasing the transportation equipment on both sides of the pipe section. For instance, adding track-type hydraulic trolleys on both sides would require the destruction of the ground concrete structure and the installation of embedded trolley tracks. In order to maximize the utilization of shipyard equipment resources, avoid additional investments in infrastructure and equipment, and simultaneously reduce the deformation during pipe section transportation, it is proposed to utilize tire module cars at a pitch of $\pm 18.9\text{m}$ along with track-type hydraulic trolleys at a distance of $\pm 7\text{m}$. This approach facilitates the joint transportation, overloading, and landing of the pipe sections while considering the structural strength of the pipe sections and the barge deck walking channel.

To minimize the transverse deformation of the steel shell, all 136 axes of the tire module vehicles are utilized and divided into four groups, evenly arranged on both sides of the steel shell. Similarly, the track-type hydraulic cars are also organized into four groups, with a total of 32 sets (refer to Figure 1-4 and Figure 1-5). The wheeled module cars serve as auxiliary bearing equipment, providing sufficient bearing capacity to enhance the operational space. They are designated to bear a total weight of 3,000 tons for the steel shell, while the remaining 8,000 tons are supported by the 32 sets of track-type hydraulic cars, averaging 250 tons per car.

Figure 4. Joint transport of steel shell section laying car by track type hydraulic car and tire type module car (Plan).

Figure 5. Joint transportation steel shell layout of track type hydraulic car and tire type module car (cross section).

2.3 Theoretical check calculation

The Partran software was utilized to evaluate the combined transportation conditions and obtain the calculation results for the deformation of the steel shell as depicted in Figure 1-6. It can be observed that the maximum deformation of the steel shell during transportation is 15.1mm, which satisfies the requirement of a maximum allowable deformation of 20mm. Therefore, the proposed joint transportation scheme is theoretically feasible.

Figure 6. Deformation cloud map of joint transport of the steel shell by rail type hydraulic trolley and tire type module vehicle (maximum deformation 15.1mm).

2.4 Analysis and solution of technical difficulties

The local climate of Guishan Island in Zhuhai is characterized by unstable weather conditions, including strong winds and waves throughout the year. The barges docked at the Guishan Island Pouring Plant's wharf experience significant swaying due to these environmental factors. Under such challenging circumstances, it becomes exceedingly difficult to use two sets of equipment for transporting steel shell from the barge to the shore. This is especially true when employing this joint transportation method for

the first time, as it requires both sets of equipment to perform complex joint actions, necessitating the resolution of various technical difficulties.

The transportation of pipes demands high precision, not only in terms of controlling overall deformation within a 20mm limit but also due to the compact design of the casting station. Even a slight deviation in the centerline or flatness during onshore transportation can result in contact with the workshop edge or the pier below. Therefore, ensuring synchronous accuracy in the joint actions of the two sets of equipment is crucial.

To address this challenge, specific operational strategies are formulated based on the performance characteristics of the two sets of equipment. Manual control is employed to achieve high synchronization between the two sets of equipment at key stages. During simultaneous jacking up/down actions, the main strategy involves using the track hydraulic car, which has a large load capacity and sensitive operation, while utilizing the tire module car with a smaller load and better controllability as an auxiliary unit. Pressure monitoring and manual remote control enable the wheeled module car to follow the synchronous jacking/descending movements of the track hydraulic car. When both sets of equipment need to move together, the traction is provided by the tire module car, which boasts strong driving/braking capabilities, while the track-type hydraulic car follows suit. This approach ensures the complete synchronization of the two sets of equipment during their movement.

Based on the aforementioned strategy, the operational process for jointly transporting the track-type hydraulic car and the tire-type module car is formulated.

- 1) The track-type hydraulic car and the tire-type module car are positioned according to the layout plan at the designated location beneath the steel shell tube section.
- 2) Only the track-type hydraulic car performs synchronous jacking, lifting the pipe section 10-20mm above the ground. The actual weight of the steel shell is then measured and recorded before placing it back onto the support pier.
- 3) The track-type hydraulic car is pre-jacked to ensure that all cars are in close proximity to the bottom of the pipe section.
- 4) The track-type hydraulic cars are grouped based on the center of gravity. Typically, they are divided into four groups (1-4), and the force value for each group is manually set by inputting the difference between the actual weight and the carrying weight of the tire-type module car (3000t) divided by four.
- 5) The tire-type module cars are also grouped based on the center of gravity, generally divided into four groups labeled as ABCD.
- 6) The wheeled module car is lifted first, and all ABCD groups lift the same weight until the total load reaches 3000t.

- 7) Both the tire-type module car and the track-type hydraulic car are simultaneously raised until the steel shell is lifted away from the support pier.
- 8) The wheeled module car is driven by remote control, with the track-type hydraulic car following behind (clutch open). They transport the pipe section to the barge. During transportation, if there are significant changes in the steel shell orientation, adjustments are made by individually raising or lowering the major groups of the track-type hydraulic car and the tire-type module car.
- 9) Once the pipe section is in position, it is placed on the pier of the barge.
- 10) The same method is employed to transport the pipe section to Guishan Island and transfer it ashore.

2.5 Advantages and application promotion of combined transportation

The joint transportation method of the track-type hydraulic car and the tire-type module car allows for the efficient utilization of high-quality equipment resources in the shipyard, eliminating the need for redundant investments in equipment and facilities and saving operating costs. This method is not only applicable to the manufacturing project of deep-middle channel submerged tube tunnel steel shells but also highly suitable for promoting and implementing ship barge launching operations in the shipbuilding industry with diverse product types. It effectively combines the advantages of both sets of equipment: The track-type hydraulic car, with its large carrying capacity per unit area, is utilized as the jacking equipment for the ship's fore and stern lines, avoiding the need for extensive tooling. On the other hand, the tire-type module car, with its small carrying capacity per unit area, is ideal for the flat outsole area of the ship's cargo hold which has a larger carrying area. This choice of jacking equipment is not only convenient and flexible but also compatible with any wide ships, including super large marine products.

Figure 7. Layout diagram of the joint transport ship of the track type hydraulic car and the tire type module car.

The successful implementation of this method on the steel shell of the ultra-large submerged tube tunnel in the Shenzhen-Middle Passage not only facilitates the transportation of products from the platform line to the barge but also enables the transportation of products from the barge to the shore. This achievement lays a solid foundation for future closure of the platform line after the construction of products at different

locations, thereby expanding the product business scope of the shipyard's platform line.

Figure 9. Successful landing of steel shell of immersed tunnel on Guishan Island.

3 DESIGN AND RESEARCH OF TEMPORARY STORAGE SUPPORT SYSTEM OF STEEL SHELL OF IMMERSSED TUNNEL IN THE UNLOADING AREA

3.1 Design objectives

1) The design of the support system should meet the requirements of the original structure's design bearing capacity in the unloading area. The foundation treatment for the unloading area adopts the "PHC pile + cast-in pile" scheme. Concrete piers are installed on top of the piles to serve as the supporting foundation for the steel shell (refer to Figure 2-1). The design bearing capacity of each individual concrete pier should not exceed 200t. Considering factors such as the construction organization, economic cost of the immersed tube tunnel, and other considerations, the existing structure in the unloading area is maintained as much as

possible, and major modifications are avoided. The support system is designed using the existing concrete piers to ensure that both the concrete piers and pile foundation can meet the required design bearing capacity during the period of pier lowering and temporary storage of the steel shell.

Figure 10. Layout of cement buttress piers in the unloading area.

- 2) The design of the support system should accommodate the system conversion requirements. Once the steel shell is transported to the unloading area in the prefabrication yard, it is first unloaded onto the support using the "track type hydraulic trolley + tire type module car" method, and then transferred from the support to the track trolley in the prefabrication yard. This process is known as the steel shell support system conversion. The conversion process of the steel shell support system can be divided into two main stages. In the first stage, the steel shell is unloaded from the "track type hydraulic car + tire type module car" onto the support, where the support surface maintains a consistent elevation. Through the stroke of the equipment cylinders, the full weight of the steel shell is actively placed onto the support. The second stage involves transferring the steel shell from the support to the rail platform car in the prefabrication yard.
- 3) The design of the support system must meet the precision control requirements for the steel shell. The maximum allowable deviation for the flatness of the steel shell's bottom plate is $\pm 10\text{mm}$. Therefore, the design of the support system should prevent the bottom plate's flatness from exceeding this allowable deviation value.

3.2 Design difficulties

Based on the current structure status of the unloading area and equipment conditions, the design of the support system faces the following challenges in achieving the aforementioned design objectives:

- 1) The hydraulic jacks used in the track trolley of the prefabrication yard, which were left over from the construction of the Hong Kong-Zhuhai-Macao Bridge, have a limited lifting stroke of only $\pm 25\text{mm}$. This stroke is insufficient to actively push the steel shell away from the support surface

and complete the second stage system conversion. To address this issue, it is necessary to design a support system with a pressure relief device that can reduce the supporting surface through pressure relief, allowing for the transfer of the steel shell's weight to the rail trolley.

- 2) During the process of steel shell lowering, the elastic deformation of the middle arch and the sinking of the four corners result in the two ends of the steel shell making contact with the support first. Additionally, the bottom plate may not be perfectly flat (with a maximum allowable deviation of $\pm 10\text{mm}$). As a result, there is a risk of localized excessive support force during the pier lowering process, which could potentially damage the concrete piers or pile foundation. Effective measures need to be taken to avoid structural overload and mitigate potential damages.
- 3) The longitudinal spacing between concrete piers on-site varies, with most of them being 5m apart. However, the transverse partitions of the steel shell have a spacing of 3m. Consequently, it is not feasible for each cement pier to correspond directly to each transverse partition of the steel shell. This mismatch can lead to some supports falling on the weaker parts of the steel shell structure (refer to Figure 2-2), resulting in deformation of the steel shell and uneven distribution of support forces.

Figure 11. Corresponding relationship between cement piers and steel shell transverse partition (longitudinal section).

3.3 Design scheme

In light of the aforementioned design challenges in the support system, an innovative support form has been devised. The specific scheme is outlined as follows:

- 1) Drawing inspiration from the design scheme of a floating pier used in the shipping industry for inclined ship platforms, the depressible support main structure employed during the construction of the Hong Kong-Zhuhai-Macao Bridge is selected (refer to Figure 2-3). This structure allows for passive support that can be lowered to facilitate pressure relief when converting between the support and the mobile trolley in the unloading area. By sliding down the slope of the depressible support, the weight of the steel shell can be unloaded onto the mobile trolley.

Figure 12. Passive support mode.

- 2) To mitigate the risk of overloading the supports at the two ends caused by the initial lowering of the piers at the steel shell's four corners, a solution has been devised that does not require altering the existing foundation of the unloading area. Additional piers have been installed to strengthen the foundation at the Shenzhen end of the steel shell, totaling 8 piers in number. Additionally, a total of 12 piers have been strategically placed at corresponding pile positions along the middle section (refer to Figure 2-4). By adding these piers, the safety factor of the supports at both ends of the steel shell has been enhanced, ensuring the safety of the steel shell pier during the lowering process.

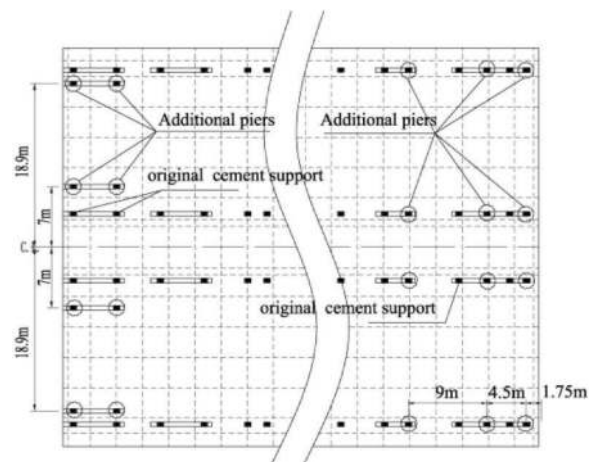

Figure 13. Adding piers at both ends of a steel shell.

- 3) To prevent deformation of the steel shell caused by the support force point falling on vulnerable areas, two types of supports are designed due to the mismatch between the cement piers and the transverse partition of the steel shell. Firstly, steel piers and passive supports are placed on the cement piers that correspond to the transverse partition of the steel shell. Secondly, passive supports and box beams are placed on the cement piers and new steel piers that do not align with the transverse partition of the steel shell. Additionally, to mitigate uneven support force when

the pier falls as a result of an uneven bottom of the steel shell, a 30mm buffer rubber is installed on top of the support (refer to Figure 14).

Figure 14. Schematic diagram of the combination of the two support forms.

- 4) After implementing the aforementioned design, the layout scheme of the support system in the unloading area is illustrated in Figure 15.

Figure 15. Overall layout of the support system in the unloading area.

3.4 Finite element calculation check

To analyze the design effectiveness of the support system, we employ the finite element calculation method for theoretical verification and compare the calculation results under two working conditions: before and after the implementation of this design scheme.

1) Finite element modeling

The MSC PATRAN software was utilized to establish a comprehensive three-dimensional finite element model, encompassing all the key structures of the steel shell. A plate and BEAM composite model was employed to simulate the internal and external panels, vertical and horizontal partitions, platforms, and the web of the main components (girder) of the steel shell using 2D plate units (SHELL). Additionally, 1D beam units (BEAM/BAR) were used to represent components such as bones and reinforcements. Some minor structures that had negligible impact on the calculation results, such as the aggregate end bracket, were not included in the model. The grid was divided based on the spacing of the

aggregates, with a typical cell size of approximately 500×500mm. The origin of the model's coordinate system was located at the sealing plate of the Shenzhen end pipe section. Specifically, the X-axis was oriented longitudinally along the pipe section towards the middle end, while the Y-axis pointed to the left in the width direction of the pipe section. The Z-axis originated from the bottom of the pipe section and extended upwards along the height direction (refer to Figure 16).

Figure 16. Stereogram of finite element model of steel shell.

2) Calculation results

The MSC NASTRAN program was employed to compare and calculate two scenarios: one before implementing the design scheme (with the steel shell directly resting on the support surface of the cement pier) and another after implementing the design scheme. The following aspects were analyzed:

- a) Deformation comparison of the steel shell: The maximum deformation of the steel shell was calculated as 5.97mm before incorporating this design scheme. However, after implementing this design scheme and utilizing the load distribution function of the box beam, the maximum deformation of the steel shell was reduced to 3.74mm.

Figure 17. Deformation cloud picture of steel shell before adopting this design scheme (maximum deformation 5.97mm).

Figure 18. Deformation cloud image of steel shell after adopting this design scheme (maximum deformation 3.74mm).

- b) Comparison of vertical forces on concrete support piers. Before adopting this design scheme, the vertical load of 32 of the original 136 concrete piers exceeded the design load by 200t, and the maximum vertical load of a single pier was 404t; After this design scheme is adopted, the maximum load of the original concrete support pier is reduced to 188t, and the load of each pier is more uniform. The comparison of the loading results of each pier is shown in Figure 19 (taking one of the piers as an example).

Figure 19. Comparison of vertical stress results of the first column pier.

In summary, the proposed design scheme successfully fulfills both the precision control requirements of the steel shell and the load-bearing requirements of the existing concrete piers. This design approach avoids extensive reinforcement work on the foundation, resulting in cost savings and a shortened construction period. Overall, the support system design scheme effectively meets the project's requirements.

4 CONCLUSIONS

The steel shell tube section of the deep and middle passage ultra-large submerged tube tunnel adopts a new transportation method, which combines rail-

type hydraulic cars and tire-type module cars. This approach presents a novel way to transport products from the shipyard platform line. The successful application and popularization of this method not only expands the range of suitable products for the shipyard platform line but also lays the foundation for constructing large-scale marine products on the platform line. It enables the closure of the upper platform after off-site construction of half the ship and facilitates repairs to the ship's upper platform. Furthermore, it provides a reference for leveraging the advantages of shipyard equipment resources in the future and achieving more diversified platform barge launching operations through equipment combinations. This will help promote the integration of shipyard resources and reduce enterprise investment costs.

The innovative design scheme of the support system, based on the current foundation conditions and equipment status in the unloading area of the immersed tube prefabrication yard, not only meets the requirements for converting the support system in that area but also prevents overload damage and deformation caused by uneven local forces acting on the piers and steel shell. This design ensures the long-term storage safety of the steel shell and the smooth conversion process of the system. Additionally, the support system design is rational, avoiding extensive transformations, saving costs, and shortening the construction period. It realizes "factory prefabrication and on-site assembly" of components, while maintaining high construction quality and efficiency that align with project requirements. The design methodology and its application in the support system have significant reference value for the design of support systems in super-large immersed tube tunnels and large components.

Innovative research on key technologies for dredging construction of immersed tunnel

Dingqiang Ma, Peng Zhang, Zhonghao Li & Yifan Yao
CCCC Guangzhou Dredging Co., Ltd., Guangzhou, China

ABSTRACT: This study seeks to investigate the key technological innovations in the dredging construction of immersed tunnels, with the objective of addressing the challenges encountered during the construction process. We employed a range of research methods including simulation experiments, field observations, and numerical calculations, and combined them with an analysis of the specific characteristics of dredging in immersed tunnel construction. We addressed key issues in the dredging process and implemented a series of equipment and technological improvements at different stages. Specifically, we developed new technologies such as precision dredging equipment for shallow shoals and deep troughs, and environmentally-friendly rock-breaking excavation methods, and applied them to the dredging process of immersed tunnels. The outcomes of the application demonstrate that these innovative technologies not only satisfy the requirements of on-site construction, ensuring that the construction quality meets the design and specification standards, but also enhance the efficiency and quality of the dredging construction. As a result, they provide a more robust assurance for the long-term operation of immersed tunnels. Overall, this study provides in-depth insights into key technological innovations for dredging in the construction of immersed tunnels. We propose a series of new technologies and improvement measures that offer effective reference for research and application in related fields.

Keywords: immersed tunnel, dredging construction, deep water foundation trench, equipment modification, rock drilling technology

1 INTRODUCTION

In recent years, with the completion of Hong Kong-Zhuhai-Macao Bridge, immersed tunnel technology has been rapidly developed and widely used. Immersed tunnel has become an important choice for crossing rivers, lakes and seas today due to its advantages such as shallow burial depth, large traffic capacity, short route, flexible selection of cross-sectional shape, easy quality control of tube element prefabrication and good waterproof effect [1]. By the end of 2020, there were 23 immersed tunnels, accounting for 10% of the total number of underwater tunnels in China. Shenzhen-Zhongshan River Crossing Link Project (hereinafter referred to as “Shenzhong Link”) is located in the core area of the Pearl River Delta. The overall design adopts the scheme of “east tunnel and west bridge”, with a total length of about 24km and an undersea tunnel of about 6.8km, which is an important transportation hub connecting the Pearl River Delta. The foundation trench dredging construction of Shenzhong Link immersed tunnel is restricted by many factors such as geological conditions, marine environment and navigation safety. The construction

conditions are extremely complex and the construction technology is difficult. In view of the difficulties in the construction of Shenzhong Link, innovative researches have been carried out on key technologies for dredging construction of immersed tunnel, and new technologies such as shoal and deep groove accurate desilting, environment-friendly rock breaking excavation, and precision dredging of foundation trench have been developed to further improve the construction level of immersed tunnel dredging and perfect the construction theory and method, which will certainly promote the development of immersed tunnel technology.

2 PROJECT OVERVIEW

The Shenzhong Link immersed tunnel consists of 32 elements of immersed tube, including 26 standard tube elements and 6 non-standard tube elements. The standard tube element is 165m long and 10.6m high. The non-standard tube element is 123.8m long and 10.6m high. The bottom width of the foundation trench in the standard tube section is 50.0m, and that

Figure 1. Schematic diagram of vertical section of immersed tunnel.

in the widest section is 59.46m. The standard section and the widest section are gradually connected from 50.0m to 59.46m, with a bottom elevation of -12.76 ~ -37.08m (elevation 85, the same below). Where the trench bottom elevation changes suddenly due to different cushion thicknesses, a gentle slope shall be adopted for transition, which is a longitudinal slope with a gradient not steeper than 1:10. The section of the tunnel foundation trench is complex, and the method of transverse gradation and longitudinal segmentation is adopted, as shown in Figure 1.

3 KEY CONSTRUCTION TECHNOLOGIES AND INNOVATIONS

3.1 Shoal and deep groove accurate desilting equipment

The hydrology and sediment in the Shenzhong Link site area are complex. According to the siltation observation test study of trial trench carried out in the early stage, after one-year siltation observation period, the siltation intensity of trial trench in flood season is about 2.0 cm/d, and the natural siltation intensity of foundation trench is at least twice that of Hong Kong-Zhuhai-Macao Bridge, Island and Tunnel Project. Therefore, siltation and desilting during construction period will be one of the difficulties of the Project. In addition, nearby waterway dredging and sand mining operations, disturbance of substrate by large transport ships and abnormal severe weather will cause increased siltation of foundation trenches or even sudden siltation.

In view of the strong back-silting intensity of the Shenzhong Link and the risk that sudden siltation may be caused by surrounding sand mining operations, the special dredging vessel “Jielong” used in the Hong Kong-Zhuhai-Macao Bridge Project has been improved and equipped with a novel dredging construction system with higher construction efficiency and more accurate positioning specifically for dredging operations at the trench bottom before rubble dumping and gravel leveling. The addition of a high-pressure water tank and high-pressure nozzle enables the spraying of water at a higher pressure, effectively enhancing the impact on seabed silt and ensuring more thorough cleaning. Furthermore, by

augmenting the power of the dredging pump, the suction capacity for silt is increased to three times that of the Hong Kong-Zhuhai-Macao Bridge Project. This results in a clean water flow rate of 7,000 m³/h, leading to a remarkable improvement in desilting efficiency. We have independently developed a high-precision suction head positioning and monitoring system. This cutting-edge system enables real-time display and bottom-out monitoring of the dredging suction head, effectively addressing the challenge of achieving highly accurate dredging of the foundation trench during construction.

Following the silt suction power increase of “Jielong”, the flow velocity at the silt outlet experienced a significant rise, reaching 5.5 m/s. Previously, the conventional loading method involved directly attaching the silt discharge pipe to the side of the silt barge. However, this approach posed a risk of damaging the ship equipment due to high-speed silt ejection, and stable loading could not be guaranteed. To mitigate the risk, a dredging and loading system consisting of T-structure silt discharge pipe, energy dissipation pipe and semicircular buoy has been developed, as shown in Figure 2. An energy dissipation device, equipped with internal ribs, is installed at the silt discharge pipe outlet to make high-speed silt form a large turbulent vortex in the device for energy dissipation. As a result, the flow rate can be decreased to be lower than 2 m/s. This solution ensures the stable loading of the silt, effectively addressing the issue posed by the excessive impact kinetic energy experienced at the silt discharge pipe outlet.

Figure 2. Composition diagram of dredging and loading system.

3.2 Environment-friendly rock breaking excavation

According to the design data, there are a large number of completely, highly and moderately weathered rocks within the design elevation range of the foundation trench of Shenzhong Link immersed tunnel, mainly distributed in E6-E12 and E24-E30 tube element sections, which are characterized by wide distribution, deep burial depth and high strength. In dredging operations, conventional underwater blasting technology is typically employed to crush hard rocks within foundation trenches. However, considering the specific circumstances of the construction area being situated within the White Dolphin Nature Reserve and the proximity to Shenzhen Bao'an Airport, along with the high volume of ship traffic, only rock drilling technology can be used for physical crushing of hard rocks.

Rock drilling construction is improved from grab dredger, in which the grab of grab dredger is changed into rock drilling rod. During construction, the rock drilling rod is lifted to a certain height and then falls freely, hits the underwater rocks by its own impact force, and crushes the rocks with longitudinal impact load. This construction method started late, but developed rapidly. It is used in foreign projects such as the Friendship Port Dredging Project and Zawr Dredging Project in Saudi Arabia.

The impact range of vibration wave generated by rock hammer construction is related to the weight and lifting height of the hammer, and the surge wave generated is related to the shape of the rock hammer. The commonly rock hammers include axe type, cylindrical type, quadrangle pile type and quincuncial pile type. Different shapes of rock hammers have different characteristics of impact damage to rocks, and their kinetic energy loss process is also different, as shown in Figure 3.

Figure 3. Kinetic energy loss process curve of rock breaking hammers with different shapes.

The main parameters affecting the rock drilling effect include the lifting height of rock drilling rod, row spacing, position spacing of drilling points, and number of drilling. The construction parameters with the best construction effect are mainly determined through single-factor test and multi-factor test.

Based on the results of single-factor test and multi-factor test, the influences of various factors on drilling effect and reef removal thickness are studied. The main conclusions are as follows:

- 1) It is found that the average lumpiness and non-uniformity coefficient are positively correlated with lifting height, row spacing, and position spacing, but are negatively correlated with number of drilling. The fractal dimension is negatively correlated with lifting height, row spacing and position spacing, but is negatively correlated with number of drilling. The reef removal thickness is positively correlated with lifting height and number of drilling, but is negatively correlated with row spacing and position spacing.
- 2) Through the range analysis of multi-factor test results, it is shown that the primary and secondary order of influence on rock drilling effect is: lifting height > number of drilling > row spacing > position spacing; the primary and secondary order of influence on construction efficiency is: row spacing > number of drilling > position spacing > lifting height, as shown in Figure 4 and Figure 5.
- 3) Based on the results of multi-factor orthogonal in-situ tests, for moderately weathered granite (strength range: 80.01 MPa ~ 133.63 MPa) at Shenzhong Link site, the optimized drilling parameters under water depth of 40 m are determined as follows: lifting height 27 m ~ 34 m, row spacing about 2.5 m, position spacing 1.4 ~ 1.7 m, and number of drilling 2-3. The damage development and fissure distribution under the optimized parameters are numerically studied. Under the optimized parameters, the damage degree near the drilling point is high, the fissures are relatively developed, the damaged areas between the two rows of drilling points are connected as a whole and in a critical connection state, the fissure connection degree between the drilling points in the position distance direction is high, the rock is effectively broken, the drilling effect is good, the drilling efficiency is high, and the construction effect of the optimized scheme is better.

Figure 4. Relationship curve between various factors and rock excavation effect.

Figure 5. Relationship curve between various factors and rock excavation efficiency.

3.3 Improvement of precision dredging process for foundation trench

For immersed tunnels, water leakage between tube elements is primarily attributed to differential settlement, and the control of differential settlement is closely related to the shear keys between tube elements, the setting of water-stop facilities and the bearing capacity of the shear keys. In order to ensure the safe operation of the immersed tunnel within its design service life, the immersed tunnel foundation trench must be accurately dredged under the condition of adapting to large excavation depths, and efforts shall be made to minimize any occurrence of differential settlement from the first step of the foundation trench construction as much as possible.

The difficulties in precision dredging of the foundation trench are mainly reflected in the following aspects:

- 1) The cross-section design of the foundation trench of the immersed tunnel is complex: multi-stage slopes are set horizontally, with many break angles on the variable slope line, and dozens of combinations of gentle slopes and variable slopes are set longitudinally, making construction difficult. Furthermore, given that the foundation trench depth for large-scale immersed tunnel projects typically exceeds 30m, the range of applicable dredgers becomes limited, and grab dredgers are commonly selected in such scenarios.
- 2) The elevation deviation standards for excavating the foundation trench surpass the specifications commonly observed in current water transportation engineering practices. It is often the case that conventional large grabs fail to meet the precision dredging requirements, necessitating specific modifications.
- 3) The connection between the grab and the hull is primarily established through steel wires, constituting a flexible connection. When carrying out foundation trench dredging operations at significant dredging depths, achieving precise depth control becomes notably challenging.

In response to the above difficulties, functions such as over-depth limit and comprehensive deviation adjustment are incorporated into the original

dredging control system of the precision dredging ship. As a result, a precision dredging computer measurement and control system has been established, making the construction process visible, controllable and measurable. At the same time, based on the principle of iterative fitting, the system automatically controls the dynamic sinking of the grab through controlling the bucket rope. This facilitates the achievement of a horizontal undulating trajectory curve for the actual soil mass cutting throughout the grab closure process, as shown in Figure 6. The actual construction results substantiate that the plane dimensions and elevation fully meet the design requirements, and the maximum over-depth is controlled within 0.5 m.

Figure 6. Schematic diagram of the precise excavation function of the grab bucket.

3.4 High-precision desilting technology for multi-stage slope of foundation trench

During the installation process of the immersed tube, a gradual accumulation of silt occurs on the slope after the formation and the period of being left alone of the foundation trench. If the thickness of back-silting exceeds the slope's siltation capacity, it can potentially trigger the collapse of the slope, resulting in detrimental consequences to the foundation trench and foundation bed treated through rubble dumping. This, in turn, could lead to quality issues such as differential settlement and unbalanced stress of tube elements after installation. To ensure the protection of the completed foundation trench against slope collapse and dredging construction, it is necessary to accurately desilt the foundation trench slope, which requires high desilting construction accuracy.

The desilting of the foundation trench slope is carried out using a specialized suction drag head fitted on a drag suction dredger. Construction parameters, including the desilting track line and slope desilting control elevation for each layer, are pre-determined based on the slope's post-formation shape and back-silting distribution. To ensure precise movement along the planned track line, the DPDT system is employed to control the vessel. The DTSPS provides accurate guidance for drag depth, while the computer-aided dredging decision-making system assists in analyzing parameter variations throughout the desilting process.

At the same time, considering the loose and non-adhesive nature of the silt on the slope, there is no need for drag teeth to mechanically cut the soil.

Figure 7. Schematic diagram of actual navigation trajectory of DPDT system.

Instead, only the vacuum of the dredging pump is made use of to absorb the silt from the slope into the hopper through the drag head and suction pipe. Throughout the suction process, intelligent control is employed, utilizing feedback signals such as flow, density and pressure, and the special drag head is used in collaboration to consistently maintain a distance of 500 mm between the suction plane of the movable cover and the seabed during operation. This ensures thorough desilting of the multi-stage slope while effectively preventing damage to the original slope. Compared with traditional construction methods, there is no need to adjust the drag depth

according to changes in the slope section, and the drag head can be prevented from damaging the formed slope, achieving the best desilting effect.

4 CONCLUSIONS

To sum up, the equipment technical improvement and innovation measures carried out based on the foundation trench dredging work of immersed tunnel in Shenzhen Link have addressed the difficulties encountered in the construction process, and significantly improved the efficiency and quality of dredging construction. At the same time, consideration has been given to construction, navigation and environmental protection, which promotes the progress of immersed tunnel dredging technology and provides reference for similar projects.

Immersed tunnels – knowledge sharing in the past showing the way towards sustainable solutions in the future

Tommy Olsen*

COWI A/S, Kongens Lyngby, Denmark

ABSTRACT: The immersed tunnel technology has seen many developments since the first immersed tunnel projects were constructed more than 100 years ago. New requirements and constraints have led to original and innovative solutions. People and organisations moving from project to project and exchanging experience have led to significant improvements by combining existing local knowledge with expertise from abroad. Growing demand for sustainable solutions now and in the future will require organisations to collaborate and share knowledge about new solutions at an even brisker pace. Throughout modern history, innovations within immersed tunnel technology have been introduced and further developed in later projects, either by the organisation initially presenting the innovation or by other organisations elsewhere. This paper shows examples where immersed tunnel solutions developed on one continent have been further developed with great value in another continent. Selected examples of specific developments are presented in this paper, e.g., steel vs concrete immersed tunnels to fit local constraints, watertight concrete to improve performance, construction of elements under factory conditions to reduce construction time while maintaining or improving quality, and casting elements floating without use of a casting yard due to lack of space and/or access. Knowledge sharing across organisations and cultures is needed to face global challenges. This paper also briefly identifies some of the contemporary challenges regarding immersed tunnel technology, as well as the sustainable benefits immersed tunnel solutions can offer across the world.

Keywords: Immersed tunnel, knowledge sharing innovation, sustainability, concrete technology

1 INTRODUCTION

Let us go back in time to Paris in the period called “Belle Époque” (1871-1914), an idyllic place and time for visionary, scientists, engineers, authors, philosophers and political thinkers, all sharing thoughts and dreams for a new and better world. The era hosted three World Exhibitions (1879, 1889 and 1900), all showcasing mind-blowing innovations, and the one in Paris in 1889 marked the 100-year anniversary of the French Revolution.

Skilled bridge engineer Gustav Eiffel was asked to design a tower to be a landmark for the exhibition, and his project was constructed as a temporary structure. Although at first many Parisians did not like the project, considering it not feasible, useless and even “monstrous”, it became one of France’s most distinguished symbols: the Eiffel Tower turned out to be a “valuable asset” for the Parisiennes, initially for telegraph companies and later for tourism. It was the world’s tallest structure until it was surpassed by the Chrysler Building in

New York in 1930. That goes to show that, when large and innovative structures are planned – also within transportation and mobility – it is difficult to know precisely what a structure will be used for in the future.

Paris was a growing metropolis, with the needs of a modern city. Public transportation comprised steam trains connecting other cities and horse-driven trams. In competition with London, New York, Budapest and Berlin, Paris also wanted an underground metro, and initially six lines were planned. Metro line 4 had to go beyond the Seine River, connecting Châtelet to Saint-Michel Notre-Dame through Île de la Cité. At this location, due to the proximity to the Notre Dame Cathedral, the metro line could not be a bridge; instead, it was designed as a subsea tunnel. Figures 1 and 2 show the tunnel construction with a floating caisson. Constructed in 1905, this stretch of the tunnel was built before the first registered immersed tunnel but is not defined as an such because the casting was on site and not at a remote location later towed in place.

Figure 1. Floating caissons, line 4 at Île de la Cité (1905).

Figure 2. Paris metro, casting of caissons, crossing river Seine.

As inspiration to engineers of today through examples in the past, this paper points to the need for global collaboration and knowledge exchange across fields of engineering and across geographies, to facilitate innovation.

1.1 Sustainable development for the future

When designing future infrastructures, it is valuable to know the challenges faced by similar constructions in the past. Most of the lines from the first metros constructed in European cities 100-150 years ago are still in use today.

Metro lines connect residential areas where people live with areas of business and/or recreation. Metros keep the cities moving. In many places in Europe, heavy industries and manufacturing jobs are moving out of the city, where land value generally increases, and new jobs are being created in the service sectors. It is difficult to imagine how metro lines will look 100-150 years from now. However, any future plans must prioritize sustainable development and incorporate the necessary flexibility to ensure their success.

We all know that the construction industry is facing challenges to comply with current and future expectations and requirements to support infrastructures that are more climate friendly, lead to more biodiversity, use more recycled material, allow for higher operational performance, etc., all at the same or lower cost. This paper encourages engineers to look into the past to seek inspiration from when the need and the challenge appeared for the first time, to understand the roots of the problems and the constraints of the past and of today, helping find solutions for the future.

1.2 Local context and international trade

Large transportation infrastructures are planned within a local context. Infrastructures are constructed to the benefit of society, most often by public funding. It is commonly accepted in Europe that it is the public that assesses the benefits of a transport infrastructure. In contrast, it is the market that controls the construction cost via competition, and the price is often reduced by elements of innovation.

The examples and perspective of this paper are based on the experience of the author (from Copenhagen, Denmark) and his 30 years working in civil engineering as a specialist in immersed tunnels. It shows project examples that have shaped the industry from a Danish-European perspective. The examples may give indications on the directions for the future of Northern Europe. Other parts of the world have a different background and, therefore, a different path. Globalisation has been an effective facilitator in the dissemination of the development of immersed tunnels for the last 70 years, but it is uncertain how development and knowledge sharing will develop over the next 70.

People, nature, climate, geology, political systems, all contribute to the development of major projects as much as technology itself. We may assume science, technology and cost are the main factors in all decisions, but we should not underestimate that it is people working together and their combined knowledge and experience that decide what will be built and how it will be done. To make significant changes, it is necessary to think and act differently.

Trade routes around Denmark can be traced back thousands of years. The Danish soil consists of sand and clay left by the glacial period that ended some 20,000 years ago, making farming a good source of income. It lacks mountains and has no tradition of mining for resourcing metals, but it is composed of a bedrock of limestone, forming an excellent source of cement-based construction materials.

In the late 1800s, roads, railways and harbours were planned to help the country's economy grow. Danish engineers sought new ways of construction techniques in the United Kingdom, France, Germany, and the United States. Inspired by Hennebique and Monier, the first reinforced concrete bridge in Denmark - Gefion-bridge (1896) (Figure 3) - was designed by Professor A. Ostenfeld from the faculty of Structural Engineering, School of Polytechnic (Chr. Ostenfeld, 1976).

2 EARLY TECHNOLOGY, LEARNING TO MASTER

2.1 First immersed tunnel

It is accepted that the first immersed tunnel was the Michigan Central Railway Tunnel (1910) in Detroit (Figure 4). Constructed by concrete-filled steel shells, towed, and immersed in place, it was a shallow

Figure 3. Gefion bridge (1896), at Langelinje in Copenhagen.

Figure 4. Michigan Central Railway Tunnel (1910).

alternative (good for a railway) compared to the shield tunnel technology known from the Thames tunnel (1843) and metro lines in London.

2.2 Danish pioneers learning from working abroad

In 1900, young engineer Rudolf Christiani graduated from the Danish School of Polytechnics. Aware of a new trend, Professor Ostenfeld recommended Christiani to go to Paris to get some experience in a new composite construction material: *reinforced concrete*. A few years in Paris and in Düsseldorf made Christiani more familiar with reinforced concrete and in 1904, together with his partner Aage Nielsen, he founded the engineering and construction company Christiani & Nielsen (C&N) in Copenhagen.

In 1905, C&N designed and constructed Amtmand Hoppes Bro, the first reinforced concrete bridge for road traffic in Denmark. The company was ready to explore the potential of this new composite material and was able to convince owners, especially owners of marine infrastructures, of its benefits. In Denmark, large quantities of steel needed for construction projects had to be imported and treated to prevent corrosion. Meanwhile, the availability of local cement made reinforced concrete a highly cost-effective alternative.

Aalborg Harbour, in the western part of Denmark, was undergoing expansion; agricultural produce such

as meat, corn and dairy products were exported to nearby countries. C&N offered to design and construct a new quay wall of concrete caissons (Figures 5 and 6). Due to his background as a captain of the Naavy, Nielsen was familiar with shipbuilding. That knowledge, and the understanding of scaling up production from shipbuilding, was used as an advantage in the construction of large infrastructures, with repetitive works.

Figure 5. Aalborg Harbour (1906) reinforced concrete caissons.

Figure 6. Aalborg Harbour (1906) launching caissons.

Between 1900 to 1935, Danish contractors opened offices around Europe and were involved in activities with the design and construction of reinforced concrete for civil works, especially within marine works. Engineers of all ages gained a lot of experience that way.

Denmark is a country with more than 443 named islands, 78 of which are inhabited; some are some connected by ferries, some by bridge. During the 1930s, several large bridge projects were planned to replace the slower and weather-sensitive ferries. The first major bridge was the Little Belt bridge (1935). At 3,6km long Storstrømmen bridge (1937) (Figure 7) was the longest bridge in Europe at the time, a record it held for 30 years.

With experience from projects outside Denmark, it was a challenge taken on by Danish designers and contractors. C&N oversaw the substructure and concrete foundations cast inside steel caissons, using compressed air to access the foundation (see Paris metro earlier). The steel structure came from English company Dorman Long (Tyne Bridge, Memorial Bridge Bangkok and Sydney Harbor Bridge). As earlier, this large project

Figure 7. Storstrømsbridge (1937).

provided new knowledge and experience to a new generation of engineers (marine works, repetitive production, prefabrication, and pre-casting at scale).

2.3 Maas tunnel

In The Netherlands, also in the 1930s, another important infrastructure had been planned for a while: a fixed link, a road crossing river Maas in Rotterdam, in one of the largest harbours in Europe. The project was tendered out by the Engineering Department of the City of Rotterdam, who was open to alternatives and new technology, focusing on reducing the cost and time and with desire to learn from leading innovations.

The project was tendered with two alternatives: as a suspension bridge or as an immersed tunnel of two circular tubes of steel, similar to the concept that had been developed and used in the US since the Detroit Michigan Central Railway Tunnel inception.

At the time, a short reinforced concrete immersed tunnel of 120m for pedestrian traffic had already been constructed in Berlin (Der Spreetunnel at Friedrichagen, 1927). For the Mass tunnel, a reinforced concrete alternative was proposed by C&N in a joint venture with a group of Dutch contractors. The alternative was accepted by the owner, and construction started in 1937. The Maas tunnel project (Figure 8) was completed and opened to traffic in 1942 (Rasmussen, 1987). Table 1, based on ITA database, shows immersed tunnels since 1910.

2.4 Deas Island and Havana immersed tunnels

The story about the construction of the Maas Tunnel went around the world. Here are the words of the Chief Engineer of the Maas Tunnel, M. Lassen-Nielsen, who was based in Rotterdam at the time:

“Christiani & Nielsen’s interest in the traffic problem was first aroused ten years ago by Mr. George Massey, a very enterprising man, who owns a machine shop in a small town in the vicinity of Vancouver, Mr. Massey read an article on the tunnel under the River Mass in Rotterdam and wrote to the company to find out if a similar tunnel could be built under the Fraser River. Correspondence with Mr. Massey continued for many years until, in 1955, Mr. Lassen-Nielsen went to Vancouver to investigate the matter on the spot. As a result of this investigation Christiani & Nielsen decided to collaborate with Foundation of Canada Engineering Corporation Limited (Fenco), the executive Vice-President of which is Mr. Per Hall.” (Lassen-Nielsen, M., 1959).

In 1956 the agreement to design and construct the Deas Island tunnel was made (Figure 9). Again, work was done in collaboration between the local construction companies and the international immersed tunnel specialists. Around the same time, an immersed tunnel was planned in Cuba, crossing the Havana harbour, constructed by French company Grand Travaux de Marseille (G.T.M).

Figure 9. Deas Island Tunnel (1958).

2.5 European immersed tunnels in the 1960 - 1970

After the success of the Deas Island tunnel and Havana immersed tunnels - both projects involving European contractors - and with the economic stability and growth in Europe, there was a boom in the construction of immersed tunnels in Europe starting up in the 1960.

See Table 2 for a list of worldwide immersed tunnels in the period 1958-1969. New technologies were developed, and some immersed tunnels had multiple functions, as concrete casting allowed for a flexible cross section with several tubes and several functions. Some of the new immersed tunnels were constructed in soft soil conditions and some were placed on piles, like the Tingstad Tunnel in Gothenburg, Sweden.

The first immersed tunnel and first major subsea tunnel project in Denmark, Limfjordstunnel, was opened on the May 6, 1969. The project used the experience gained from the designs and constructions of the immersed tunnel, bridge, and marine projects abroad.

Table 2. Immersed tunnel 1958 -1969.

Europe	Outside of Europe
Rendsburg, Germany	Havana, Cuba
Liljeholmsviken, Sweden	Deas Island, Canada
Coen, The Netherlands	Webster Str, US
Viex Port, France	La Fontaine, Canada
Tingstad, Sweden	Parana, Argentina
Rotterdam metro, The Netherlands	Dojima River, Japan
Ij, Amsterdam, The Netherlands	
J.F. Kennedy (Schelde), Belgium	
Heinenoord, The Netherlands	
Limfjord, Denmark	

Concrete technology had been under development for many years, and in the Netherlands, it was assessed that new immersed tunnels could be constructed without an external waterproofing membrane, as opposed to earlier immersed tunnels. That required concrete without through-going cracks and control of cracks.

The Vlakte tunnel (1975) (Figure 10) was the first concrete immersed tunnel built without a waterproofing membrane and the first segmental

Figure 10. Vlakte tunnel, casting with no early-age cracking.

immersed tunnel (Glerum, 1976). The method was proved to be cost-effective and has been used on immersed tunnels in The Netherlands ever since.

2.6 Concrete immersed tunnels around the world

Concrete tunnels have been constructed around the world since the Deas Island tunnel opened in 1958. The Louis-Hippolyte Lafontaine Bridge-Tunnel in Montreal opened in 1967. Cut & cover tunnels with 4 or more road lanes are often provided with permanent transverse prestressing. This immersed tunnel in Canada, like the Havana tunnel, also had permanent transverse prestressing; until recently, very few immersed tunnels have made use of permanent transverse prestressing.

The company Per Hall, involved in Deas Island and Louis-Hippolyte immersed tunnels, used the experience from Canada in the first immersed tunnel in Hong Kong, the Cross-Harbour tunnel (1972), where a monolithic concrete tunnel was a cost-competitive alternative compared to the initially proposed steel solution option.

Note the first immersed tunnel in Japan was the Dojima River (1969), inspired by US steel shell type, much driven by seismic considerations which are not relevant for immersed tunnels in Northern Europe.

The concrete method used on the first immersed tunnel in Hong Kong has been used on all six immersed tunnels constructed in Hong Kong since 1972. The first immersed tunnel in Australia was the Sydney Harbour Tunnel (1992), also using concrete type, with inspiration taken from the immersed tunnels built in Hong Kong.

A specially constructed concrete immersed tunnel was the Singapore cable tunnel (1986), a project that gave inspiration to the later Øresund tunnel (2000). Inspired by Øresund, The Busan-Geoje immersed tunnel was constructed between 2004-2010. It was the first immersed tunnel in South Korea and the first segmental concrete tunnel in Asia, (Figure 11) (Olsen 2009).

Figure 11. Busan-Geoje immersed tunnel, casting yard.

It was a brave decision to use segmental concrete immersed tunnel in South Korea for the first time. It followed the European practice, relying on high-quality concrete, and differed significantly from the practices adopted in Hong Kong and China, based on monolithic elements with a waterproofing membrane, or steel shell used in Japan.

The concept of segmental concrete immersed tunnels was introduced in China with the Hong Kong – Zhuhai – Macao immersed tunnel (2018), with successful outcome.

3 LONG IMMERSED TUNNELS

After the opening of the Deas Island tunnel, confidence built within the industry and companies were ready for the next major immersed tunnel projects. Since the 1930s, it had been a long-term ambition in Denmark to connect more of the many islands of the country, either by long bridges or tunnels. Proposals for fixed links, both at Storebælt (Great Belt) and at Øresund, were put forward, revising a proposal made in 1930. A proposal for an immersed tunnel under the Channel (UK-France) was put forward by C&N in 1963.

In the United States, the first major fixed link, the Chesapeake Bay Bridge–Tunnel, a 28,3km fixed link crossing the mouth of the Chesapeake Bay in the state of Virginia, opened in 1964. It replaced ferries that had operated since the 1930s. This fixed link, combining bridges and tunnels with artificial islands, has been the inspiration for many fixed links around the world, in projects like the Great Belt Link (1998) in Denmark and the Tokyo Bay Aqua-line (1997) in Japan.

In 1985 a 2,6km long subsea tunnel was planned in Singapore by C&N (Figure 12). Inspired by segmental bridge construction - an innovative method to increase production rate and maintain sufficient water tightness in concrete quality - a factory-like production set-up was made. A segmental-type immersed tunnel was used (Rasmussen 1987). Young engineers involved in the Deas Island tunnel (1958) were now senior engineers working in Singapore.

A similar type of immersed tunnel for water intake was constructed for the Kilroot power station, in Northern Ireland (1978). Like the Singapore cable tunnel, the segments were cast under factory-like conditions, assembled and post-tensioned on a ship-lift made specifically for the project.

The length of the tunnel elements was 100m, using 29 elements with segments of 3,5m, and 754 segments were used in total. The project served as inspiration for the factory-like construction method for the Øresund tunnel (Figure 13), with same people from the Singapore cable tunnel developing the concepts.

The Øresund tunnel is a combined road and rail immersed tunnel, 3,6km in length, constructed by 20 tunnel elements of 180m. The length and scale required special considerations around the construction methodology of the elements. Two production lines allowed the production of two elements every second month.

Figure 12. Singapore cable tunnel.

Figure 13. Øresund tunnel element fabrication.

When the Hong Kong – Zhuhai – Macao immersed tunnel project was planned in 2008, with a length of 6,0km, considerations were made to construct the tunnel elements either as in Busan (casting yard) or as in Øresund (production lines). Site constraints on one of the available sites on Niutou Island led to the decision to use a production-line setup (Figure 14). The tunnel element length of 180m was selected, similar to Øresund and Busan, in a total of 33 tunnel elements.

The Femern tunnel, with 18km of length, is under construction and uses experience from concrete immersed tunnels from the last 65 years.

Figure 14. Hong Kong – Zhuhai – Macao element factory.

4 SHORT SPECIAL ELEMENT IMMERSSED TUNNELS

On another scale, with a different type of complexity, we find a shorter special type of underwater tunnel like the Paris metro, where the immersed tunnel type can be made to fit a specific element construction method or to fit the ground conditions. An example from the Stockholm metro, the subsea tunnel at Liljeholmsviken (Chr. Ostenfeld 1968) had a shallow alignment, with the immersed tunnel element structurally spanning like a bridge beam (Figure 15).

Figure 15. Liljeholmsviken immersed tunnel.

Figure 16. Söderström immersed tunnel.

Söderströmtunnel (Glückert 2014), located close to Liljeholmsviken, is a more recent example. Steel shells were constructed several hundred kilometres away, in Estonia, and towed on a barge to

Stockholm, Sweden for installation. The method was developed to handle specific constraints on-site with limited water depth and with an opportunity to optimise cost and risk (Figure 16). The tunnel elements on Söderström were placed on piles, naturally inspired by bridge design and construction.

5 CONCLUSION

This paper delineates some important steps taken in the evolution of immersed tunnel technology when transferring between continents, emphasizing the preservation of core principles including waterproofing, durability, joints, and longitudinal performance.

Highlighted innovations in immersed tunnels (IMT):

Now: Very long immersed tunnel: 18km, Femern tunnel,

2016: Steel shell concrete IMT floating: Söderströmtunnel,

2000: Gravel bed for concrete IMT: Øresund tunnel,

1986: Production line: Singapore cable tunnel,

1975: Segmental construction: Vlake tunnel,

1964: Immersed tunnel for Fixed link: Chesapeake tunnel,

1942: Concrete monolithic: Maas tunnel,

1910: First immersed tunnel: Michigan central railway.

Innovation and knowledge sharing is important for the development of sustainable solutions.

The past shows that changes are made when inspired by other fields of engineering and across geographies. While learning from the past, new thinking can guide us towards the future. Some lessons learned:

- 1) *Knowledge sharing and technology implementation follow people and organisations more often than what can be heard, taught and read about.*
- 2) *Owners shall be open to new ideas, and willing to take risks on new technologies to make noteworthy changes.*
- 3) *Globalisation is a facilitator for knowledge sharing, striking a good balance between collaboration and competition between organisations in the global market.*

Future sustainable immersed tunnels need innovation within low-carbon materials based on renewable energy, recycling, equipment electric powered and much more.

As an industry, we should celebrate owners, consultants, contractors, suppliers, and influenced stakeholders for being brave in promoting new technologies. Had it not been for curious persons like the late George Massey in Vancouver, Canada, and M. Lassen-Nielsen, Chief engineer of C&N in Rotterdam and the Engineering Department of the City of Rotterdam, the owner of the Mass tunnel, the immersed tunnel technology, at least in Northern

Europe, would have developed in a completely different direction.

Question: Who are the “George Masseys” and “M. Lassen-Nielsens” of today, to inspire a culture of innovation and develop it for future immersed tunnel projects?

ACKNOWLEDGEMENTS

The author would like to thank Niels Iversen, former Technical Director of Christiani & Nielsen, for inspirational discussions and showing a way through extensive use of CN Post - with technical articles from C&N projects during the years - how the development of new technology in the past, can be an inspiration for the development of new technology now and in the future.

Small-scale model test for the dynamic behavior of submerged floating tunnels considering the coastal connection with subsea bored tunnels

Joohyun Park*, Seok-Jun Kang, Jun-Beom An, Jin Kim & Gye-Chun Cho

Department of Civil and Environmental Engineering, Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Republic of Korea

ABSTRACT: Due to the displacement imbalance between the submerged floating tunnel (SFT) and the subsea bored tunnel, the coastal connection of the SFT has weak stability. Therefore, it is necessary to accurately analyze the dynamic characteristics of the SFT by considering the interaction between the ground and the tunnel structure in the coastal connection. In this study, a small-scale model test was performed to evaluate the effect of ground-tunnel interaction on the dynamic characteristics of an SFT in the coastal connection due to horizontal displacement induced by the dynamic behavior of the SFT. In the model, the coastal connection has been simplified to a situation in which a bored tunnel and SFT were connected on a cliff-shaped coastal ground. The experiment was performed by changing the horizontal displacement of the end of the SFT. The vibration of the SFT was induced by impacting the outer side wall of the SFT with a hammer. The vibration response of the SFT was measured using accelerometers. The measured time domain acceleration response spectrum signal was converted to a frequency domain signal through fast Fourier transformation (FFT), and the natural frequency of SFT was analyzed. As a result, the horizontal displacement caused deformation in the ground around the bored tunnel and reduced the ground stiffness. Depending on the induced strain, the natural frequency of SFT decreased linearly, then nonlinearly in the form of an exponential function, and then tended to converge. It has been experimentally confirmed that ground-tunnel interaction in coastal connections affects the dynamic characteristics of SFT. Therefore, to accurately predict the dynamic behavior of a SFT, it is essential to reflect ground deformation and non-linear characteristics considering the interaction between the ground and tunnel at coastal connection.

1 INTRODUCTION

Bridges, subsea bored tunnels, and immersed tunnels are known as representative infrastructures used to cross the sea or river. However, they have the problem of being greatly affected by the geotechnical factors of the construction site. In particular, when the seabed is deep, they require excessive construction costs and practical limitations (Jiang et al. 2018). Recently, as an alternative, research has been actively conducted on submerged floating tunnels (SFT), in which a tunnel module floats at a specific water level through mooring and tethering methods. They have the advantage of being less affected by meteorological factors above the water. Still, they behave dynamically under the influence of tidal currents in a maritime environment, so accurate analysis is required (Long et al., 2009). For SFTs to provide a path between

lands, they must be connected to the ground (Xiao and Huang 2010). In Figure 1, a representative schematic diagram of the coastal connection for the connection between the bored tunnel and the SFT is presented. Unlike SFT, which has relatively dynamic behavior, a bored tunnel is constrained by the surrounding ground. Due to the displacement imbalance between the SFT and the bored tunnel, the coastal connection of the SFT has poor dynamic stability, so this characteristic must be considered when the SFT is connected to the ground through the connection with the bored tunnel (Kang et al., 2020).

In previous literature considering coastal connection, research on earthquake excitation in SFT was conducted (Xiao and Huang, 2010). Still, there was a limitation in assessing the boundary condition only as a bearing element. The soil-structure interaction (SSI) plays a crucial role in determining the response

*Corresponding author: joohyun.park@kaist.ac.kr

Figure 1. Schematic diagram of coastal connection for connecting subsea bored tunnel and submerged floating tunnel.

of structures to static or dynamic loading. This influence extends beyond the soil behavior alone and encompasses the structural response under load (Kavitha et al. 2016). Therefore, a comprehensive analysis should consider both soil characteristics and structural features. The effect of connection stiffness at the end of the SFT on the natural frequency of the SFT system was determined through an experimental study conducted by Park et al. (2021). Kang et al. (2020) performed a numerical analysis to assess the stress concentrations at coastal connections when subjected to static conditions. They found that implementing a coastal connection with a flexible joint could effectively mitigate the stress concentration at this junction. Park et al. (2022) conducted a series of parameter studies by numerical methods to confirm that the resonant frequency of the SFT system can be controlled by implementing a ring-type joint between the SFT and the boundary. Kang et al. (2023) employed a three-dimensional numerical analysis to assess the impact of coastal connection design in the presence of dynamic loading conditions. However, the previous studies have not effectively determined the alterations in dynamic characteristics while accounting for the interaction between soil and the tunnel structure. According to Doebling et al. (1998), ground condition alterations impact the vibration characteristics of structures. Hence, the assessment of changes in dynamic properties with a variety of SSI can be conducted through an analysis of the free vibration response of the SFT. Therefore, the current study aims to experimentally analyze the effect of changes in soil-tunnel interaction on the dynamic characteristics of SFT in the coastal connection due to horizontal displacement induced by the dynamic behavior of SFT. A small-scale model was used to simulate the coastal connection between the bored tunnel and SFT. The experiment was performed by changing the horizontal displacement of the end of the SFT. The vibration of the SFT was induced by impacting the outer side wall of the SFT with a hammer. The vibration response of the SFT was measured using

accelerometers attached horizontally to the impact inside the SFT. The measured time domain signal was converted to a frequency domain signal through FFT, and the natural frequency of SFT was analyzed.

2 EXPERIMENTAL STUDY

In this study, an experimental study was conducted using a small-scale model to evaluate the dynamic characteristics of a submerged floating tunnel considering the coastal connection with the subsea bored tunnel. In the experiment, a rope was used to simplify the SFT module floating in the water by a mooring line system. When designing an SFT in practice, various buoyancy weight ratios (BWR) are considered, but in experiments, only the case where BWR is 1 was considered. Using water has the advantage of considering various BWRs and the effect of hydrostatic pressure. However, this has the limitation that it complicates the behavior of SFT and makes it difficult to clearly understand the interaction with the ground in the coastal connection. In addition, actual SFT exhibits various dynamic behaviors depending on load combinations in the marine environment, but the most dominant behavior during operation is lateral behavior due to tidal current. Therefore, only horizontal displacement was considered in the model test. A model test was performed to observe changes in the natural frequency of SFT due to horizontal displacement caused by the dynamic behavior of SFT. The main goal was to analyze the effect of soil-tunnel structure interaction on the dynamic characteristics of SFT at coastal connection.

2.1 Small-scale model test setup

The setup for the small-scale model test consisted of a subsea bored tunnel, a coastal ground restraining it, and a submerged floating tunnel connected to the bored tunnel and supported by a rope at one end (Figure 2a). The rope was connected to a crane to

simulate the horizontal displacement caused by the dynamic behavior of the SFT. To model the cliff-shaped ground, a soil box combined with a separable bulkhead was used. The bulkhead was installed at the boundary of the coastal connection to distinguish between the bored tunnel and SFT. Polyethylene sheets, characterized by their elastic properties, exhibit deformation in response to the behavior of SFT and concurrently serve as a barrier to prevent the loss of ground materials and water. Polyethylene sheets were utilized around the tunnel to allow the tunnel and surrounding ground to interact according to the dynamic behavior of the floating tunnel (Figure 2b). To measure the acceleration response of the SFT, sensors were attached to the inner side wall of the tunnel in the horizontal direction parallel to the ground (Figure 2c).

2.1.1 Weathered soil ground

A soil box was manufactured to simulate the conditions under which a tunnel was constructed on soil, and the width, length, and height of the box were 100 cm, 100 cm, and 90 cm, respectively (Figure 3a and 3b). To enhance visibility, acrylic was employed as the material for the soil box. The ground was modeled as weathered granite soil widely distributed in Korea. This proves effective for assessing tunnel interaction, demonstrating substantial strength and self-support when compacted to the optimal moisture content. As shown in Table 1, the soil has a passing quantity of #200, a sieve passing rate of 2.31%, a uniformity coefficient (C_u) of 3.47, and a curvature coefficient (C_c) of 0.94. It is classified as poorly graded sand (SP) by the Unified Soil Classification System (USCS).

2.1.2 Tunnel structure

The tunnel was modeled as an acrylic hollow tube with the physical properties shown in Table 2. The diameter, length, and thickness of the tunnel were 25 cm, 150 cm, and 1 cm, respectively (Figure 3a and 3b). Since the distance between the tunnel axis and the ground surface, C , is 37.5 cm, the shallow tunnel condition $C/D = 1.5$ was considered. The tunnel structure consisted of a 100cm bored tunnel section confined by weathered soil and a floating tunnel section protruding 50cm outside the bulkhead (Figure 3b). The end of the bored tunnel was fixed to the wall of the soil box. The end of the floating tunnel was supported by a rope connected to the crane so that the dynamic behavior of the SFT could be simulated through crane operation.

2.2 Measurement and analysis system

The measurement system to determine the dynamic response characteristics of the floating tunnel was configured as shown in Figure 4. Inside the tunnel, an accelerometer was attached in a direction parallel to the hammer impact and horizontal to the ground. The accelerometers were located 5 cm and 1 cm from the bulkhead toward the bored tunnel (Figure 3c). A hammer with a length of 20 cm and a weight of 0.5 kg was freely dropped from a 45-degree point and struck in a direction parallel to the tunnel. A widely used rubber tip was selected for the hammer to measure the response in the low-frequency region.

To measure the fine-scale vibration response of the structure, two accelerometers (353B18, PCB Piezotronics, NY, USA) with a sensitivity of 10 mV/g and capable of measuring accelerations of up to 500 g and frequencies of 1 Hz to 10 kHz were used. After hammer impact, the signals measured by the accelerometer were filtered, amplified, and acquired by a signal conditioner (482C54, PCB Piezotronics, NY, USA), oscilloscope DSOX3024T, Keysight Technologies, CA, USA), and a laptop computer. Noise elimination was achieved through a signal conditioner, ensuring the acquisition of high-quality

signals. During this process, the signal underwent amplification to facilitate the reception of the target signal in the time domain. Furthermore, the utilized oscilloscope was specifically configured to capture free vibration data resulting from hammer impact, encompassing the triggering system. The recorded time domain data was converted to frequency domain data through fast Fourier transform (FFT) using MATLAB (MathWorks, MA, USA). From the results obtained after filtering by removing random noise through a low-pass filter and a high-pass filter, the pre-dominant frequency was evaluated as the natural frequency of the SFT. Additional data processing included improving the quality of the FFT data through offset processing and zero-padding.

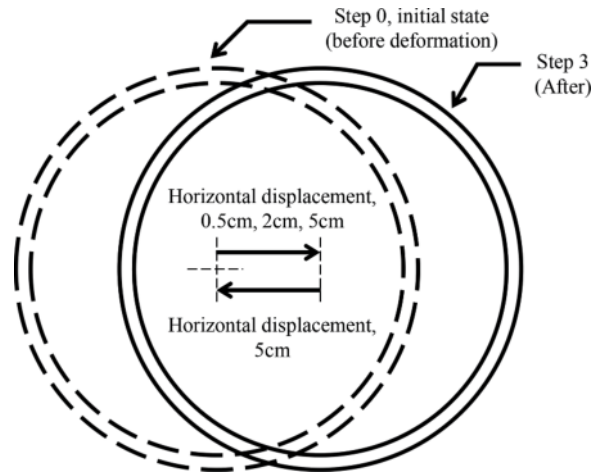

Figure 5. Horizontal displacement at the end of SFT by step.

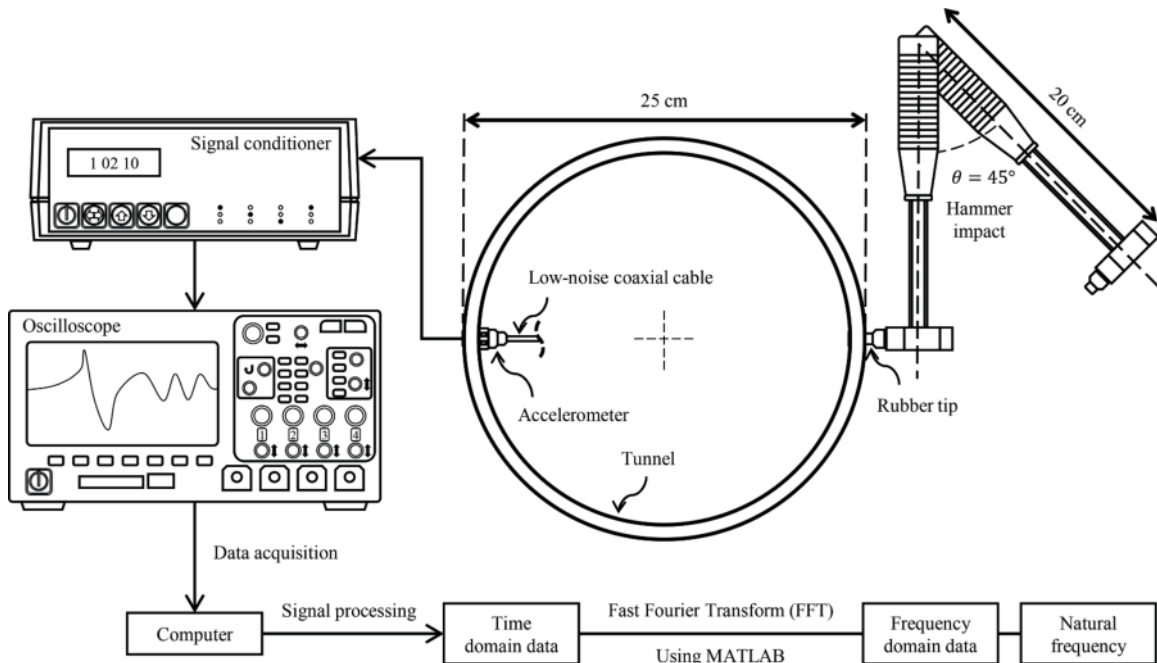

Figure 4. Measurement system.

Table 3. Small-scale model test procedure.

Step 0	Initial state: static equilibrium with the soil confinement
Step 1	A state where the horizontal displacement of the end of the SFT is 0.5cm (+ 0.5 cm)
Step 2	A state where the horizontal displacement of the end of the SFT is 2.0cm (+ 1.5 cm)
Step 3	A state where the horizontal displacement of the end of the SFT is 5.0cm (+ 3.0 cm)
Step 4	A state in which the end of the SFT returns 5cm in the opposite direction. (- 5.0 cm)

2.3 Test procedure

In the small-scale model test procedure, the assessment of natural frequencies was conducted for four distinct horizontal displacement states, ranging from step 0 (the initial step) to step 4 (the final step), as illustrated in Figure 5 and summarized in Table 3. Up to step 3, the state where horizontal displacement at the end of SFT of 0.5 cm, 2 cm, and 5 cm occurred in the same direction was evaluated. In step 4, the condition with a return of 5 cm in the opposite direction was assessed. To minimize the influence of changes in rope tension, a 0.5 cm unit was adopted.

3 EXPERIMENTAL RESULTS AND DISCUSSION

After performing a small-scale model test, the signals measured at each step were compared and analyzed. Figure 6 presents time domain data acquired through the measurement system (Figure 6a) and frequency domain data processed through FFT

(Figure 6b). As shown in the time domain result, the amplitude of free vibration of the SFT model due to the impact load showed a transient response in which the amplitude decreased exponentially with time.

Due to the influence of sensor location, the response was observed first from sensor 2, which was installed closer to the hammer impact. Nevertheless, as shown in the frequency domain graph in Figure 6b, it was found to have similar natural frequency values. This means that the natural frequency of the SFT system was well captured. The natural frequencies evaluated for each step are presented in Table 4. As the step increases, the natural frequencies of SFT gradually decreased as the step progressed and showed a tendency to converge. The natural frequencies from sensor 2 offering the same trend as sensor 1.

The results of plotting the natural frequencies of the SFT obtained at each step according to horizontal displacement are presented in Figure 7a. As a horizontal displacement of 0.5 cm occurred from step 0 to step 1, the natural frequency of SFT tended to decrease linearly. The natural frequency is reduced due to an additional horizontal displacement of 1.5 cm from step 1 to step 2. As the horizontal displacement increased by 3 cm from step 2 to step 3, there was a decrease in the natural frequency. However, the rate of decrease diminished significantly, indicating a tendency towards gradual convergence. These results can be confirmed more clearly through the natural frequency reduction rate results according to the accumulated horizontal displacement presented in Figure 7b. In step 3, where the maximum displacement occurred, the natural frequency reduction rate of SFT was found to be 15.49% in sensor 1 and 13.48% in sensor 2. There

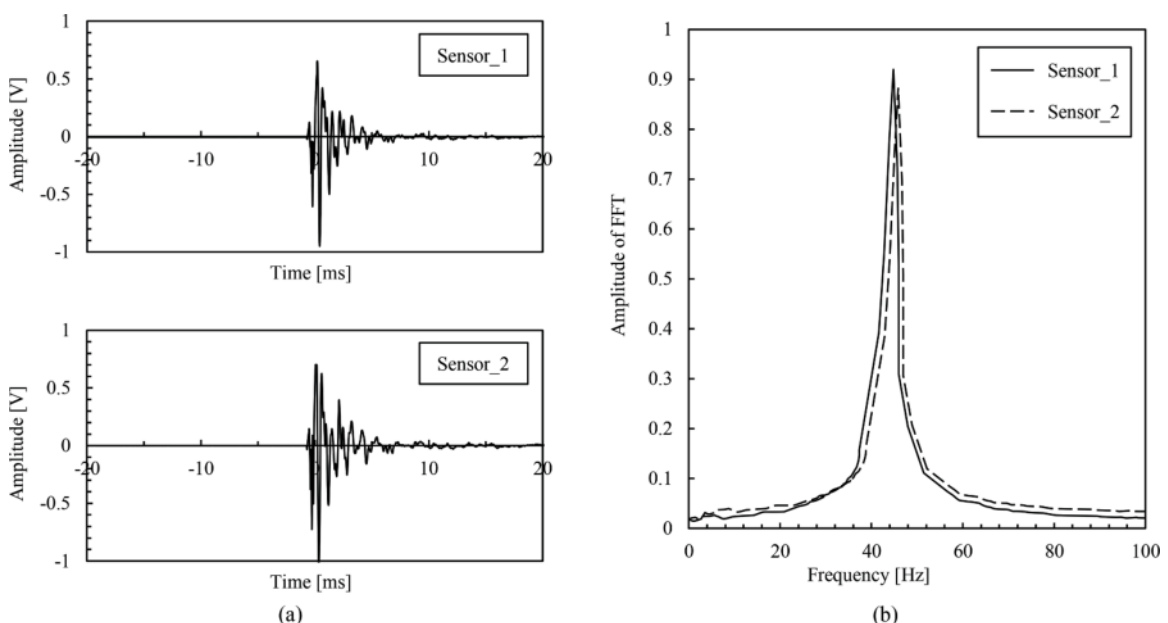

Figure 6. Measured signals: (a) time domain data and (b) frequency domain data.

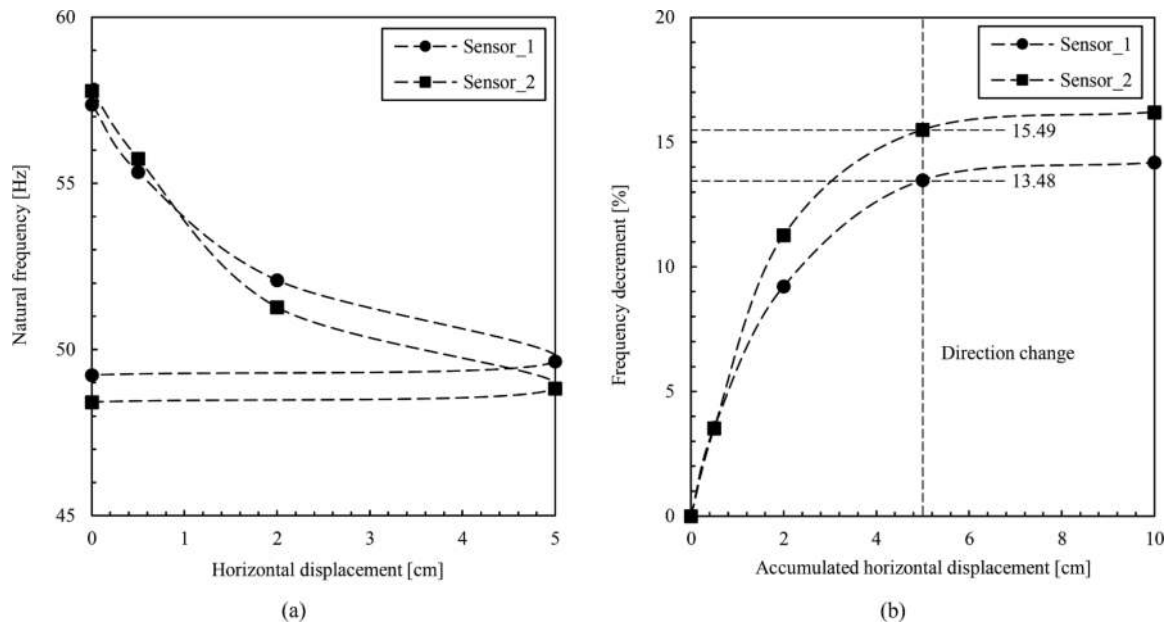

Figure 7. Natural frequency of SFT evaluation results at each step: (a) natural frequency of SFT according to horizontal displacement and (b) natural frequency reduction rate according to accumulated horizontal displacement.

Table 4. Natural frequency of SFT for each step.

Step #.	Horizontal displacement [cm]	Natural frequency by sensor_1 [Hz]	Natural frequency by sensor_2 [Hz]
0	0	57.37	57.78
1	0.5	55.34	55.75
2	2	52.08	51.27
3	5	49.64	48.83
4	0 (Return)	49.26	48.42

was a slight decrease even after the direction change, but it generally tended to converge. This can be explained by the fact that plastic strain induced in the soil occurred in the process of generating the maximum horizontal displacement.

The results of the experimental study indicate that the dynamic properties of SFT are changed by soil-tunnel structure interaction (SSI) at the coastal connection. This is consistent with the literature (Kavitha et al. 2016), as an increase in horizontal displacement causes soil deformation around the tunnel, which leads to a decrease in confining pressure and the natural frequency of the structure interacting with the surrounding ground. A substantial horizontal displacement from stage 0 to stage 3 leads to a significant compressive force on the ground in the direction of the SFT movement. Conversely, in the opposite direction, the ground undergoes stretching, resulting in reduced confinement. The reduction in confining pressure at the SFT-ground interface leads to a decrease in the natural frequency of the SFT. Consequently, plastic strain is induced around the SFT, leading to plastic permanent displacement.

This means that even in the process of returning to the initial state from step 3 to step 4, the natural frequency of the SFT is not recovered and is still reduced to a converged value, which can be inferred that permanent deformation has been caused in the soil. It was experimentally confirmed that the dynamic behavior of SFT causes permanent deformation and a decrease in the confining pressure of the ground at the coastal connection and that the resulting SSI also affects the dynamic properties of SFT.

4 SUMMARY AND CONCLUSIONS

In this study, a small-scale model test was performed to evaluate the effect of ground-tunnel interaction on the dynamic characteristics of an SFT coastal while the horizontal displacement occurs. The experiment was performed by changing the horizontal displacement of the end of the SFT. The main conclusions obtained through this study are summarized as follows.

- 1) As the horizontal displacement of the SFT increases, the natural frequency of the SFT appears to decrease, and SSI at the coastal connection affects the dynamic characteristics of the SFT.
- 2) The behavior of the SFT impacts the magnitude of ground deformation, and the consequent confining pressure influences the change in natural frequency.
- 3) The excess dynamic behavior of SFT may cause permanent deformation in the soil, resulting in the natural frequency of SFT not being recovered after being reduced.

ABSTRACT: The development of large urban agglomerations has led to a demand for large-scale infrastructure construction. In response to this trend, the immersed tunnel structures has been evolving towards longer spans and deeper burials. Compared with traditional reinforced concrete structures, steel-concrete-steel immersed tunnels have gradually demonstrated their advantages of high load-bearing capacity, good waterproof properties, and low construction site requirements. The immersed tunnel of the Shenzhen-Zhongshan Link is a typical application of steel-concrete-steel immersed tube tunnel. However, due to the lack of application cases and relevant studies on this type of structure, the load-bearing mechanism of steel-concrete-steel structures is unclear. This has brought great challenges to the design and construction of the immersed tunnel of the Shenzhen-Zhongshan Link. This study is based on sufficient structural experiments, and the structural mechanism of the steel-concrete-steel immersed tube tunnel has been studied in terms of bending and shear resistance. The study has fully considered the multi-axis effect of concrete, multi-mechanism shear resistance and has developed a complete calculation method for steel-concrete-steel immersed tunnels. This paper provides comprehensive guidance for the design and construction of engineering structures with similar forms.

1 INTRODUCTION

With the development of the economy, human activities are gradually expanding to the underground and marine domains. The exploration of these new areas will provide more space, resources and opportunities. To meet the transportation needs in the underground and marine domains, the immersed tunnel structures, with low environmental disruptions and little climate dependencies, have been widely utilized in engineering projects (Chen, 2017).

The concept of immersed tube tunnels originated in the United States and later saw significant development in Europe and Japan (Grantz, 1997). Traditional immersed tunnels can be classified into two categories: reinforced concrete tunnels and steel-concrete composite tunnels. However, it was not until the 1980s that a new type of structure, known as the steel-concrete-steel tunnel structures, emerged (Tomlinson et al., 1989). Compared to traditional type, the steel-concrete-

steel tunnel offers several advantages including smaller size, material savings, increased load-bearing capacity, improved earthquake resistance, and better resistance to explosive impact. Steel plates can serve as concrete formwork during construction and provide both structural support and waterproofing during operation. Due to these numerous advantages, the steel-concrete-steel tunnel structure has become one of the most promising development directions for future immersed tunnels.

The steel-concrete-steel immersed tunnel structure is relatively novel with limited research and application. Existing methods for the bending and shear capacities calculation, as well as some related research, are as follows.

In terms of bending capacity, the relevant regulations generally adopt the classical plastic design method based on section equilibrium (Bowerman et al., 2000). However, research has also indicated that steel-concrete structures may exhibit other brittle failure modes when subjected to bending moments

*Corresponding author: zhang-hs22@mails.tsinghua.edu.cn

with improper design (Xie et al., 2007). By installing steel end plates, a combination effect can be achieved between the steel and concrete, promoting ductility and enhancing bending capacity (Wang et al., 2016).

The initial calculation method for shear capacity referred to concrete design theory and involved summing the capacities of the concrete and steel portions (Narayanan et al., 1994). For combination immersed tube tunnels without reinforcement, the diaphragms were considered as the reinforcement, and the shear capacity was calculated separately for longitudinal and transverse diaphragms. The larger value between the two cases was taken as the design capacity. Further studies have shown that the effect of flange dowel action on structural shear capacity is significant, and the original calculation method tends to be conservative (Yan et al., 2015).

The immersed tunnel of the Shenzhen-Zhongshan Link has a total length of 5,035m. The standard section consists of a double eight-lane configuration with a width of 46.0m and a maximum water head of 38m. To meet the construction requirements of this extra wide and deep-buried immersed tunnel, the steel-concrete-steel immersed tunnel structure has been adopted. However, the design traditional approach cannot be directly applied to the Shenzhen-Zhongshan Link. On one hand, the the immersed tunnel structure approximates a plane strain state, and the influence of multi-axial stress needs to be considered when calculating the bending capacity. On the other hand, the utilization of diaphragms introduces multiple shear transfer paths within the structure.

To address the issues of unclear mechanisms and inappropriate calculation methods for the steel-concrete-steel immersed tunnel structure, this study focuses on the immersed tunnel of Shenzhen-Zhongshan Link and establishes a comprehensive set of stress mechanisms for the structure, including bending and shearing. Through numerous experimental tests, the accuracy of these mechanisms is verified, resulting in a practical and reliable design calculation method for the load-bearing capacity.

2 BENDING CAPACITY WITH MULTI-AXIAL EFFECTS

This section focuses on the critical components of the steel-concrete-steel tunnel structure and investigates its bending mechanical characteristics by experiments. Seven large-scale bending tests were conducted to analyze the bending mechanism considering the multi-axial effect and validate the calculation methods.

2.1 Bending experiment

The bending test layout is shown in Figure 1, and the specimen parameters are shown (Table 1). The specimen was named as W1-W6 and W8. The height of the specimen is 800mm, the span is 6000mm, the width is

600mm, the upper flange thickness is 6mm, the lower flange thickness is 10mm, the axial diaphragm thickness is 10mm, the transverse diaphragm thickness is 6mm, s_a is the spacing between axial stiffeners, d_G is the height of the concrete void, and f_c' is the compressive strength of the concrete cylinder specimen.

Figure 1. The bending test layout.

Table 1. The specimen parameters of bending test.

No.	Specimen	s_a (mm)	d_G (mm)	f_c' (MPa)
1	W1	250	0	38.8
2	W2	100	0	38.8
3	W3	250	5	38.8
4	W4	250	10	38.8
5	W5	150	0	38.8
6	W6	250	15	20.3
7	W8	100	0	20.3

The final state of the specimen W1 is shown in Figure 2, while the load-displacement curve is depicted in Figure 3. Except for specimen W8, which failed due to the fracture of the lower flange steel plate, the failure of the other specimens was dominated by the crushing of the concrete, accompanied by localized buckling of the upper flange.

Figure 2. The final state of the specimen W1.

In the experiment, most components exhibited good ductility and showed evident confinement between the compressed flange plate and concrete before failure.

2.2 The mechanism of multi-axis effects in bending

Some existing design methods consider steel plates as steel bars and assume that they are in uniaxial stress

Figure 3. The load-displacement curve of bending experiment.

states. However, in actual tunnel structures that are continuously distributed with considerable length, steel plates are subjected to bidirectional strain states. Concrete supports the flange plate and restricts its transverse deformation, generating transverse stress. Therefore, a multiaxial stress analysis is conducted for the steel-concrete-steel composite tunnel during bending. The yield condition under multiaxial stress states is as follows:

$$\sqrt{\frac{(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2}{2}} = f_y \quad (1)$$

Where, σ_i ($i=1,2,3$) represents the principal stresses, and f_y is the yield strength of steel. Since the thickness of the flange is extremely small, the normal stress out of plane is negligible. Substituting $\sigma_3=0$ yields:

$$\sigma_1^2 + \sigma_2^2 - \sigma_1\sigma_2 = f_y^2 \quad (2)$$

According to Hook's Law:

$$\begin{cases} \varepsilon_1 = \frac{\sigma_1}{E_s} - \nu_s \frac{\sigma_2}{E_s} \\ \varepsilon_2 = \frac{\sigma_2}{E_s} - \nu_s \frac{\sigma_1}{E_s} \end{cases} \quad (3)$$

Where, ε_1 represents the strain corresponding to the principal stress σ_1 ; ε_2 represents the strain corresponding to the principal stress σ_2 ; ν_s is the Poisson's ratio, and E_s is the elastic modulus. Assuming the longitudinal direction as the direction corresponding to σ_1 , then ε_2 equals zero.

$$\sigma_2 = \nu_s \sigma_1 \quad (4)$$

$$\sigma_1 = \frac{1}{\sqrt{1 - \nu_s + \nu_s^2}} f_y \quad (5)$$

When $\nu_s=0.3$, $\sigma_1=1.125f_y$. This result indicates that due to the influence of multiaxial stress, the structure's elastic limit increases by 12.5%. The

steel-concrete-steel tunnel structure exhibits bidirectional reinforcement due to lateral constraint.

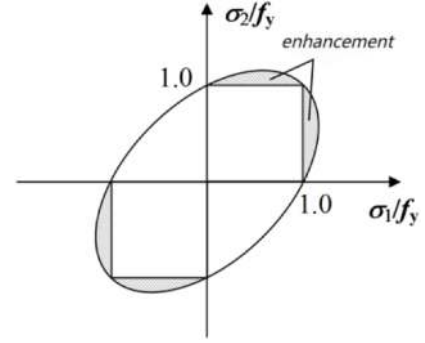

Figure 4. The yield surface of Von-Mises under 2D stress state.

When the structure enters the plastic state, it must satisfy the stress-strain conditions of elastic-plastic mechanics:

$$f = \sigma_1^2 + \sigma_2^2 - \sigma_1\sigma_2 - f_y^2 = 0 \quad (6)$$

$$d\varepsilon_p = d\lambda \frac{\partial f}{\partial \sigma} = d\lambda \begin{bmatrix} 2\sigma_1 - \sigma_2 \\ 2\sigma_2 - \sigma_1 \end{bmatrix} \quad (7)$$

$$\begin{cases} d\sigma_1 = \frac{E_s}{1-\nu_s^2} (d\varepsilon_1^e + \nu_s d\varepsilon_2^e) \\ d\sigma_2 = \frac{E_s}{1-\nu_s^2} (\nu_s d\varepsilon_1^e + d\varepsilon_2^e) \end{cases} \quad (8)$$

$$d\varepsilon = d\varepsilon^e + d\varepsilon_p \quad (9)$$

Where, $d\varepsilon_p$ represents the plastic strain increment; $d\sigma_1$, $d\sigma_2$ represent the stress increments, and $d\varepsilon_1^e$, $d\varepsilon_2^e$ represent the elastic strain increments. The equations mentioned above take into account that the shear stress and shear strain are assumed to be zero in this state.

When the stress state reaches a stable point, $d\sigma_1 = d\sigma_2 = 0$, which implies $d\varepsilon_1^e = d\varepsilon_2^e = 0$. Consequently, $d\varepsilon = d\varepsilon_p$. Since $d\varepsilon_2 = 0$, we find that $d\varepsilon_{p2} = 0$. Substituting this into equation (7) yields $2\sigma_2 - \sigma_1 = 0$, $\sigma_2 = 0.5\sigma_1$, so $\sigma_1 = 1.125f_y$.

This result indicates that, due to the influence of multiaxial stress, when using the plastic design theory, a 15% bidirectional reinforcement coefficient can be used in calculations to consider the enhancement of material performance caused by lateral constraints.

2.3 Methods for calculating bending capacity

When the structure is properly designed, it is recommended to calculate the bending capacity using plastic theory:

$$M_u = C_s y_{st} + C_c y_c + C_w y_{cw} - T_w y_{tw} \quad (10)$$

Where, M_u represents bending capacity; $C_s=f_y A_{st}$ is the compressive force of top flange; $y_{st}=h_s-0.5t_t-0.5t_b$ is the distance between the center of the top flange and bottom flange; $C_c=\beta f_c b_c x$ is the compressive force of concrete; $y_c=h_s-t_t-0.5x$ is the distance from the center of compression in the concrete to the center of the bottom flange; $C_w=f_y x t_{wx}$ is the compressive force of longitudinal diaphragm; y_{cw} is the distance from the center of the compressed section of the longitudinal diaphragm to the center of the bottom flange, which is equal to y_c ; $T_w=f_y(h_s-t_t-t_b-x)t_{wx}$ is the tension force of longitudinal diaphragm; $y_{tw}=0.5(h_s-t_t-x)$ is the distance from the center of the tensed section of the longitudinal diaphragm to the center of the bottom flange; A_{st} is the area of top flange; b_c is the width of concrete; h_s is the height of structure; t_{wx} is the thickness of longitudinal diaphragm; t_t and t_b are the thickness of flange; β refers to relevant code; x is the height of the compressed concrete zone which is obtained by:

$$C_s + C_c + C_w = T_s + T_w \quad (11)$$

Where, $T_s=1.15f_y A_{sb}$ is the tension force of bottom flange; A_{sb} is the area of bottom flange.

Figure 5. Schematic diagram of bending capacity calculation.

The comparison of relevant calculation methods with experimental capacity is shown (Table 2). The calculation method proposed in this paper demonstrates an improved accuracy of 5%-10% due to a more reasonable consideration of the mechanism. On the other hand, when using the yield strength of steel for calculation, it still yields lower values compared to the experimental results with an average error of -13.9%. This is attributed to the fact that the bending members possess good ductility, resulting in flange entry into the strengthening stage. In actual design, material strengthening is generally not considered, and can be regarded as a safety reserve.

In conclusion, the computation method for bending capacity provided in this paper aligns well with experimental results, with approximately a 10% safety margin reserved.

3 SHEAR CAPACITY WITH MULTIPLE MECHANISMS

This section focuses on the critical components of the steel-concrete-steel tunnel structure and

investigates its shear mechanical characteristics by experiments. Sixteen large-scale shearing tests were conducted to analyze the shear mechanism and validate the calculation methods.

3.1 Shear experiment

The shear test layout is shown in Figure 6, and the specimen parameters are shown (Table 3). The standard test specimen is half the actual size of the structures. The experiment was conducted with three-point loading mode and simply supported boundary conditions.

Figure 6. The shear test layout.

The specimen was named as J1-J14 and J16-J17. The height of the specimen h is 800mm; the span l is 1500,3000,3600mm; the width b_s is 400,600mm; the width of concrete b_c is 100,200,400,600mm; the spacing between axial stiffeners s_1 is 100,150,300mm; the upper flange thickness t_t is 6,25,30,40mm; the lower flange thickness t_b is 10,25,30,40mm; the axial diaphragm thickness t_{wx} is 6,10,12mm; the transverse diaphragm thickness t_{wy} is 6,10mm; compressive strength of the concrete cylinder specimen f_c' is 20.3,38.8MPa.

The final state of the specimen J1 is shown in Figure 7, while the load-displacement curve is depicted in Figure 8.

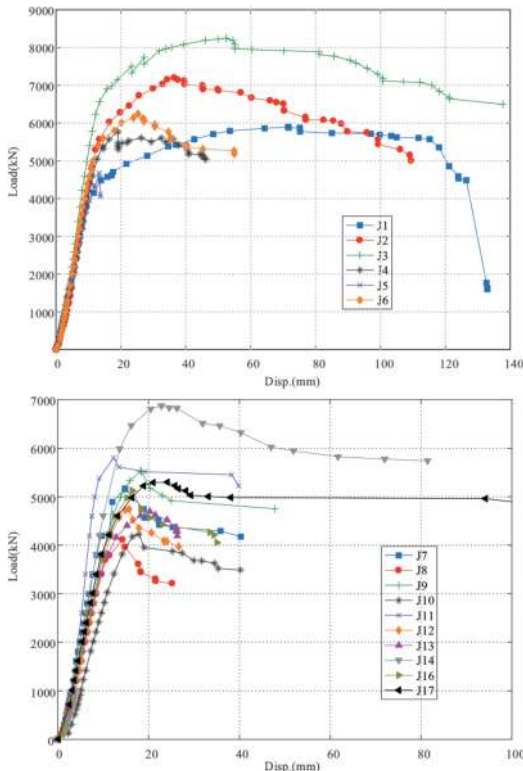

Figure 8. The load-displacement curve of shear experiment.

3.2 Several mechanisms of shearing

The shear capacity of the steel-concrete-steel composite immersed tunnel structure is not simply the sum of the concrete and steel parts, but is composed of three anti-shear mechanisms: composite truss, web pure shear, and dowel action.

3.2.1 Composite truss mechanism

In steel-concrete-steel structure, the concrete and longitudinal diaphragm are continuously distributed. The concrete experienced inclined compression failure in the experiment, indicating its role as an inclined compression strut. To balance the inclined compression stress, the axial and transverse diaphragm can provide tensile resistance, acting as tension rods. In this truss model, the upper chord is composed of both concrete and top flange, while the lower chord is made up of bottom steel plates. The composite truss mechanism is shown in Figure 9.

Figure 9. The composite truss mechanism.

The shear capacity of the structure controlled by the inclined strut is given by:

$$V_{uc} = f_{vud} b_c z \quad (12)$$

$$f_{vud} = 1.25 f_c'^{1/2} \quad (13)$$

where V_{uc} represents the shear capacity dominated by the concrete inclined compression strut; f_{vud} is the shear design strength of the concrete in inclined compression strut (JSCE, 2016); z denotes the height of the concrete shear region, which is equal to the height of the concrete when bending moments are not considered.

In the loading process, both longitudinal and transverse diaphragm can reach yielding. The shear capacity dominated by the failure of the tension rod is:

$$V_{ut} = \frac{\sin\alpha_1}{\sin\theta} z t_{wx} f_y + \sin\alpha_2 \frac{(\cot\theta + \cot\alpha_2)z}{s_w} A_t f_y \quad (14)$$

where V_{ut} represents the shear capacity dominated by the diaphragm yielding; A_t is the area of transverse diaphragm; θ represent the angle between the concrete strut and the horizontal direction; α_1 represents the angle between the tension rod and the horizontal direction; α_2 represents the angle between the transverse diaphragm and the horizontal direction.

Based on relevant literature and the experimental research conducted in this paper, it is recommended that $\theta=30^\circ$, $\alpha_1 = 60^\circ$, $\alpha_2 = 90^\circ$. The shear capacity of composite truss mechanism is as follows:

$$\begin{aligned} V_{truss} &= \min(V_{uc}, V_{ut}) \\ &= \min(1.25f_c^{1/2}, \sqrt{3}f_y \frac{t_{wx} + A_t/s_w}{b_c}) b_c z \end{aligned} \quad (15)$$

3.2.2 Web pure shear mechanism

It is assumed that the steel material has good ductility, allowing for sufficient stress redistribution between different mechanisms. This allows for the maximum shear capacity to be achieved in possible combinations. In the ultimate shear state, the axial diaphragms first participate as inclined tension rods in the shear truss mechanism. If there is still surplus capacity, they then contribute as steel webs in the pure shear mechanism.

Figure 10. The web pure shear mechanism.

The stress distribution of different shear mechanisms in the longitudinal diaphragm can be illustrated by the Mohr circle shown in Figure 11: Point A represents the ultimate stress in the composite truss mechanism in the direction of α_1 , where it is under pure tension; Point B corresponds to rotating state A to the vertical direction, where the normal stress is σ_{rx} and the shear stress is τ_r ; Point C represents the superposition of stress state B and the pure shear stress τ_p of the second mechanism, which is the actual stress state in the vertical direction. Based on the Mohr circle and the Von-Mises

yield theory, f_t and τ_p satisfy the following equation when the steel yields:

$$f_t^2 + 3f_t\tau_p \sin 2\alpha_1 + 3\tau_p^2 = f_y^2 \quad (16)$$

Figure 11. Stress distribution of shear mechanisms in diaphragm.

When $\theta=30^\circ, \alpha_1=60^\circ, \alpha_2=90^\circ$:

$$f_t = \frac{f_{vud} b_c}{\sqrt{3}(t_{wx} + \frac{A_t}{s_w})} \quad (17)$$

$$\tau_p = -\frac{\sqrt{3}f_t}{4} + \frac{\sqrt{12f_y^2 - \frac{21}{4}f_t^2}}{6} \quad (18)$$

The shear capacity of web pure shear mechanism is as follows:

$$V_{web} = \tau_p z t_{wx} \text{ (if } V_{uc} < V_{ut} \text{)} \quad (19)$$

3.2.3 Dowel action mechanism

In the steel-concrete-steel immersed tunnel structure, the top and bottom flanges are supported by concrete, similar to longitudinal bars in reinforced concrete. During the shear loading process, the flanges will provide shear resistance through the action of dowelling. The shear capacity of this mechanism is calculated by regression analysis of the experimental data:

$$V_{dowel} = 0.05f_y b_s (t_t + t_b) \quad (20)$$

where V_{dowel} is the shear capacity of dowel action mechanism; b_s is the width of flanges; t_t, t_b are thickness of flanges.

Based on the above analysis, the total shear capacity V_u of the steel-concrete-steel immersed tunnel structure is:

$$V_u = V_{truss} + V_{web} + V_{dowel} \quad (21)$$

3.3 Methods for calculating shear capacity

Based on the experimental data, it is recommended to make the following modifications to the calculation formulas for the shear capacity of two parts: the composite truss mechanism and the dowel action mechanism.

$$V_{\text{truss}_n} = \frac{4.3}{\lambda + 2.4} V_{\text{truss}} \quad (22)$$

$$V_{\text{dowel}_n} = \max\left[\frac{0.24f_y b_s (0.5t_t + t_b)}{1000} - 900(\text{kN}), \frac{0.05f_y b_s (t_t + t_b)}{1000}\right] \quad (23)$$

The theoretical model's predictions for the shear capacity are compared with experimental results in Table 4. The proposed approach has better accuracy, with an average error of 4.0%.

Table 4. Comparison of shear capacity calculation (kN).

4 CONCLUSION

This paper investigates the steel-concrete-steel composite immersed tunnel structure, with a focus on the bending and shear mechanisms, and the establishment of design methods. The following conclusions can be obtained:

- (1) During the bending load process of the steel-concrete-steel composite immersed tunnel, there

exists significant constraint between the steel and the concrete, resulting in the steel being in a multi-axial stress state. This effect can improve the actual flexural resistance capacity of the structure.

- (2) The shear capacity of the steel-concrete-steel composite immersed tunnel structure is mainly composed of three parts: the composite truss mechanism, the web pure shear mechanism, and the dowel action mechanism. The actual shear bearing capacity of the structure is the sum of the shear resistance provided by these three mechanisms.
- (3) A set of bearing capacity calculation methods suitable for practical structure design is proposed, which is well agree with experimental results and superior to existing design methods.

This research addresses key aspects of the bearing capacity of tunnel structures and has significant value on scientific research and practical application

ABSTRACT: The immersed tunnel of Shenzhen-Zhongshan Link is the highway immersed tunnel in the world with both the widest element tube and the widest single-carriageway hole. The construction standard is the highway with two-way four lanes (eight lanes total) and some super-wide sections even exceed two-way five lanes (ten lanes total). The width of the standard tubes is 46m and the maximum width of the widest tube is over 55m. The structure adopts the sandwich composite structure filled with high-flow and self-compacting concrete into the double-layer steel shell. The requirements for the tubes prefabrication quality and accuracy are strict. Then it needs some key technologies for the concreting construction of the super-wide tubes, such as the pouring process of self-compacting concrete, intelligent equipment development, deformation control, and so on. The construction organization design is mainly carried out around the conditions of prefabrication inside the dock. The final acceptance measurement data of the widest element tube shows the success of the prefabrication scheme. The experience summary is also drawn at the end.

Keywords: Shenzhen-Zhongshan Link, Immersed tunnel, Sandwich structure, Concreting

1 INTRODUCTION

Although the Hong Kong–Zhuhai–Macao Bridge has been successfully built and opened to traffic, with the sustained and rapid economic development of the Pearl River Estuary, traditional reinforced concrete immersed tunnels can no longer meet the demand for greater traffic flow and more lanes in the future. The Shenzhen–Zhongshan Link is located in the Lingding Sea area about 38 km upstream of the Hong Kong–Zhuhai–Macao Bridge. Its construction standard is the highway with two-way four lanes (eight lanes total) and the widest section even exceeds two-way five lanes (ten lanes total). It is the first large-scale application of steel-concrete-steel composite structure (“sandwich” structure) in tunnel engineering in China.

The sandwich structure immersed tunnels first appeared in Japan, which is a composite structure with hundreds of compartments composed of steel shell, partition, rib, and infilled concrete. With the development of high-flow self-compacting concrete

technology and the shortage of land for dry dock, this structure has been developed in Japan. Several sandwich structure immersed tunnels have been built, including the Kobe Port Minatojima Tunnel (1999), the Naha Tunnel (2011), and the Shin–Wakato, Tunnel (2012). Their construction standards did not exceed two-way three lanes (six lanes total) and the longitudinal division did not exceed 10 elements. In terms of length, width, the number of elements, the amount of steel and concrete, and complex construction conditions, the construction scale and difficulties of the Shenzhen–Zhongshan Link have exceeded those of Japan.

The civil works of the Shenzhen–Zhongshan Link immersed tunnel are divided into two sections, and the Steel shell tube manufacturing works are divided into another two sections. Here we present some key technologies of the concreting construction of the widest element tube, which is connected to Shenzhen, such as the pouring process of self-compacting concrete, intelligent equipment development, deformation control,

*Corresponding author: zongxiansu@hkust-gz.edu.cn

and so on. The construction organization design is mainly carried out around the conditions of using a dock in the shipyard for prefabrication. The final acceptance measurement data of the widest element tube shows the success of the prefabrication.

2 PROJECT OVERVIEW

The Shenzhen–Zhongshan Link is a strategic crossing channel across the Pearl River estuary, integrating a super-wide underwater tunnel, super-long span bridges, deep water artificial islands, and underwater interchange. It is also another mega project in China after the Hong Kong–Zhuhai–Macao Bridge (Shown in Figure 1).

Figure 1. The Route of the Shenzhen–Zhongshan Link.

The immersed tunnel is 5035m long, which is divided into 32 elements longitudinally. The width of the standard tubes is 46m and the maximum width of the widest tube is over 55m. After scheme comparison, taking into account factors such as structural bearing capacity and dredge volume of the foundation trench, the element tube of the immersed tunnel adopts a sandwich composite structure filled with self-compacting concrete inside the double-layer steel shells.

The main dimensions of standard elements are 165m long, 46m wide and 10.6m high. E28 to E32 are in curve elements with ultra-width from 46 to 55.467m and shorter length of 123.8m. Figure 2 shows the cross-section of the element tubes. Each standard element tube consists of 2255 compartments filled in over 29000 m³ of self-compacting concrete. The non-standard one in curve consists of approximately between 1700 to 2000 compartments filled in over 22500 m³ of self-compacting concrete. Figure 3 shows the steel shell structure with compartments. The compartments are relatively isolated from each other.

Figure 2. Cross-section of the element tubes.

Figure 3. Steel shell structure with compartments.

The closure joint of the immersed tunnel is located between E23 and E24. Then the construction of the immersed tunnel is divided into two contract sections for implementation after the steel shell manufacturing, including concreting, floating, immersion and installation of the elements. The S08 Contract Section is responsible for the implementation of 9 elements from E32 to E24. The steel shell manufacturing is also divided into two contract sections, which are located in the shipyards on Longxue Island in the northwest of the tunnel site with about 21 km floating voyage. Then the S08 contract section rented a portion of the shipyard's dock space for concreting and primary outfitting. The first implemented element of the S08 contract section is the widest element E32, which is connected to the eastern artificial island at the Shenzhen end. It is the most difficult and typical non-standard element tube.

3 CONCRETING SCHEME

3.1 Construction site

The element tube prefabrication area is set up in the shipyard's dock, which simultaneously accommodates the overall assembly of steel shells, concreting, and the original shipbuilding work. The steel shell assembly and concreting station of element E32 is arranged in the dock on the northwest side. The information control center, the concrete quality testing area, the concreting equipment layout area, and the outfitting material storage yard are equipped near the dock shore. The route of the concrete transportation is about 1.2km long and the running speed of the concrete delivery trucks should be controlled within 20km/h inside the shipyard. It takes about 5 minutes for the new concrete to reach the quality control room for tests and it takes about 8 minutes for the verified concrete from the quality testing area to the farthest discharge port.

3.2 Concreting process

In the dry environment inside the dock, the concreting is carried out after the completion of the steel shell assembly, with a general order of bottom slab, wall and roof.

The bottom slab concreting adopts the process of “Bailey channel + concrete delivery truck + funnel conduit + intelligent pouring vehicle”, as shown in Figure 4. The concrete delivery truck travels from the dock shore onto the Bailey channel and stops at the discharge through-hole opened through the channel and the roof of the tube, then the concrete is discharged through the funnel conduit into the hopper of the pouring vehicles inside the element tube. The vehicle adopts a gantry structure and a big pouring hopper. The vehicle moves longitudinally through the rails laid inside the shell tube, and the hopper moves laterally on the main girder of the gantry.

Four sets of pouring vehicles are equipped, which means four pouring points are arranged for the bottom slab concreting. The vehicles can achieve certain intelligent functions such as precise automatic positioning of pouring holes, keeping constant pouring speed, automatic switching of pouring speed, and automatic starting and stopping.

Figure 4. Cross section of the tube with bottom slab concreting.

The concrete pouring of the wall and the roof is located on the top of the element tube, with a relatively open space. Then the flexible folding arm distributors are available and the process of “Concrete trailer pump + concrete distributor” is adopted, as shown in Figure 5. The pumps are placed on the dock shore, and the connecting pipes and the distributors are laid on the top surface of the tube.

Four pouring points are also arranged for the wall and the roof concreting, but six distributors are equipped to reduce the frequency of moving and for emergencies.

Figure 5. Cross section of the tube with wall and roof concreting.

3.3 Main control parameters

Due to the structural characteristics of the steel shell compartments, it is necessary to apply a large amount of high-flow self-compacting concrete without vibration. It is required to have good flowability, filling ability, cohesiveness, passing capacity through gaps, and anti-segregation. After the experimental research of self-compacting concrete in the early stage of the project, the main required performance control indexes of self-compacting concrete are shown in Table 1.

Table 1. Performance control indexes of self-compacting concrete.

Performance	Parameters	Requirements
Filling ability	Slump flow /mm	600~720
	T_{500} expending time /s	2~5
Passing capacity through gaps and anti-segregation	V-shaped funnel passage time /s	5~15
	L-type testing instrument / (H_2/H_1)	≥ 0.8
Others	Density /(kg/m^3)	2300~2400
	Gas content /%	≤ 4
	Temperature / $^{\circ}\text{C}$	≤ 30 , output; ≤ 32 , into the compartment

To ensure that the working performance of self-compacting concrete can be relatively stable within the requirements, it is required that the single truck concrete must be strictly controlled within 90 minutes from discharge of the mixer to finish up. Meanwhile, the pouring inside a single compartment must be strictly controlled within 90 minutes from the start to the completion. Due to the volume of a single compartment (the standard one is approximately 15.75m^3) is greater than the loading capacity of the concrete delivery truck (9m^3), then the compartments that cannot be continuously poured inside must also be completed within the specified time. This requires high synergy and continuity through the production, transportation, and pouring.

After preliminary steel shell compartment model tests and the transverse full-scale model tests, the main control parameters for the concrete pouring into the compartment have been determined:

- 1) The lower space of the compartment with a thickness of 130cm is poured at a speed of $30\text{m}^3/\text{h}$, while the remaining upper space with a thickness of 20cm is poured at a speed of not more than $15\text{m}^3/\text{h}$.
- 2) When pouring into the compartment, the distance between the nozzle of the pouring conduit and the concrete upper surface should not be greater than 1m at the beginning, and later it remains not more than 0.5m until the pouring of the compartment is fulfilled.

- 3) The pouring of the compartment is judged to be completed based on not less than a 30cm rise of the concrete level in the exhaust pipes.

These parameters can be automatically controlled by the intelligent concreting equipment and the intelligent management system.

4 INTELLIGENT CONCRETING EQUIPMENT

4.1 Variable span pouring vehicles

As E28 to E32 are in curve elements with variable width, in order to meet the construction requirements of the bottom slab concreting, variable span pouring vehicles have been developed, as shown in Figure 6. The main structure adopts a gantry type and the length of the main girder can be adjusted in four levels. The distance between support legs can be adjusted between 8.45~15.58m, which can make the rail suitable for non-standard element tubes. The pouring hopper can run on the outer side of the support legs, with the main girder in a cantilever-bearing state.

Figure 6. Variable span pouring vehicle.

The vehicle is mainly composed of a main girder structure, an entire structure longitudinal traveling mechanism, a trolley transverse traveling mechanism, a hopper with its weighing system, a pouring speed control module, a discharge control mechanism, and an electrical control system. Its key technologies are the automatic intelligent positioning of the pouring port and automatic speed regulation.

(1) Before concreting the tube, the relative positions of each compartment and the pouring port can be input into the industrial control computer system for storage. When receiving a working instruction for a certain compartment, the PLC(Programmable Logic Controller) drives the vehicle's longitudinal and transverse traveling system (motors and traveling wheels) to travel a specified distance. Then the hopper on the vehicle automatically moves above the designated compartment to achieve coarse positioning. Currently, the deviation between the center of the pouring conduit nozzle and the center of the pouring port of the compartment is within $\pm 30\text{mm}$ in plane. Subsequently, the intelligent analysis camera, intelligent analysis video server, and intelligent algorithm DSP(Digital Signal

Processing) are utilized to achieve recognition. The server calculates the accurate deviation between the two centers and then sends instructions to the PLC for precise positioning. Then the deviation can be achieved within $\pm 10\text{mm}$ in plane.

(2) The pouring speed control mechanism mainly consists of a concrete storage hopper with a weighing function, an electric control sluice valve, a concrete upper surface level measuring instrument (installed above the exhaust pipes at the compartment corners) and a PLC control system. The measurement of the concrete upper surface level adopts several laser rangefinders, which is an integrated application of various technologies such as laser, electronic, microcontroller control, signal control and processing, precision mechanical, and so on. Since the pouring operation is started, the pouring conduit under the hopper is controlled by PLC to maintain the required distance from the concrete upper surface. The initial speed is set at $30\text{m}^3/\text{h}$ until the concrete upper surface in the compartment reaches a height of 1.3m(0.2m left). The subsequent pouring speed is reduced to no more than $15\text{m}^3/\text{h}$. The pouring speed is controlled by the openness of the sluice valve and adjusted based on the reduction of concrete weight inside the hopper and the rising speed of the concrete upper surface inside the compartment.

4.2 Concrete distributors and delivery pumps

For the concreting of walls and roofs, the pumping process has higher convenience and efficiency. The distributors are customized based on the size and concreting characteristics of the tubes. The arm frame of the distributor has three arm rods and a total length of 17m, with a maximum pouring range of 16.5m radius. Due to its connection with the metal pump pipe fixed on the top surface of the tube, it cannot move autonomously during the pouring process.

Automatic control of concrete pouring speed is still required. The concrete delivery pumps are upgradable with PLC. The pump speed can be adjusted according to the needs of the pouring speed. The control module inside the machine can receive wireless command signals and adjust the pumping frequency. The rise of the upper surface of the concrete inside the compartment is still monitored by laser rangefinders. The monitoring information will be wirelessly sent to the intelligent management system that integrates various functional modules. After independent analysis, the pouring speed adjustment command is automatically issued to the control module installed inside the machine.

5 INTELLIGENT MANAGEMENT SYSTEM

During the concreting of the element tubes, a series of data, such as concrete production, delivery trucks, concrete performance index, timing, and monitoring information, etc. will be generated. To automatically process these massive data and achieve efficient,

refined, and standardized management of the concreting process, an intelligent management system has been developed. It covers raw material inventory management, concrete production management, concrete index detection, guidance for concrete delivery trucks, intelligent pouring, video monitoring and other processes. It combines BIM, IoT, and intelligent sensing technology to control various terminal equipment, such as the pouring vehicles and pumps, to complete the intelligent concreting task of the element tubes. The map of the construction plant and virtual construction information models of each tube with each compartment are constructed in the management system.

Based on real-time monitoring data, decisions and actions are made and executed in the varying external environments (not traditionally operated automatically according to fixed programs), in order to meet the on-site concreting requirements of the compartments, including the concrete delivery, pouring speed control, automatic extension and contraction of the pouring conduits, automatic stopping of pouring, automatic positioning and so on. At the same time, integrated management of various data can be conducted. Figure 7 shows the interface of the intelligent management system on the central control screen. The lower half of the middle part is the real-time pouring information of the four pouring points, including the current pouring speed, the position of the upper surface of the concrete inside the compartment, and the current real-time status of each compartment of the entire steel tube (poured, in pouring, and not poured). The upper half of the middle part is mainly the real-time concrete delivery truck information, including the current location along the route and the consumed time for the new concrete. The intelligent management system can also guide the delivery trucks to different unloading points based on the concrete allowance at four pouring points.

The intelligent management system adopts an advanced multi-layer technology architecture, which

integrates multiple technologies such as C/S (Client/Server) architecture, B/S (Browser/Server) architecture, App, and microservices. The C/S architecture is mainly used for connecting with laser ranging sensors, pouring equipment, radio frequency identification sensor equipment, etc. The B/S architecture is mainly used for system applications and all supporting modules. Apps are mainly applied to iPad monitoring operations at pouring sites, vehicle positioning mobile terminals, and quality detection module mobile terminals. Microservices are used for coupling services between various modules in the system. Establish such an intelligent pouring management system to accurately and efficiently control the equipment and to conduct real-time linkage with concrete mixing stations and delivery vehicles to achieve intelligent production control and dynamic allocation of material transportation. Specifically, the following functions have been developed and integrated into the intelligent management system:

- (1) Develop an intelligent pouring system to achieve multi-point collection of the rising height of the concrete upper surface in the compartment and to control the pouring speed based on the height and rising speed, which can drive the developed equipment and can be visually displayed on mobile devices.
- (2) Develop vehicle positioning and onboard equipment to collect real-time locations of delivery trucks, visualized on the central control screen, and to receive delivery information, providing guidance to drivers from mobile terminals.
- (3) Develop a pouring data management platform that integrates on-site data for real-time analysis and provides early warning prompts.
- (4) Established a BIM for the element tubes, utilizing BIM technology to dynamically and vividly display pouring progress and management construction data.

Figure 7. The interface of the intelligent management system on the central control screen.

6 DEFORMATION CONTROL DURING CONCRETING

6.1 Requirements for prefabrication accuracy of tubes

The prefabrication of the tubes is divided into two stages: steel shell manufacturing and concrete casting. The concreting of the compartments shall be carried out after the steel shell is inspected and accepted. Before undocking, primary outfitting work shall be also completed, mainly including the installation of ballast water tanks, pipelines and bulkheads.

Table 2 shows the requirements for the inspection and evaluation indicators of the two stages. It can be seen that for the super large tubes with lengths of 123.8~165m and a maximum width of 55m, when the deviation of the steel shell manufacturing is within the allowable limit at the measuring points, the allowable deviation of the subsequent concreting shall reach the millimeter level. In extreme cases, the reduction of the net height of the inner hole shall be controlled within 10mm.

In the past, the concreting sequence of the steel shell in Japan mainly considered the concrete casting afloat. As a single hole contains only two lanes, its cross-sectional deformation is so small that the deformation control is not a constraint factor for design and construction. The simplified longitudinal variable section beam model was used for numerical analysis in the Naha port immersed tunnel project by Kimura, et al. in Japan. The method is to divide longitudinal elements of the tube as a beam and to convert the cross-sections of different casting states into different section moment of inertia (EI) and different load conditions, which are assigned to different positions of the beam body. It mainly solves the problem of overall deflection and longitudinal deformation caused by the floating casting. Muramoto established a 3D finite element tube model for analysis and compared the results with those of the simplified longitudinal variable section beam model, but he did not simulate the stiffeners inside the compartment of the shell.

6.2 Finite element simulation analysis

As the first non-standard tube E32 weighs about 68000t (including outfitting) and the standard tube weighs about 78000t after concreting, which exceeded the historical record of shipbuilding weight in the dock of Huangpu Wenchong Shipyard, it is necessary to calculate the bearing capacity of the bottom foundation. At the same time, the foundation deformation will also affect the deformation of the tubes. The finite element model of the tube needs to be provided with the foundation stiffness parameters by the foundation bearing capacity calculation. Therefore, the tube structure analysis and foundation-bearing capacity calculation shall be systematically organized.

As the cross-section of the widest tube is adopted in calculation with 2D FEM in the early design stage, the concreting sequence and spatial mechanical effect are not taken into account. The downward deflection of the roof after concreting is quite large (about 28mm), so for reliability, the original construction drawing design requires the setting of temporary support rods inside the lane hole during the concreting of the roof. In order to further exploit the spatial mechanical effects of the structure and make a good choice of the concreting sequence, 3D FEM is used to create a detailed model of the steel shell-concrete composite structure of the tubes during the construction scheme preparation stage. Shell elements are used to simulate the steel shell, solid elements are used to simulate the concrete, and spring elements are used to simulate the bottom supports. For the first non-standard tube E32, both a full structure model considering the curve widening and an equal-width structure model based on the widest cross-section are established for parallel calculation. Besides, the stiffening ribs inside the compartments can be simulated by beam elements. Figure 8 shows one of the Vertical displacement results.

The concreting process is simulated by the “live-dead element” method. Experiments of compressive strength and elastic modulus of concrete at an early age conducted by Yang W. J. showed that the

3	Length of tubes	$\pm(10+(L-20)/10)$	$\pm(15+(L-20)/10)$	± 5
4	Net width of the lane holes	-5, +15	-5, +20	0, +5
5	Net height of inner holes	-5, +20	-15, +20	-10, 0
6	Longitudinal deflection of tubes	-	± 10	± 10

Note: L is for Length, value in units of m.

measured elastic modulus of C50 concrete can reach 66.2% in 3 days and 88.2% in 7 days; the elastic modulus of C60 concrete can reach 70.4% in 3 days and 89.1% in 7 days. The measured strength of C50 concrete prepared in this project is close to that of C60 concrete, so in the calculation process, it is simplified to consider that the elastic modulus of the third day is 70%, and that of the fourth day and later is 90%. For the simulation of concreting in each batch, the concrete solid elements on the first day are “killed to dead”, the density and elastic modulus of the concrete are not involved in the calculation, then the concrete gravity loads are directly applied to the steel plates at the bottom of the compartments; on the second day, the solid elements are “activated to alive”, and the elastic modulus is approximately set to 40%, the concrete gravity loads applied on the steel plates are removed and then replaced by the concrete density of the solid elements; on the third day and the fourth day and later, the elastic modulus of solid elements are set to 70% and 90% respectively.

Figure 8. Vertical displacement of E32 /m.

6.3 Concreting sequence

As the tubes are concreting inside the dock, it is necessary to complete the concrete filling of the bottom slab as quickly as possible to form a stiffness to facilitate the bearing capacity and reduce the deformation. The overall concreting sequence in the cross-section of the tube is bottom slab → wall → roof. According to the principles of making stress even, reducing load concentration and spacing the adjacent areas of concrete not less than two batches, several trial schemes of concreting sequences are calculated, mainly as follows (without temporary support rods). The sketch maps are shown in Figure 9~11.

- (1) Scheme 1: bottom slab concreting sequence① + wall concreting sequence① + roof slab concreting sequence①;
- (2) Scheme 2: bottom slab concreting sequence① + wall concreting sequence② + roof slab concreting sequence②;
- (3) Scheme 3: bottom slab concreting sequence② + wall concreting sequence① + roof slab concreting sequence①.

Figure 9. Sketch concreting sequence of the bottom slab.

Figure 10. Sketch concreting sequence of the wall.

Figure 11. Sketch concreting sequence of the roof.

Preliminary analysis shows that the change of clearance inside the steel shell tube (vertical deformation) during the concrete casting is mainly caused by the self-weight of structural materials, The change of tube in length and width (horizontal deformation) may be mainly caused by temperature effect. Among the acceptance indicators of dimensional accuracy of the tube prefabrication, the control of inner clearance is the most difficult to achieve. In addition, the construction design requires adding temporary support rods inside the tube, which directly affects the construction process and the prefabrication schedule.

In addition, considering that most of the hydration heat of concrete is released in the first 3 days, the concreting batches within 3 days should be spaced out a certain distance, then the influence of hydration heat on deformation is mainly in the local scope. After the temperature drops, most of the temperature deformation can be recovered, which has a limited impact on the overall structure. Therefore, the selection of concreting sequence is mainly based on the calculation of deformation caused by the dead weight of structural materials. During the construction, the concreting has avoided the high-temperature period on summer days (concreting at night). Thus, the temperature effect analysis is taken as the check.

Three back-to-back parallel computations have been organized, adopting the equal-width tube model with the widest dimension, the non-equal-width tube model with actual dimensions, and the equal-width tube model considering the temperature effect during the construction process. The comparison of calculation results for the four listed concreting sequence schemes can be seen in Table 3. On the other hand, the calculation result of reduction in net

height with temporary support rods is about 7.5mm, but it will cause a delay of one month in outfitting operation inside the dock. Then the concreting sequence scheme 1 is adopted.

7 ACCEPTANCE MEASUREMENT RESULTS AFTER CONCRETING

7.1 Concreting quality inspection

After the prefabrication of the steel shell concrete immersed tube is completed, its concreting quality is tested using a combination of impact imaging method for full inspection and neutron method for partial re-inspection. The effectiveness of these two void detection methods has been verified in the previous full-scale model concreting process test. The inspection works are carried out by third-party units entrusted by the owner of Shenzhen-Zhongshan Link. Table 4 shows the statistical results of the void detection for element tubes E32 and E31. It shows that the concreting quality is good and meets the inspection and evaluation standards (including all subsequent tubes). For suspected void areas, there is no need for grouting reinforcement after retesting using the neutron method. The adoption of this concreting process and the introduction of intelligent pouring control can effectively eliminate the adverse effects of human non-standard or inconsistent operations on concreting quality, and reduce the risk of voids which need reinforcement.

7.2 Geometric dimensions inspection

Before concreting of the E32 tube, 15 profiles were selected within the steel shell tube (with 3 pairs of inner net height monitoring points set for each lane hole) for acceptance measurement. The maximum and minimum inner net height measurement values were compared with the design values, which were within the allowable deviation range. After concreting, acceptance measurements were carried out again

on the 15 profiles, and the maximum variation measured in the net height of the inner hole was -10mm. (The accuracy of the laser rangefinder used is 1mm.) It appeared at the widest end, matching the calculation result. The final qualification rate in length, width, and height is 100%. In addition, the deformation in longitudinal length after concreting is basically within ± 3 mm. Under the constraints of the dock bottom supports, the deformation of the tube caused by the temperature effect of concrete hydration heat is mainly reflected in the horizontal direction, with little impact on the final deformation of the overall structure. Table 5 shows the geometric dimensions inspection qualification rates of E32 and E31 after concreting. All the inspection qualification rates are greater than 95% (including all subsequent tubes), meeting the acceptance standard requirements.

8 REMARKS AND CONCLUSIONS

The immersed tunnel tubes E32 to E24 of Shenzhen-Zhongshan Link have been successfully prefabricated with concreting in the dock, especially tube E32, the widest and the first one. Both the deformation control and the concrete filling quality have passed the acceptance with excellent inspection data.

To reduce labor and improve construction efficiency, a self-compacting concreting technology is developed for the steel shell of immersed tunnel element tubes according to the environmental construction conditions. Intelligent concrete pouring vehicles and folding arm distributors have been developed. The information and automation technologies with BIM, IoT and intelligent sensing have been employed, which can effectively reduce the quality risk and mechanical injury caused by human error during the concreting process.

Data statistical analysis shows that through the intelligent self-compacting concreting process, the daily average concreting volume is about 800m³. The main limiting factor for its efficiency is the impact of

daytime temperature during summer on the working performance of concrete. The concreting process and intelligent management system can operate continuously for 24 hours.

By refining 3D FEM numerical analysis and optimizing the concreting sequence, the net height deformation inside the element tubes was controlled within 10mm, and the temporary support rods inside the lane hole were successfully canceled, enabling the initial outfitting operation inside the tube to be started about one month earlier, which can be parallel to the wall and roof concreting.

ABSTRACT: It is the first time in the world that the immersed tunnel elements of Shenzhen-Zhongshan Link (hereinafter referred to as the “Shen-Zhong Link”) is placed on the seabed and resists against typhoon in the semi-open sea area on a large scale. In order to ensure the safety of the immersed tunnel element when stored on the seabed, an experimental study was carried out. Accurate evaluation of the safety and stability of the tunnel element during typhoon period can provide a strong scientific basis for the design of gravel foundation, submerged tunnel load and cable selection. This paper takes different immersed tunnel elements of Shen-Zhong Link as the research objects based on the given undersea deposit layout scheme and dynamic characteristics of the engineering water area. Through qualitative analysis, the most unfavorable wave direction to the stability of immersed tunnel elements against typhoon is determined and then a physical model test of the wave forces of different directions under different conditions of water level, wave height and foundation laying rate was carried out. According to the measured wave forces, given friction coefficient and negative buoyancy, the anti-typhoon stability of the immersed tunnel elements was evaluated.

Keywords: Immersed tunnel elements, Undersea deposit, Typhoon resistance, Foundation laying, Shen-Zhong Link

1 INTRODUCTION

With the accomplishment of the 21st century Hong Kong-Zhuhai-Macao Bridge project, the construction projects of domestic immersed tunnels have been increasing rapidly. There are nearly 20 immersed tunnels under construction or proposed, among which are mainly inland immersed tunnels. According to statistical data^[3], the immersed tunnels which have already completed mostly adopts the form of axis dry dock or independent dry dock for batch prefabrication. After the completion of the docking, a series of processes such as tunnel elements floating transportation, mooring, and installation are carried out. Therefore, immersed tunnel production has become a key step of the project

construction. Shen-Zhong Link is the first project in China to customize the production of immersed tunnel elements by the form of “prefabricated factory + shipyard”. During the construction process, the foundation groove of the tunnel on Shenzhen side was affected by force majeure, resulting in that the first element E32 could not be installed immediately after the prefabrication. In order to make sure that 4 elements of tunnel have been prefabricated before the E32 is settled so that the prefabrication does not occupy the key line, the tunnel element needs to be stored underwater for up to one year in the semi-open sea area of Longxue Harbor, which requires that the safety of the tunnel element at the bottom must meet the working condition of a typhoon once in 50 years.

Due to its large size and water depth limitation in the storage area, the water depth of the tunnel top after sitting on the bottom is small and the force area is large, meaning that the force state during the bottom sitting and typhoon resisting is very complicated. The influences of multiple factors such as ballast, waves, water level, geological conditions etc. should be fully considered. The bulkhead door may be damaged by long-term wave force impact. The tunnel may be affected by the uneven silt substrate in the bottom area, causing large settlement, uneven settlement, and serious deformation. Meanwhile, if the ballast capacity is not enough and the negative buoyancy is insufficient, it would lead to slippage of the tunnel element. In addition, a large amount of silt and the long time storage of the tunnel may lead to a series of problems such as excessive bottom suction and the inability of the tunnel to float smoothly. In-depth analysis of the force on the tunnel element is required through physical model tests or numerical simulations. Based on actual engineering, domestic scholars have carried out a series of force analysis and tests of large-scale structures sitting underwater. Wang Baoxing et al.^[4] carried out the research on the “XIWANG” super-large tanker bottom sitting scheme, and conducted a comprehensive analysis on the various factors, calculation methods and hull structure reinforcement methods considered in the new topic of using the method of large ships sitting on the bottom to build offshore isolated building. Under different negative buoyancy conditions and the settlement of crushed stone bed, Shang Qiankun et al.^[5] carried out experimental studies on the friction coefficient of reinforced concrete immersed tunnel element model and crushed stone bed. Lin Wei et al.^[6] analyzed the sensitivity of friction coefficient to the crushed stone particle size, pressure, direction, area etc. through the pulling, correction operations and movement of adjacent tunnel elements during the tunnel jointing process, combining with the data during tunnel elements pulling operation of the Hong Kong-Zhuhai-Macao Bridge. Through theoretical analysis and experimental methods of different models, Gao Zhanfeng et al.^[7] proposed a method to estimate the substrate suction force that different shapes of structures submerged on the seabed need to overcome when leaving the bottom. Shu Ning et al.^[8] gave the friction coefficients between the bottom surface of different steel structures and the crushed stone foundation bed through experimental methods.

Although the research results above certainly have guiding significance for the development of similar projects, it is the first time in the world that such a large-scale tunnel element is placed on the seabed in semi-open water area. The immersed tunnel element needs to face the test of the stability by waves in typhoon weather for a long time. In order to ensure the safety of the tunnel element, it is necessary to comprehensively consider the influences of combined factors such as the basic processing of the element, the negative buoyancy control, the strength and direction of the waves, and the terrain around the harbor.

In this paper, the element stored in Longxue harbor is taken as the research object. The horizontal wave force and lifting force encountered by the tunnel element under the condition of typhoon once in 50 years are studied, and the friction coefficient is set to be 0.4. At the same time, in order to reduce the cost and increase the foundation groove silt accommodation capacity under the premise that the stability meets the requirements, the stability of the tunnel element under the conditions of different foundation laying rate is also compared and analyzed.

2 PROJECT OVERVIEW

The Shen-Zhong link is a major infrastructure project in China, with unprecedented scale, complex construction conditions and complicated technologies. It is a world class super large tunnel-island-bridge cluster project spanning the Pearl River estuary after the Hong Kong-Zhuhai-Macao Bridge. The total length of the main project is about 24km, with the technical standard of two-way eight-lane is adopted and the designed speed of 100km/h. The overall layout of the project is shown in Figure 1.

Figure 1. General layout of Shen-Zhong Link.

Figure 2. Top view of the storage area.

The immersed tunnel project of Shen-Zhong link is 6845m long, of which the immersed tunnel is 5035m long, consisting of 26 standard tunnel elements, 6 non-standard tunnel elements and 1 final joint. The tunnel is a combined steel shell-concrete structure type and has a shape of cuboid. The immersed

tunnel element was poured at the site of the Longxue Shipbuilding Base of CSSC. After being assembled in the dock, the tunnel continues to complete the whole-land-wide pour (dry dock pour) in the dock and then is transported out of the dock. Mooring, typhoon resisting and subsequent outfitting operations are carried out in the harbor of Longxue shipbuilding base, beside of the berm pier of Huangpu shipbuilding factory. The harbor has a dredging area of 670m (East-West)×608m (South-North). The top elevation of the bottom sitting area the elevation of the waters bottom where the immersed tunnel gyrate and float are both -12.5m (with the elevation standard of 1985 and the same below).

The layout and bottom sitting storage scheme of the tunnel element which needed a stability appraisal is shown in Figure 3. When the tunnel element sits on the bottom, besides the role of providing uniform support, the foundation could also decrease the suction force between silt and the tunnel bottom. After the berth excavation, the gravel bed with thickness of 1m is needed. When sitting on the bottom, the free-board of tunnel element can be gradually eliminated by ballasting the tunnel inside the tunnel and then the tunnel could be slowly located on the gravel bed. Continue to increase the ballast to make sure that the negative buoyancy and friction between the tunnel and gravel bed are able to stand the wave force caused by typhoon. Then wait for proper window period to float, moor and carry out secondary outfitting operation. The gravel bed is designed to be 5m shorter than the tunnel in the front and rear each, and 5m wider than the tunnel in the left and right each. In order to hold silt, the form of ridge, which is 1.8m wide, and ridge top, which is 0.3m wide, is applied. Single gravel cushion is shown in Figure 4.

Figure 3. Layout of tunnel and wave data detecting point in the harbor.

3 MODEL DESIGN AND TEST CONDITIONS

3.1 Experimental conditions

The layout of wave data detecting point is shown in Figure 3. The experiment would not consider the effect of water flow as the wave speed in the harbor is

Figure 4. Single gravel cushion.

relatively low. The water level in the harbor is shown in Table 1.

Table 1. Water level in the harbor.

Object	Elevation(m)
Average water level	0.64
Designed high water mark	1.98
Designed low water mark	-0.73
Extremely high water mark	3.18
Extremely low water mark	-1.36

The average wind velocity at 10m elevation under typhoon is predetermined to be 35.9m/s (within 10 minutes) and 47.4m/s (within 3 seconds). Extremely high water mark of 3.18m, extremely low water mark of -1.36m and wave superposition working condition, once in 50 years are considered to be the combined condition.

3.2 Parameters of the tunnel

S08 segment consists of 4 standard and 5 non-standard elements. The standard element is 165m long, 46m wide and 10.6m high while the non-standard element is 123.8m long, 55.5m wide at the widest end and 10.6m high. The cross-section of the element is shown in Figure 5. After the tunnel submerges completely in the water, the maximum of negative buoyancy of standard tunnel element is 10222.8T when the concrete density of the main structure of the tunnel element is taken as the upper limit 2.35T/m³ and the buoyancy of tunnel element drainage is taken according to the lower limit of water severity, while the lower limit value is 7061.9T when the concrete density of the main structure of the tunnel element is taken as the lower limit 2.30T/m³ and the buoyancy of tunnel element drainage is taken according to the upper limit of water severity. While for non-standard tunnel elements, (take E32 as an example) the values are 8956.2T and 6650.5T.

Figure 5. The cross-section diagram of the element.

3.3 Selection of unfavorable wave direction condition

To meet the actual needs of the project and shorten the test cycle, it is necessary to test under the most unfavorable wave direction condition. According to the storage plan, the tunnel element is located in the northeast corner of the harbor. According to Figure 3, it can be seen that waves can only come through the northeast-facing gate of the harbor. Given a combined condition of water level and wave height, the wave direction determines the magnitude of the incoming wave energy and the area of the tunnel element directly facing the wave. Take the

Figure 6. The affected harbor area under ENE~SE wave direction.

Figure 7. ESE wave vertical projection width.

E wave direction as an example and the red zone is the area of direct action of waves, where forces are relatively large. While the wave force in the indirect action zone is mainly the result of wave diffraction and reflection and the force is relatively small, as shown in Figure 6. The four wave directions ENE~SE that have a large impact on the engineering waters were analyzed and the ESE direction was found out to be the most unfavorable wave direction, as shown in Figure 7. Based on previous calculation, at the entrance gate GC0, the magnitude relationship of the wave features around each direction is: ENE>E>ESE.

With different selections of wave directions, water levels, foundation laying rates etc., there are 30 test conditions in total. Considering that the effective wave height in the E direction that occur once in 50 years at extremely low water levels is very close to that in the ESE direction, there are actually only two wave heights at this water level. See Table 2 for details.

3.4 Similarity guidelines

Given that the immersed tunnel element is a box-shaped blunt body, this test is a physical model test of the force of the structure under the action of wave dynamics. Complying with the “Wave Model Test Procedure JTJ T234-2001”^[9], the normal physical test model was used. When the model and the prototype meet the similarity of Fu Rude, the similarity of the force on the tunnel element can be ensured. When the stability of the tunnel element meets the requirements under the action of external load, the tunnel element is fixed, and its force is similar to the force of fixed structure under wave conditions. Therefore, when carrying out the force simulation of the tunnel element, it is only necessary to ensure that the tunnel element strictly meets the geometric similarity, and there is no need to ensure that it strictly meets the weight similarity. The scales of each physical quantity are shown in Table 3:

3.5 Model fabrication

The model tunnel element is made of waterproof plywood. A reinforced frame is included to ensure sufficient stiffness to avoid significant bending deformation. The bottom foundation of the model is laid with a certain amount of crushed stone according to different working conditions of 50%, 75% and 100% laying rate. Supports for force measurement are installed in the corners. The simulation of the harbor and offshore terrain is completely based on geometric scales and make the terrain in the test pool. Modelling controlled elevation with the pile point method and the control point elevation error is less than $\pm 2\text{mm}$. The terrain of the model is filled with sand, plastered with cement mortar. See Figure 8.

Table 2. Conditions of test of tunnel element sitting bottom against typhoon.

Condition	Wave direction	Storage location	Tunnel element	Water level	Wave height	Stone foundation laying rate
1-1~3					2.37m (effective wave height in ENE direction once in 50 years)	50%/75%/100%
2-1~3				Extremely high water mark	2.17m (effective wave height in E direction once in 50 years)	50%/75%/100%
3-1~3		Measuring point GC5 berth (The wide end faced the southeast side)	Non-Standard tunnel element E32		2.00m (effective wave height in ESE direction once in 50 years)	50%/75%/100%
4-1~3				1.12m (effective wave height in ENE direction once in 50 years)	50%/75%/100%	
5-1~3				Extremely low water mark	1.03m (effective wave height in ESE/E direction once in 50 years)	50%/75%/100%
6-1~3	ESE				2.37m (effective wave height in ENE direction once in 50 years)	50%/75%/100%
7-1~3				Extremely high water mark	2.17m (effective wave height in E direction once in 50 years)	50%/75%/100%
8-1~3		Measuring point GC4 berth	Standard tunnel element		2.00m (effective wave height in ESE direction once in 50 years)	50%/75%/100%
9-1~3				1.12m (effective wave height in ENE direction once in 50 years)	50%/75%/100%	
10-1~3				Extremely low water mark	1.03m (effective wave height in ESE/E direction once in 50 years)	50%/75%/100%

Table 3. The scale of each physical quantity in model test.

Variable name	Symbol	Calculations	Scale
Length/Water depth/Wave height	λ	λ	40
Time/Period	λ_t	$\lambda^{1/2}$	6.32
Force	λ_F	λ^3	64000
Pressure	λ_p	λ	40

4 TEST RESULTS AND ANALYSIS

4.1 Wave force

4.1.1 Vertical lift force

The following reference coordinate system form is defined: The geometric center of the tunnel element is the coordinate origin, the longitudinal southeast direction of the tunnel element is the positive X-axis, the transverse northeast direction of the tunnel

Figure 8. The site model and force support settings.

element is the positive Y axis, and the vertical up direction is the positive Z axis.

The statistical results of vertical lifting force under each working condition of non-standard tunnel element E32 and standard tunnel element are shown in Figures 9 and 10. As the results illustrated, the vertical lifting extreme value is positively correlated with wave height and negatively correlated with the laying rate. Non-standard and standard elements stored in different berths have almost equal lifting forces under the same dynamic conditions, with the non-standard element, which has a small bottom area, slightly larger in general. This is mainly due to the different coverage against the waves at the two berths, which can also explain that GC5 berth is more significantly affected by waves. The extreme value of vertical lifting force of the standard element at each wave height is 5000~9000 kN for extremely low water level and 15000~32000kN for extremely high water level. The most unfavorable lifting force reaches 45% of its lower limit of negative buoyancy. For non-standard element, the extreme value becomes 4000~11000 kN and 15000~37000 kN separately. And the most unfavorable lifting force reaches 55% of its lower limit of negative buoyancy.

The reduction of the lifting force at the condition of 100% laying rate of the foundation compared with 50% laying rate is shown in Table 4. For non-standard and standard element, the extremum of this index can attain 40% to 60% and 30% to 40% respectively. Both indicate that when the gravel base is fully laid, the sliding resistance of the element could be greatly increased.

4.1.2 Horizontal wave force

For non-standard element, the wave force extremum in X direction: 1821~2309kN at extremely low water level, 3450 ~ 5320kN at extremely high water level. In Y direction: 1666 ~ 2358kN (low), 3892 ~ 4609kN (high). General: 2159 ~ 2535kN (low), 4378 ~ 5585kN (high). For standard element, in X direction: 2350 ~ 2876kN (low), 3947 ~ 5862kN (high). In Y direction: 1704 ~ 2055kN (low), 4028 ~ 6220kN (high). General: 2474 ~ 3220kN (low), 4878 ~ 6348kN (high). The test result indicates that the extremum in the X direction, Y direction and its actual direction of the horizontal wave force are all positively correlated with wave height and do not change significantly with laying rate, as shown in Figure 10 to 12.

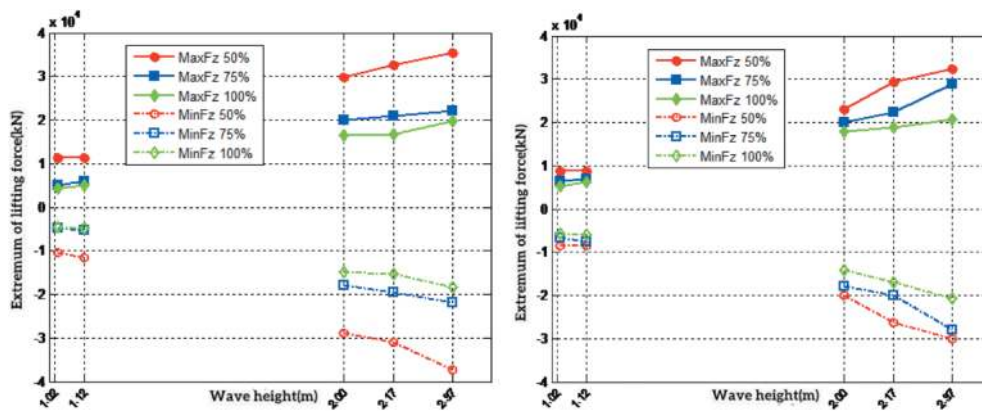

Figure 9. Vertical force extremum V.S.wave height of non-standard tunnel element and standard tunnel element.

Table 4. Reduction of the extremum of vertical lifting force at the condition of 100% compared with 50% laying rate.

Tunnel element type	Water level/effective wave height(m)	Extremely low water level		Extremely high water level		
		Wave height 1.03 m	Wave height 1.12 m	Wave height 2.00 m	Wave height 2.17 m	Wave height 2.37 m
Non-standard E32	Reduction degree (maximum) (%)	62.2	56.9	44.7	48.9	44.1
	Reduction degree (minimum) (%)	56.9	57.9	48.2	50.6	50.6
	Reduction degree (maximum) (%)	38.6	28.6	23.1	35.6	36.5
Standard	Reduction degree (minimum) (%)	34.3	29.5	29.1	36.2	30.9

Figure 10. EVI of wave force V.S. wave height(X direction) for non-standard and standard tunnel element.

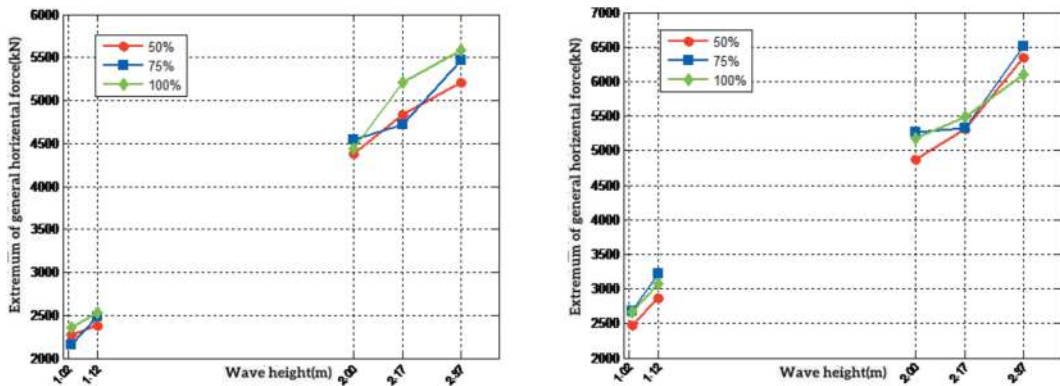

Figure 12. EVI of wave force V.S. wave height(General) for non-standard and standard tunnel element.

4.2 Stability of the tunnel

4.2.1 Analysis method

Since the lifting force of the tunnel element is less than the negative buoyancy force, the stability analysis of the tunnel element against typhoon mainly considers the performance of anti-slip. Therefore the rigid body limit equilibrium method^[10,11] was used. The prerequisite for the tunnel element not to

slip is that the static friction between the tunnel element and the foundation is sufficient to overcome the wave force. Assume that the transverse and longitudinal horizontal forces of the tunnel element under the action of waves are F_x and F_y separately and lifting force is F_z . M_x , M_y and M_z are the torque around the longitudinal, transverse and vertical directions about the origin of the tunnel element. Then the prerequisite should be satisfied:

$$F_R = \mu(Mg - F_z) - \sqrt{F_x^2 + F_y^2} - \tau_{M_z}BL > 0,$$

among which F_R is residual resistance, that is the difference between resistance and slip force, μ is the static friction coefficient between the tunnel element and the crushed stone bed, M is the negative buoyancy of the tunnel element, g is the gravitational acceleration, B is the element width, L is the element length. The torque M_x and M_y may change the vertical pressure distribution at the bottom of the tunnel element, but not change the total load on the foundation imposed by the element, which is considered to be invalid to the general resistance of the tunnel element. So its impact on the residual resistance force is neglected. τ_{M_z} is the equivalent thrust stress corresponding to the torque M_z in Z direction, which is used to indirectly consider the friction loss of the contact surface caused by suppressing the rotational trend caused by torque. The equivalent thrust stress τ_{M_z} is calculated as follows:

Assuming that the rotational thrust stress is proportional to its distance from the center of the tunnel element, the maximum rotational thrust stress τ_{max} is:

$$\tau_{max} = \frac{|M_z|}{I_z} \cdot \frac{\sqrt{B^2 + L^2}}{2},$$

where I_z is the pole moment of inertia with respect to the Z -axis rotation:

$$I_z = \frac{BL}{12} (L^2 + B^2).$$

To ensure safety, the maximum thrust stress τ_{max} is used as the equivalent thrust stress τ_{M_z} . The relationship should be satisfied if the tunnel element does not slip:

$$F_R = \mu(Mg - F_z) - \sqrt{F_x^2 + F_y^2} - |M_z| / \left(\sqrt{B^2 + L^2} / 6 \right) > 0$$

Divide the left and right ends of the residual resistance calculation formula by μMg to make it dimensionless as:

$$F'_R = 1 - F'_Z - F'_{xy} - M'_z,$$

where F'_R is dimensionless lifting force: $F'_Z = F_z / Mg$, F'_{xy} is dimensionless horizontal thrust stress:

$$F'_{xy} = |F_{xy}| / \mu Mg = \sqrt{F_x^2 + F_y^2} / \mu Mg,$$

M'_z is dimensionless torque:

$$M'_z = \frac{6}{\sqrt{B^2 + L^2}} \cdot \frac{|M_z|}{\mu Mg},$$

and F'_R and is dimensionless residual resistance force:

$$F'_R = F_R / \mu Mg,$$

when $F'_R > 0$, the anti-slip stability of the tunnel element meets the requirements and vice versa.

4.2.2 Stability of the tunnel element under different condition

For safety, when calculating the anti-slip residual resistance, the negative buoyancy of non-standard and standard element takes the lower limit value. The minimum dimensionless residual resistance under each working condition is shown in Table 5.

It can be seen that the anti-slip stability of the tunnel element meets the requirements under each working condition of the normal combination of the load component. The anti-slip stability of the tunnel element decreases with the increase of wave height, and the decrease of laying rate. At extremely high water levels, the anti-slip stability decreases significantly with the decrease of laying rate. That corresponds to the fact that the increase of lifting force is larger with the decrease of laying rate at extremely high water level.

Table 5. The minimum dimensionless residual resistance when the load components are normally combined.

Foundation laying rate	Water level/effective wave height(m)	Extremely low water level		Extremely high water level		
		Wave height 1.03 m	Wave height 1.12 m	Wave height 2.00 m	Wave height 2.17 m	Wave height 2.37 m
Non-standard E32	50%	0.717	0.706	0.385	0.319	0.296
	75%	0.749	0.725	0.476	0.435	0.386
	100%	0.827	0.831	0.521	0.463	0.416
Standard	50%	0.735	0.689	0.272	0.312	0.190
	75%	0.771	0.750	0.415	0.423	0.369
	100%	0.786	0.737	0.499	0.497	0.436

Table 6. The smallest dimensionless residual resistance when unfavorable extremum of load components occurs at the same time.

Water level/effective wave height(m) Foundation laying rate		Extremely low water level		Extremely high water level		
		Wave height 1.03 m	Wave height 1.12 m	Wave height 2.00 m	Wave height 2.17 m	Wave height 2.37 m
Non-standard E32	50%	0.598	0.556	0.148	0.080	-0.068
	75%	0.637	0.719	0.278	0.156	0.077
	100%	0.734	0.690	0.286	0.266	0.165
	50%	0.624	0.595	0.225	0.011	-0.189
Standard	75%	0.690	0.612	0.252	0.170	-0.093
	100%	0.708	0.618	0.315	0.221	0.157

The probability of the load components reaching an unfavorable extreme value at the same time is very small, however, the possibility of its appearance is not excluded in the long-term effect. When this happens, the smallest dimensionless residual resistance force under different working conditions is shown in Table 6. It demonstrates that at extremely low water level and different laying rates, the smallest dimensionless residual resistance forces of non-standard and standard element both exceed 0.5, which meets the requirement. However, at extremely high water level, the smallest dimensionless residual resistance force might be negative when laying rate is 50% or 75% and the tunnel elements are on the risk of instability. While when laying rate is 100%, that value exceeds 0.15 for every condition and the anti-slip stability meets the requirement.

5 CONCLUSION

The wave forces in all directions are positively correlated with wave height, and the laying rate of the foundation bed has little effect on the vertical outward wave force, but has a significant effect on the vertical wave force.

With the increase of laying rate, the vertical wave force decreases, and the anti-slip stability of tunnel element increases. Under the normal combination of load components, the anti-slip stability of non-standard and standard tunnel element meets the requirements.

In the case of combinations of extreme load components, When the foundation laying rate is 50% and 75%, there is a risk of instability at extremely high water level. And when the laying rate is 100%, the stability can be ensured. Therefore, the recommended laying rate is 100%.

The bulkhead door locates close to the waterway of port gate of the harbor and is easily affected by hydrodynamic action as well as collisions with ships, which deserves high attention. Although the influence of wave growth in closed harbors has been considered, the study does not include experimental analysis of wave evolution during the actual period of typhoon, which is relatively long. According to the experience and other researches, waves in the

harbor will evolve from high to low frequency. Besides, the latter stage of typhoon may also be accompanied by surges of low frequency. Therefore, the stability monitoring of the element during the typhoon season should be strengthened, and relevant risk plans should be formulated.

Assessing the suitability of coarse sand for the sand flow method in immersed tunnel foundations

Xavier Szadkowski*, Michel van der Molen & Rick Hermsen
Ballast Nedam, Nieuwegein, The Netherlands

Roline Montijn
MH Poly, Bergen op Zoom, The Netherlands

ABSTRACT: This research aims to investigate the feasibility of using coarse sand for the sand flow method in immersed tunnel foundations, with a specific focus on achieving the desired pancake diameter. The study was conducted in the context of the Khor al Zubair Immersed Tunnel project, Iraq, which faces light seismic activity. Traditionally, gravel beds are chosen as foundation for earthquake-prone areas, but the project opted for the innovative and cost-effective sand flow method using coarse sand with specific particle size requirements. The methodology involved conducting sieve analysis on Iraqi sand samples intended for sand flow foundation use. Based on the results, similar materials available in the Dutch market were examined and compared in terms of mineralogy and particle distribution. The relative density range was determined through laboratory tests, using Cone Penetration Test (CPT) values to derive the in situ relative density values. The test setup, comprising a water-filled basin and a modular enclosed plane simulating the tunnel element's underside was used to perform full scale pancakes. Measurements of hydraulic pressures, density, flow rates, and pressures during sand flow were recorded. Subsequently, CPTs were conducted after sand flowing and thereafter the plates were dismantled to make a point-cloud analysis measuring the pancake diameter. The results indicated that the desired relative density could not be achieved, irrespective of using coarse sand or the conventional fine sand typically employed for immersion tunnel foundations. However, the targeted pancake diameter was successfully attained. The conclusion suggests the need for further testing and the consideration of additional adhesives to potentially enhance the liquefaction resistance. Additional full-scale tests are recommended to investigate the feasibility of coarse sand in the sand flow method for immersed tunnel foundations. This research underscores the importance of advancing the sand flow method and exploring alternative materials for immersed tunnel construction in seismic zones.

Keywords: Sand flow, Immersed Tunnels, full-scale model, sand deposit foundation, liquefaction susceptibility

1 INTRODUCTION

The installation of immersed tunnels has significant implications for the surrounding soil. Excavation and backfilling processes during tunnel construction alter the soil structure, leading to uncertainties and increased risks, particularly in earthquake-prone regions. The choice of foundation layer between the trench and tunnel bottom varies, with options including sand, gravel, or grouted foundations, often requiring additional support measures (Lunne et al., 1997; Lunniss & Baber, 2013).

The sand flow method, notably used in recent projects like the Marieholm tunnel in Sweden and the Maasdeltatunnel in the Netherlands, seeks to have each tunnel element supported by subsoil (sand) instead of temporary supports. Sand and water are pumped through embedded pipelines in the tunnel elements' floors. Outflow openings beneath the elements discharge the sand-water mixture, allowing it to settle and form a sand ring at ground level, resembling a "pancake." This process repeats until the sand ring reaches the tunnel element's bottom, generating "rivers of sand" at points of least resistance.

Figure 1. Overview of test set-up.

In the context of Iraq, traditional 0.2mm D50 sand, typically used for foundation via the sand flowing method, is unavailable. Therefore, testing the suitability of the chosen sand is crucial. A similar 0.55mm D50 sand used in the Zhoutouzui Tunnel project in China (Li et al., 2018) is being considered, as it proved non-liquefiable, given the relative density. A full-scale trial test will assess parameters such as pancake radius, uplift pressure, and sand flow rate, crucial for evaluating liquefaction stability. Liquefaction assessment can be accurately accomplished through the extrapolation of cone penetration test values (Lunne et al., 1997). Following the trial test, the sand gradation will be determined, and the addition of cement clinker will be considered if liquefaction is a concern.

Figure 2. Supports of the dragline mats.

In the design of Immersed Tunnel (IMT) structures, the arrangement of sand flow pipes has been influenced by cautious assumptions based on the Zhoutouzui tunnel test results conducted in China (Li et al., 2018). As a result, the design of the cast-in pipelines has been adjusted, expanding them from two rows to three. However, it is essential to acknowledge that a larger sand diameter can affect

the achievable pancake diameter, necessitating a thorough reassessment of these assumptions before proceeding with the sand flow process. This paper aims to provide a comprehensive evaluation of these critical considerations in the design and implementation of IMT structures.

2 TEST MODEL

2.1 Test set-up description

The test basin was constructed with dimensions measuring 19 m x 19 m x 1.6 m. It featured twelve watertight steel dragline mats, collectively representing the bottom of a tunnel element, and these mats were supported by two HEM-300 beams positioned atop six hydraulic jacks. The bottom of the steel dragline mats, replicating the tunnel element's base, was precisely set at the same height as specified in the Khor al Zubair Immersed Tunnel design, mirroring the 0.5m separation between the tunnel bottom and the trench top.

To counter uplift forces, sixteen concrete ballast blocks, each weighing 2.4 metric tons, were employed to stabilize the mats. In a separate mixing tank, the creation of a turbulent environment was achieved using jets to thoroughly mix sand and water before being pumped into the primary basin.

The testing encompassed a comprehensive examination of sand materials. Initially, a baseline test was conducted using Zeeuws sand, following the methodology established by Griffioen (Griffioen & van der Veen, 1972). Subsequently, four additional tests utilized Kaliwaal 41, a material chosen after conducting a comparison of the mineralogy and particle distribution of the available Dutch market materials to the Iraqi sand samples intended for sand flow foundation use. These tests aimed to assess material behaviour under varying flow speeds, both increased and reduced from the required flow speed, providing valuable insights into the material's response in different flow conditions.

Figure 1 provides an overview of the test configuration, while Figure 4 presents an image of the test setup after testing Kaliwaal material. For specific details on the arrangement of the hydraulic jacks, please refer to Figure 2.

Figure 3. Particle size distribution.

Figure 4. Test set-up after sand flowing Kaliwaal 41.

2.2 Test materials

The susceptibility of sand deposits to liquefaction induced by seismic activity (Hashash et al., 2001) underscores the importance of maintaining the quality of sand within artificial sand deposit foundations. To minimize the risks associated with liquefaction, it is essential to utilize well-graded sand free from chemical admixtures and environmental contaminants, as emphasized in prior research (Guanghui et al., 2009). In accordance with the design principles established for the immersed tunnel project, the test sand has undergone rigorous screening to ensure its compliance. As illustrated in Figure 3, the particle size distribution of the sand aligns with the stipulated requirements for test materials, attesting to its suitability for use in the project. Table 1 shows the material characteristics of Zeeuws sand (Griffioen & van der Veen, 1972) and Kaliwaal 41.

Table 1. Material characteristics.

	Zeeuws (baseline)	Kaliwaal 41
D_{50}	$140 < D_{50} < 230 \mu\text{m}$	$700 \mu\text{m}$
D_{60}/D_{10}	$2,3 < D_{60}/D_{10} < 2,7$	3,5
$x < 63 \mu\text{m}$	$< 2\%$	$< 2\%$

2.3 Test parameters

A sequence of five sand flow tests was conducted, involving an initial baseline test employing Zeeuws sand. The primary purpose of this baseline test was to verify the functionality of the test setup by aligning its outcomes with the well-established methodology from Griffioen's research, thereby confirming the correct operation of the system.

Subsequently, the remaining tests utilized Kaliwaal 41 material, and they were designed to investigate the optimal process parameters, namely mixture

speed and concentration. These parameters were varied to ascertain the most favourable combination. The specific input parameters used for each of the five tests are detailed in Table 2.

The analysed output parameters included:

- Uplift forces
- Pancake diameter
- Pancake build-up
- Sand segregation
- Relative density
- Test set-up operational parameters

For a comprehensive assessment, the measured uplift forces were compared with theoretically determined uplift forces, as outlined in the theory presented by Griffioen & Westershelde (Griffioen & van der Veen, 1972).

Table 2. Input parameters.

Test	Flow rate (m/s)	Average mixture density (kg/m^3)
1	4.4	n.a.
2	4.8	1131
3	4.7	1152
4	4.1	1129
5	5.6	1109

2.4 Measurement methods

The methodology encompassed the comprehensive monitoring of several crucial parameters, allowing for a detailed examination of the test parameters:

1. **Uplift Forces:** Pressure transducers were employed to gauge the uplift forces generated by the sand pancake, which pressed against the cumulative effective weight of the dragline mats and concrete ballast blocks, effectively replicating the conditions beneath a tunnel element.
2. **Displaced Volume and Pancake Diameter:** LiDAR measurement was conducted after the test to determine the total displaced volume and pancake diameter, providing insights into the resulting formation.
3. **Conductivity (pancake build-up):** In the methodology section, ground conductivity meters (GCM) were employed to capture changes in soil height within a 40cm vertical range at specific x , y coordinates. This methodology allowed for a comprehensive examination of the sand pancake's width and height variations during the test, even underneath the plateau. To optimize data collection, sensors were strategically placed in every other hole (see Figure 5), with the remaining holes reserved for Cone Penetration Tests (CPTs) following the sand flow test. The precise operational steps for the GCM measurements are as follows:

- **Data Averaging:** Data points were averaged over a 3-second time step to mitigate electrical noise.
- **Time Standardization:** To synchronize measurements across all tests, $t = 0$ s was set as the reference point, considering variations in the start time of measurements.
- **Detection of Sand Passage:** The moment of sand passage past a sensor was determined by a significant drop in the sensor's value, as the conductivity of water markedly differs from that of a sand-water mixture.
- **Linear Analysis:** Employing linear interpolation and extrapolation, the sand height at specific time points was calculated.
- **Data Visualization:** The acquired data points across the vertical and horizontal planes, along with time, were utilized to create a comprehensive 'pancake build-up graph.' This graph visually represents the evolution of the sand pancake over time, providing valuable insights into its development.

4. **Sand Segregation:** Visual inspection of bore holes was employed to assess sand segregation.
5. **Penetration Resistance and Relative Density:** Phase 1 involved a comprehensive assessment of several key parameters, including grain distribution (D50 calculation), maximum proctor density, optimal moisture content, saturation degree, and material settling form. These measurements provided a foundation for subsequent phases of the investigation.

Phase 2 aimed to establish a calibration line that encompasses different relative densities and compaction conditions. Our goal was to closely replicate a calibration line from a prior study, which featured relative densities of 15, 50, and 70% (see Figure 6). This consistency with past research is crucial for maintaining accuracy.

The calculation of relative density, a key factor in our study, relies on the penetration resistance data obtained through the Penetrologger Cone Penetration Test (CPT) (Tufenkjian et al., n.d.). These tests were conducted by penetrating the soil through the two rows of lifting holes in the steel dragline mats, with these holes temporarily covered during the sand flow process to ensure uniform test conditions.

To determine the in-situ relative density (D_r) of the applied sand after the test, we relied on a combination of the well-established relations, such as those formulated by Jamiolkowski (Jamiolkowski et al., 2003; Lunne et al., 1997)

and results from phase 1.

The calculation of relative density is determined by considering the maximum and minimum pore content. The maximum pore content represents loose-poured sand, measuring 1660 kg/m^3 at 0.0% moisture, while the minimum pore content reflects the maximum density attained through a weighted proctor test, with a density of 1824 kg/m^3 at 10.3% moisture. This approach ensures the accuracy and reliability of our relative density calculations and offers a robust foundation for our study.

Furthermore, the methodologies that were used in order to assess the operational parameters that were tested during the study are explained as follows:

Figure 6. Cone penetration resistance from calibration test.

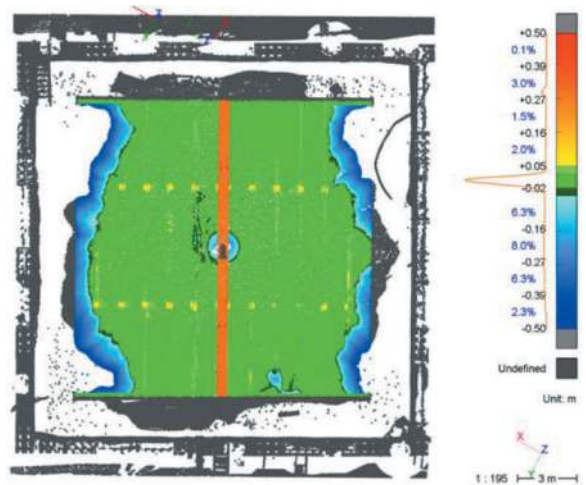

Figure 7. Sandflow test, 4th pancake with Kaliwaal 41.

Figure 5. Location of conductivity probes.

6. **Flow Velocities:** Inflow and outflow velocities to and from the mixing tank were consistently monitored to assess the fluid dynamics.
7. **Pipeline Pressure:** Pressure levels within the pipelines connecting to the mixing tank were under continuous scrutiny to maintain stable operational conditions.
8. **Mixture Concentration:** Regular recording of the density of the sand/water mixture was performed to gain insights into the mixture's composition and consistency throughout the experiment.

3 RESULTS

The results section presents key findings related to uplift forces, pancake diameter, build-up, sand segregation, relative density, and test set-up parameters. These results provide insights into the performance and behaviour of sand flow foundations in immersed tunnel construction. They form the basis for our analysis and contribute to the field's advancement.

3.1 Uplift forces

The uplift forces were measured during, immediately after and 24 hours after the test. No reduction of uplift forces was measured after 24 hours, which can be explained by the coarse character of the sand material.

The difference of the uplift force before and after the test is presented in Table 3. During test 3, a local breakthrough of the dragline mats explains the large reduction in uplift forces.

The theoretically determined uplift forces (Griffioen & van der Veen, 1972) are also shown in Table 3. It can be concluded that the results were in the same order of magnitude as the uplift forces measured during the tests, but come out lower than measured. The uplift force is highly dependent on mixture density and production speed. The difference between the measured value and the theoretical value could be due to measurement errors in the mixture density. Verification of the theory is not accomplished in this test.

Table 3. Test results.

Test	Uplift force from pancake - measured (metric tons)	Uplift force from pancake - theoretical (metric tons)	Average diameter (m)
1	15	n.a.	11
2	47	22	15.2
3	33	24	12.7
4	50	21	13.6
5	50	19	16.7

3.2 Pancake diameter

The prescribed radius for the Khor al Zubair Immersed Tunnel, set at 7.3 meters (see Figure 7), was successfully attained in two out of the four conducted tests, see Table 3. This achievement suggests an observable correlation between the flow rate and the resultant pancake diameter. Collectively, the test outcomes unequivocally demonstrate the feasibility of achieving the stipulated radius requirement for the immersed tunnel project.

3.3 Pancake development

The accumulation of sand pancakes was quantified by measuring their diameter across predefined locations marked by conductivity probes, as depicted in Figure 11. This approach facilitated real-time observations of the pancake formation throughout the duration of the test. Notably, the observed pancake evolution revealed distinct phases. Within the initial 10 to 20 minutes of sand flow initiation, the pancake exhibited a characteristic formation of a central crater. Subsequently, over a span of 40 to 50 minutes from the onset of sand flow, the central crater gradually closed, likely attributed to the consolidation of material around the previously formed ring structure at its periphery. Only after approximately 80 minutes, marking the latter stages of pancake production, did the material completely fill the void beneath the steel dragline mats. Figure 11 illustrates the data generated through the GCM measurements, providing a visual representation of these observations.

3.4 Sand segregation

Refer to Figure 9 for a representative depiction of a trial pit. The examination of both the trial pit and the soil samples extracted from each sand pancake reveals a consistent pattern of material segregation that is evenly distributed throughout the pancake's depth. However, it is noteworthy that within the uppermost 5-10 centimetres of the sand pancakes, a prevalence of coarser particles is evident. This phenomenon can be attributed to the washing out of finer particles when the gap between the pancake

Figure 8. Result of Sand flow test with Kaliwaal 41.

Figure 9. Small trial pit showing homogeneous sand build-up with a coarse top layer.

Figure 10. Cone penetration resistance made in the pancake after sand flowing.

and the tunnel element narrows, leading to an increase in flow velocities. Consequently, these finer particles tend to accumulate in the outer edges of the pancakes, thus contributing to the observed coarser composition in the upper layers.

3.5 CPT and relative density

The results of the Cone Penetration Test (CPT) conducted during the initial test utilizing Kaliwaal 41 are graphically presented in Figure 10, with similar outcomes observed in subsequent tests. Figure 10 exhibits a spectrum of coloured lines representing data obtained from various CPT locations distributed across the pancake’s surface, as indicated by numbered CPT locations in Figure 5. Notably, the black line signifies the aggregated value of multiple CPT measurements, serving as a comprehensive indicator of the CPT values for this specific pancake. To examine these results, a comparative analysis was performed against the calibration test results depicted in Figure 6. This analysis reveals that the cone resistances consistently exhibit low values, notably falling below the threshold of 15% as indicated by the blue curve labelled ‘loose’ in Figure 6. Consequently, it can be deduced that the observed cone resistances in this study are generally characterized by a “loose” nature.

4 DISCUSSION

1. Our study reveals the feasibility of creating 7.3-meter-radius sand pancakes using materials akin to Kaliwaal 41. This discovery hints at the potential use of materials falling within the range from Zeeuws sand to Kaliwaal 41 in sand flowing processes for immersed tunnels. This exciting prospect warrants further exploration and experimentation to assess the applicability of a broader spectrum of materials with intermediate properties. Future research could unveil the adaptability of sand flow techniques, accommodating diverse geological conditions.
2. Our research underscores the value of utilizing data gathered during the sand pancake formation, as measured by the Ground Concentration Measurement (GCM), for validating computational

Figure 11. Pancake development using GCM sensors for Kaliwaal 41.

tools like TUDFlow3d. TUDFlow3d, a fully three-dimensional CFD solver, designed for simulating turbulent flow on an engineering scale, stands to gain significant insights from empirical data derived from real-world sand flow operations. This fusion of experimental results and computational modelling holds tremendous promise for enhancing our grasp of sand flow processes, offering the potential for more precise and efficient engineering solutions in the realm of immersed tunnel construction. Collaborative research in this area may pave the way for an enhanced integration of computational fluid dynamics in practical sand flow applications.

3. The determination of relative density through CPT values, as prescribed by (Lunne et al., 1997), has yielded consistently low values. These values are intrinsically linked to a percentage that serves as a basis for assessing material liquefaction susceptibility. Our study has raised concerns about the accuracy of CPT values in representing reality accurately. This prompts the need for exploring alternative methods to determine relative density from CPT data. Furthermore, the determination of relative density in our calibration tests may require further scrutiny to ensure the validity of the obtained values.

Ensuring a robust calibration necessitates a direct correlation between dry densities and relative densities. The established dry densities for different relative densities, such as saturated ($D_r = 0\%$) at 1660 kg/m^3 , loose ($D_r = 15\%$) at 1685 kg/m^3 , medium dense ($D_r = 50\%$) at 1742 kg/m^3 , dense ($D_r = 70\%$) at 1775 kg/m^3 , and optimal ($D_r = 100\%$) at 1824 kg/m^3 , serve as a vital foundation for consistency with prior research and offer a valuable benchmark for future investigations and analysis.

4. Given the indications of liquefaction potential in the applied sand material based on our test results, it is prudent to consider and investigate the incorporation of cement clinker. A forthcoming test will be conducted wherein clinker material will be introduced to Kaliwaal 41. This research avenue holds the promise of shedding light on potential stabilization methods to mitigate liquefaction risks in sand flow applications.

5 CONCLUSIONS

In conclusion, the full-scale sand flow test conducted at the Ballast Nedam premises in Maarssen, Netherlands, provided valuable insights into the feasibility of using an increased grain size for sand flow applications. Several key findings emerged from this study:

1. **Uplift forces:** Uplift forces were examined during and after the tests. No significant post-test

reduction was observed, likely due to the sand's coarse nature. Test 3 experienced a notable reduction, attributed to a dragline mat breakthrough. The theoretically determined uplift forces were generally within the same order of magnitude as the measured forces, though measurements exceeded theoretical values. This difference could be attributed to factors like mixture density and production speed, possibly influenced by measurement errors. It's crucial to recognize that this test did not fully validate the theoretical model, indicating the need for further investigation and refinement.

2. **Pancake diameter:** Feasibility of Increased Grain Size: The test unequivocally demonstrated that sand flow with an increased grain size is indeed feasible. The minimum required radius of 7.3 meters was successfully achieved during the tests, suggesting that larger grains can be effectively employed in sand flow applications without compromising the structural integrity of the system.
3. **Pancake development:** Our study employed conductivity probes to monitor sand pancake formation and evolution in real-time. We observed distinct phases, including the initial central crater, gradual closure, and eventual complete filling beneath the steel dragline mats. Figure 11 visually depicts these findings. The experiments revealed that the largest sand pancakes were formed under conditions characterized by relatively high mixture velocities and low sand concentrations. This finding suggests that controlling these parameters can be crucial for optimizing sand flow processes, particularly when larger grain sizes are used.
4. **Sand segregation:** Our examination of the trial pit and soil samples from the sand pancakes indicates a consistent pattern of material distribution throughout their depth. Notably, the uppermost 5-10 centimeters of the pancakes exhibit coarser particle prevalence. This phenomenon results from increased flow velocities and the subsequent washing out of finer particles near the tunnel element interface.
5. **CPT and relative density:** An important aspect of this study was the assessment of the relative density of the Kaliwaal sand pancakes. Based on the data obtained from the calibration chamber tests and penetrometer results, the estimated relative density of these sand pancakes was found to be less than 15%. This low relative density may have implications for the stability and behaviour of the sand pancakes in practical applications.

Overall, the results of the full-scale sand flow test provide valuable information for engineers and researchers interested in utilizing larger grain sizes in sand flow systems. The successful achievement of the required radius and the insights into sand

pancake formation contribute to our understanding of the potential benefits and challenges associated with this approach. Additionally, the estimation of low relative density underscores the need for further research and consideration of factors that may affect the performance and stability of sand pancakes in real-world scenarios. This study serves as an important step toward advancing the field of sand flow technology and offers a foundation for future investigations in this area.

ACKNOWLEDGMENTS

I would like to extend my heartfelt acknowledgments to several individuals and organizations who have played a pivotal role in the development and completion of this research paper. Firstly, I am immensely grateful to Roline Montijn for her invaluable and substantive input, which significantly contributed to shaping the content and direction of this paper. Her expertise and dedication have been instrumental in the success of this project. I would also like to express my appreciation to Rick Hermsen for his fresh and insightful perspectives on various aspects of the paper, which added depth and clarity to our discussions. Furthermore, I extend my sincere gratitude to Michel van der Molen for his expertise, methodical analysis, and invaluable advice throughout the execution of the test and the writing of this paper; his contributions have been indispensable to this work.

Additionally, I would like to extend my gratitude to Ballast Nedam Infra Projects and Daewoo E&C, our esteemed partners in the Khor al Zubair Immersed Tunnel Project, for their generous support and the opportunity they provided us to write and publish this paper. Their collaboration and cooperation have been essential in advancing our research efforts.

Lastly, I extend my thanks to the various subcontractors and suppliers of sensors, materials, and

terrain, whose contributions were essential for the successful execution of the test and, ultimately, the completion of this paper. Their commitment to excellence and provision of necessary resources have been instrumental in achieving our research objectives.

ABSTRACT: The Shenzhen-Zhongshan Link immersed tunnel has eight lanes in both directions, which is the widest section immersed tunnel in the world. The special construction form and ultra-wide section of the tunnel pose great challenges to tunnel ventilation and smoke exhaust system. In order to solve the needs of normal operation and fire case, the tunnel is equipped with tunnel environment detection system, main line tunnel normal operation ventilation system, main tunnel independent smoke exhaust system, exit passageway pressurized air supply system, ramp tunnel normal operation ventilation system, ramp tunnel smoke exhaust system, and staircase pressurized air supply system. Pioneering the ultra-wide cross-section smoke exhaust system and device firstly, and the smoke exhaust efficiency was increased by 42 %. This paper provides a technical reference for the setting of ventilation and smoke exhaust system of an ultra-wide section immersed tunnel and other ultra-wide section tunnels.

Keywords: super wide section immersed tunnel, ventilation system, smoke extraction system, New smoke exhaust technology

1 INTRODUCTION

The total length of the Shenzhong Tunnel is 6845m, and the immersed section is 5035m. The tunnel is a two-way eight lane road with a design speed of 100km/h. It connects to artificial islands at each end. The width of the main tunnel has changed from 46m to 69.8m, making it the world's widest cross-section highway immersed tunnel. There is an underwater interchange at the East Artificial Island that intersects with the main tunnel. The smoke exhaust efficiency under ultra wide cross-section conditions^[1] and the smoke exhaust arrangement at underwater interchanges and confluences are the main challenges for ventilation and smoke exhaust in this project.

2 SYSTEM COMPOSITION

The ventilation system of the Shenzhong Tunnel consists of 8 subsystems: tunnel environment detection system, normal operation ventilation system of the main driving tunnel, independent smoke exhaust

(a) Schematic diagram of underwater communication

(b) Standard Cross Section of Tunnel (Unit: cm)

Figure 1. Cross Section of Underwater Interchange and Tunnel.

*Corresponding author: yxj21@mails.tsinghua.edu.cn

system, safety passage ventilation system, normal operation ventilation system of the ramp tunnel, centralized smoke exhaust system of the ramp tunnel, pressurized air supply system of the ramp tunnel staircase, and ventilation and ventilation system of the rainwater pump room. The ventilation system design follows the principle of one-time design and phased implementation.

2.1 Tunnel environment detection system

By setting detectors (carbon monoxide/visibility/nitrogen oxide detectors, temperature detectors, wind speed and direction detectors) inside the tunnel, data is provided for normal ventilation and emergency ventilation under normal operating conditions and accident conditions.

2.2 Ventilation system for normal operating conditions of the main tunnel of the train

The ventilation and ventilation function in the tunnel is achieved through the action of jet fans and piston air in the tunnel, ensuring the safety and comfort of driving in the tunnel. At the exit of the tunnel, polluted gases are concentrated and discharged from the entrance, causing the concentration of polluted gases in the tunnel site to exceed the standard. The polluted gases are centrally extracted and discharged at high level through wind towers set up on the east and west artificial islands on the exit side of the tunnel.

2.3 Smoke exhaust system

By using smoke exhaust fans, smoke is concentrated and extracted through horizontal contact with the flue and side wall smoke exhaust outlets, controlling the smoke diffusion range. Smoke is also discharged through wind towers set up on the east and west artificial islands to achieve the purpose of smoke exhaust and ensuring the safety of personnel escape.

2.4 Safe passage ventilation system

Under normal operating conditions, ventilation and air exchange functions are achieved through the pressurized fans on the east and west artificial islands to ensure personnel maintenance needs. Under fire conditions, positive pressure above the pressure in the accident tunnel is achieved through the pressure regulating fans installed in the fan rooms and safety passages of the east and west artificial islands, as well as the pressure regulating fans installed in the safety passage. This prevents smoke from entering the safety passage during fire conditions and ensures personnel escape and rescue work needs.

2.5 Ventilation system for normal operation of ramp tunnels

The ramp tunnel is equipped with jet fans to achieve ventilation and ventilation functions for the ramp tunnel.

2.6 Ramp tunnel centralized smoke exhaust system

A centralized smoke exhaust outlet is set up at the intersection of E and F ramps, and key smoke exhaust is carried out by opening the electric air valve in the corresponding area during fire conditions.

2.7 Smoke prevention system for evacuation staircase of ramp tunnel

A mechanical pressurized air supply system is installed in the evacuation staircase of the ramp tunnel to achieve positive pressure air supply function under fire conditions.

2.8 Ventilation and ventilation system for rainwater pump room

The rainwater pump room and distribution room are equipped with mechanical air supply and exhaust systems to achieve ventilation and ensure the normal operation of internal equipment.

3 VENTILATION SYSTEM SCHEME

3.1 Ventilation system for normal operation of the main driving tunnel

The normal operation ventilation of the tunnel driving hole adopts a combined ventilation scheme of longitudinal ventilation with a full jet fan and separated vertical shaft exhaust ventilation. Under normal operating conditions, the jet fan is turned on for ventilation and air exchange inside the tunnel. To ensure the air quality at the tunnel entrance, polluted gases are collected and discharged at high altitude through the wind towers on the east and west artificial islands. The wind towers have a height of approximately 30m.

Figure 2. Schematic diagram of fan room in West Island.

3.2 Smoke exhaust system

To reduce the length of smoke spread under fire conditions, this project adopts a key smoke exhaust scheme [2]. The immersed tunnel generally adopts a lateral centralized smoke exhaust mode for smoke exhaust [3]. Due to the large cross-sectional width of this

project, direct lateral smoke exhaust cannot meet the safety requirements for personnel evacuation. Through physical model experiments and numerical simulations, a centralized smoke exhaust scheme of “top horizontal connecting smoke exhaust duct (with louvered air outlets at the bottom) and electric smoke exhaust outlets on the side walls” is adopted for the super large cross-section transition section of the main tunnel and interchange underground hub section; Smoke exhaust is carried out by setting a horizontal flue connecting the lateral smoke exhaust outlet of the tunnel at the top of the tunnel. Due to structural safety reasons, the smoke exhaust outlet adopts a group of three schemes. The maximum spacing between horizontal flues is 165m. Adopting a key smoke exhaust scheme that combines top centralized smoke exhaust with lateral centralized smoke exhaust.

Figure 3. Schematic diagram of smoke exhaust duct setting.

Figure 4. Photos of on-site fire experiments.

According to physical model experiments and numerical simulations, the smoke exhaust efficiency has been verified to be more than 40% higher than that of lateral concentrated smoke exhaust.

3.3 Safe passage ventilation system

Under normal operating conditions, a stable airflow is formed by turning on the fans in the east and west artificial islands and the fans in the passage for ventilation.

Under fire conditions, it is used to maintain positive pressure ventilation of the accident tunnel and prevent smoke from entering the safe passage.

3.4 Ventilation system for normal operation of ramp tunnels

Under normal operating conditions, the ventilation and ventilation function of the ramp tunnel is achieved by setting a jet fan in the ramp tunnel, ensuring the tunnel operating environment.

3.5 Ramp tunnel centralized smoke exhaust system

On the upper part of the ramp tunnel, a mezzanine layer is used for centralized smoke exhaust, and a total of electric smoke exhaust outlets are set up for centralized smoke exhaust.

The ramp tunnel smoke exhaust room is equipped with an independent room for centralized smoke exhaust.

3.6 Smoke prevention system for evacuation staircase of ramp tunnel

The smoke prevention system is designed for the evacuation staircase of the ramp tunnel, and a mechanical pressurized air supply system is designed in the front chamber and stairwell respectively to maintain positive pressure in the stairwell and front chamber, ensuring that under tunnel accident conditions, the pressure in the stairwell is greater than that in the front chamber and greater than that in the tunnel.

3.7 Ventilation system for rainwater pump room

The underground distribution room and rainwater pump room are equipped with axial flow fan mechanical supply and exhaust systems, which exchange air with the outdoor through the louvered air vents of the island air shaft. Fire dampers should be installed when the air duct passes through the floor slab and firewall, and they should be interlocked with a fire alarm. In case of a fire, the axial flow fan stops running, the fire damper is closed, and the fire control status is switched to.

4 CONTROL STRATEGY

4.1 Smoke exhaust plan for the main tunnel

The main tunnel ventilation system utilizes the exhaust duct above the middle passage between the two tunnels, and activates a dedicated exhaust fan to exhaust smoke through a set of horizontal ducts upstream of the fire source, 2-3 sets of horizontal ducts downstream, and side wall exhaust outlets during the period. The wind speed inside the main tunnel is controlled by the jet fans. In cases where smoke exhaust needs cannot be met, an additional set of smoke exhaust outlets can be opened downstream. Further the jet fans are controlled to reduce the wind speed in the main tunnel and the length of smoke counterflow^[4].

When a fire occurs in the dimming section and entrance section of the tunnel, smoke exhaust is carried out by opening the exhaust outlet downstream of the fire source. By controlling the jet fans, the wind speed inside the main tunnel is reduced to reduce the length of smoke counterflow. After the evacuation of upstream tunnel users, it is determined whether to reverse the fans to exhaust smoke from the entrance according to the situation.

The combined air valve in the central exhaust duct is closed under normal working conditions. One end fails, smoke exhaust through the other end fan.

The safety passage ensures positive pressure through a pressurized fan to prevent smoke from entering. Opening the jet fan towards the tunnel ensures positive pressure in the opening area of the safety door and reduces pressure loss in the safety passage.

4.2 *Ventilation and smoke exhaust control scheme for ramp merging section*

Under fire conditions, smoke exhaust is carried out by opening the centralized exhaust outlet downstream of the fire source, and a jet fan 150 meters upstream is also activated to prevent smoke from flowing backwards.

5 CONCLUSIONS

The deep channel underwater tunnel belongs to an ultra wide cross-section immersed tube tunnel, which is also connected to underwater interchanges, making smoke exhaust difficult and smoke control

strategies complex. The first proposed method of converting lateral centralized smoke exhaust to top centralized smoke exhaust solves the problem of smoke exhaust efficiency in wide cross-section tunnels. In addition, the smoke control design of other areas ensures the safety of personnel under fire conditions.

ABSTRACT: The Shenzhen-Zhongshan Link has a total length of 6845m submarine tunnel and eight two-way lanes. There is an undersea interchange tunnel that intersects with the main tunnel. This project has a high traffic volume, complex traffic organization, high operational risk, and difficult linkage rescue. In order to solve the problem of the operation safety of subsea tunnel, the countermeasures are carried out from the aspects of hazard source control, accident prevention, accident early warning, accident alarm, accident disposal, emergency linkage and so on. An intelligent linkage rescue system for tunnels has been developed to realize rapid rescue linkage with accident scenarios under accident conditions. The fire rescue technology program by this project has a certain reference for the operation safety of other projects.

Keywords: Ultra-wide cross-section immersed tube tunnel, fire, fire rescue, emergency linkage

1 INTRODUCTION

The Shenzhen-Zhongshan Cross-River Link is a significant highway channel crossing the Pearl River Estuary, situated approximately 30km downstream of the Humen Bridge and 31km upstream of the Hong Kong-Zhuhai-Macao Bridge. This extensive cluster project spans a total length of about 24km, featuring a combination of a bridge, an island, a tunnel, and an underwater channel. The subsea tunnel of the Shenzhen-Zhongshan Link measures 6,845m, while the immersed tube section extends 5,035m. The project is scheduled to open to traffic in 2024.

This two-way, eight-lane tunnel is designed for a speed of 100km/h. The width of the main tunnel line varies from 46m to an impressive 69.8m, making it the widest highway immersed tube tunnel in the world. With a considerable traffic volume, a significant proportion of large vehicles, and complex traffic flow, how to ensure the operational safety of this ultra-wide steel shell immersed tube tunnel is the primary issue^[1].

Traditional tunnel fire protection facilities mainly provide safety protection by setting up fire hydrants and other facilities in the tunnel, and do not form a full-chain disaster prevention system. In order to ensure the safety of the tunnel, systematic research has been conducted on key technologies, such as hazard source elimination, accident warning and alarm systems, fire smoke extraction, fire extinguishing, emergency rescue and personnel evacuation, and so on.

2 GOALS AND PRINCIPLES OF FIRE RESCUE SYSTEM DESIGN

The design of the tunnel fire rescue system is guided by the principle of prioritizing prevention and integrating prevention with firefighting. During the design stage, aligned with the specified safety objectives, the focus is on ensuring the overall operational safety of the tunnel. This involves considerations such as fire scene design, the configuration of fire rescue equipment, and emergency ventilation plan, etc.

*Corresponding author: yxj21@mails.tsinghua.edu.cn

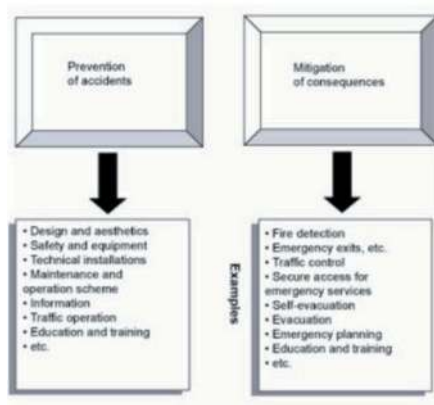

Figure 1. The global safety concept^[2].

3 CONTROL OF DANGEROUS GOODS TRANSPORT VEHICLES

Dangerous goods transport vehicles are strictly prohibited from traversing the entire route. The system is integrated with the national key operating vehicle network joint control system to enable dynamic monitoring of vehicles for highway passenger transportation, tourism passenger transportation, hazardous chemical transportation on the platform.

The capture function of the ETC mast is used to collect the data of vehicles, which is compared with the data of vehicles for highway passenger transportation, tourism passenger transportation, hazardous chemical transportation in the national key operating vehicle network and joint control system to confirm the key vehicles. The management platform confirms the precise locations of these key vehicles and tracks the vehicles that entered into the tunnel by using the tunnel's video and digital data, along with twin hardware facilities. Real-time status information is then back to the central platform for display, which significantly enhanced the safety monitoring of key vehicles.

In addition, control is maintained through the management of the road network, employing a combination of 'vehicle face recognition,' 'traffic radar,' and 'video surveillance.'"

4 FIRE ALARM FACILITIES

In the fire alarm system, the tunnel section fire alarm information is categorized into three types:

The first type: dual-wavelength flame detection, manual alarm button, fire hydrant box unpacking, fire extinguisher box unpacking, fire hydrant button signals;

The second type: fiber Bragg grating temperature sensing optical cable alarm signals;

The third type: video smoke detection alarm signals.

The fire alarm controller receives dual-wavelength flame detection, manual alarm button, fire hydrant box unpacking, fire extinguisher box unpacking, and fire hydrant button signals via the bus, and receives fiber grating temperature-sensing

optical cable alarm signals through the serial port. The fire alarms in tunnel sections and monitoring station machine rooms form a ring network through optical fiber to realize independent transmission of alarm information and has information transmission channel redundancy. Temperature detection information from the fiber grating temperature-sensing optical cable is transmitted through the industrial Ethernet ring network of the traffic monitoring system. Video smoke detection alarm information is transmitted through the surveillance system. The tunnel fire detection equipment settings are shown in the following table:

Table 1. Table of fire detection equipment layout.

Location	Equipment	Configuration
Driving Passage Inside the tunnel	Dual wavelength flame detector	Staggered arrangement on both sides
	Fiber Bragg Grating Temperature Sensing Optical Cable	Full length
	Video smoke detection	Via cameras
	manual alarm button	Staggered arrangement on both sides
strong current cable channel Inside the tunnel	Fiber Bragg Grating Temperature Sensing Optical Cable	Length settings

5 VENTILATION AND SMOKE EXTRACTION FACILITIES^[1,3]

The ventilation and smoke exhaust facilities in the main tunnel serve various critical functions. The ventilation system primarily ensures driving safety and comfort within the tunnel, while the smoke extraction system plays a pivotal role in centralized smoke extraction during fire emergencies. This helps control smoke propagation, safeguard personnel evacuation, and facilitate effective rescue operations. Additionally, the safety passage ventilation system supports normal ventilation operations and positive pressure ventilation during fire incidents.

5.1 Tunnel ventilation system

The ventilation system of the main tunnel adopts a ventilation scheme of longitudinal full jet ventilation and split-type exhaust at the tunnel entrance.

5.2 Exhaust system

The tunnel is equipped with an independent smoke exhaust duct on the upper level of the central pipe gallery along the entire tunnel length. The exhaust duct is connected to the smoke exhaust fans located on the east and west artificial islands. Approximately every 85 meters, a smoke exhaust outlet is provided,

positioned within the exhaust duct on the side of the pipe gallery in the middle of the main tunnel. The tunnel structure design unit has designed these smoke exhaust outlets in alignment with the civil structure. The outlets are arranged in groups of three.

A top smoke exhaust solution is employed, with an auxiliary flue located at intervals of about 165 meters.

Jet fans within the exhaust duct assist with auxiliary smoke extraction.

Figure 2. Diagrammatic Sketch of Exhaust Duct Settings in Top Smoke Exhaust Mode with Louver Air Outlets at the Bottom.

Through verification through numerical simulation and model experiments, this method can increase the smoke exhaust efficiency by more than 40%.

5.3 Safe passage ventilation system

A safe passage fan room will be established on each of the east and west artificial islands to provide pressurized air supply. Maintain channel positive pressure at 30-50pa through local pressurization.

5.4 Centralized smoke exhaust system for E and F ramp tunnels

Independent flue ducts are installed in ramp tunnels for the centralized smoke extraction during fire conditions.

Smoke exhaust outlets placed at the confluence section of the E and F ramp tunnels will be concentrated for smoke extraction. In the event of a fire, the electric smoke exhaust outlets positioned at the corresponding locations will be activated for centralized smoke extraction.

6 FIRE EXTINGUISHING FACILITIES

6.1 Facilities composition

In the driving tunnel, the following systems are in place: a foam-water spray combined system, a tunnel fire hydrant system (including a fixed aqueous film-forming foam fire extinguishing device), and a fire extinguisher system.

At the tunnel entrance and in the open section of the tunnel, an outdoor fire hydrant system is installed, which adopts a temporary high-pressure system.

Within the tunnel equipment cavern, a fire extinguisher system is established.

In the tunnel cable channel, fire separation facilities are installed to limit the fire to a certain area and minimize fire losses when the fire cannot be extinguished in time.

6.2 Foam-water spray fire extinguishing system

6.2.1 System composition

The tunnel is equipped with a foam-water spray fire extinguishing system. This system features water supply pipelines and foam liquid pipelines running along the tunnel. In case of a fire, the water spray pump and foam liquid pump in the affected area are activated to provide water and film-forming foam liquid to the tunnel's foam-water spray combined system.

6.2.2 System setting requirements

The application rate of the foam-water spray combined system is ≥ 6.5 L/(min·m²). The time duration of foam mixture injection is ≥ 22 minutes, and the time duration of water spray injection is ≥ 60 minutes. The concentration of the foam mixture is $\geq 3\%$, and the pressure at all tunnel-specific foam-water spray nozzles is no less than 0.35 MPa.

Additionally, the maximum spacing between deluge valves is 22 meters, and the working pressure of a single nozzle is 0.35 MPa.

6.3 Fire hydrant system

Fire equipment boxes and fire hydrant pipes are installed along the buried section of the tunnel. Outdoor fire hydrants are also placed near the main tunnel entrance and within the open section of the tunnel. In case of a fire, the tunnel fire hydrant pump and outdoor fire pump in the affected area are activated to supply water to the fire hydrants and AFFF fire extinguishing devices inside the tunnel and at the tunnel entrance.

6.4 Fire extinguisher system

Fire extinguisher boxes are positioned staggered on both sides of the tunnel lane, with a maximum spacing of 50 meters on one side. Each box contains a dry powder portable fire extinguisher for extinguishing initial fires.

In addition, fire extinguisher boxes are installed on both sides of the safety door at the traffic opening side of the upward tunnel in the safety passage, and dry powder portable fire extinguishers are placed in the boxes.

7 RESCUE FACILITIES AND EVACUATION FACILITIES^[4]

Emergency rescue follows a two-level management system: Shenzhen-Zhongshan Link Rescue Command Center — Rescue Stations.

The Rescue Command Center, located at the Ma'an Island Management Center on the Zhongshan side, is responsible for emergency rescue command for all emergencies along the entire route.

Rescue Stations are the specific execution units for rescue operations. In case of an accident, the emergency plan will be activated immediately, and the rescue stations are ready to engage in the rescue operations under the command of the Rescue Command Center.

Each Rescue Station is equipped with rescue facilities. There are three rescue stations along the entire route, located at the West Artificial Island, East Artificial Island, and Management Center on the Zhongshan Side.

The temporary evacuation passage in the middle pipe corridor of the main tunnel has a net width of 2 meters and a net height of 2.2 meters. This passage extends along the entire route with safety doors placed at intervals of no less than 90 meters. In case of an accident, personnel can enter the passage and escape from the opposite tunnel, which directly leads to the safe areas of the east and west artificial islands. Additionally, there are two escape stairs in the underwater interchange. In case of accident, people can enter the passage directly to the ground.

Relying on informatization and intelligent methods and based on accident scenarios, a fire rescue module has been developed. It is founded on event perception, situation prediction, and intelligent equipment linkage, allowing all relevant equipment to be activated with a single click to initiate disaster prevention zone linkage rescue, thereby enhancing rescue efficiency.

Figure 3. Tunnel linkage rescue platform.

8 OTHER FACILITIES

8.1 Power supply facilities

In order to improve the reliability of power supply, The 110KV external power supply is sourced from two different superior substations. Moreover, 10KV diesel generators are positioned on the east and west artificial islands as backup power sources. These generators offer support for the fire pump room, basic lighting, emergency lighting, and monitoring equipment.

An EPS (Emergency Power Supply) system is also installed to ensure continuous power supply during emergencies.

8.2 Lighting facilities

Within the tunnel, an emergency lighting system is installed to facilitate safe evacuation and rescue operations in case of a tunnel accident.

In addition, side wall light strips span the entire length of the tunnel. These strips utilize varying light colors and flashing frequencies, etc. to convey information about tunnel operating conditions, ensuring drivers and passengers are well-informed throughout their journey.

Figure 4. Diagrammatic Sketch of Side Wall Light Strip in the Tunnel.

8.3 Communication facilities

When a fire breaks out in a certain area within the tunnel passage, the operational status of emergency telephones in other areas remains unaffected. Drivers and passengers can use these emergency phones to call the monitoring center or the West Artificial Island Monitoring Station for assistance. Rescuers can also use these emergency phones near the fire site for emergency communications.

Cable broadcast control centers are established in both the monitoring center and artificial island monitoring station to manage broadcasts in the bridge section and tunnel section respectively.

The monitoring center can broadcast throughout the entire bridge section via the cable broadcast system, or broadcast in specific zones for some road sections.

A wireless FM broadcast system is deployed in the tunnel to enable one-way broadcasting. This wireless FM radio can rebroadcast traffic information and content from other radio stations. Furthermore, it can be used to transmit emergency information. Drivers and passengers can access diversion instructions via this radio system.

9 CONCLUSION

The comprehensive design considerations encompassing the removal of potential hazards, fire alarms, fire suppression, smoke extraction, emergency response, and evacuation measures are paramount in ensuring the operational safety of this ultra-wide cross-section immersed tube

tunnel. The findings and outcomes derived from this project are not only valuable for similar tunnel projects but also serve as a reference for the wide tunnel engineering industry.

Quantitative detection method and practice of voids at the interface of steel-shell concrete with complex structure

Hongbo Zhao*, Guoqing Liu, Ziwu Fan, Long Sun, Lingchao Meng & Langlang Wang
Nanjing Hydraulic Research Institute, Nanjing, China

ABSTRACT: This study employs neutron moderation theory to quantitatively detect millimeter-level voids at the interface of steel-shell concrete with complex structures. Experiments were conducted using concrete models varying in moisture content and steel-shell thickness. The results indicate a consistent decrease in the thermal neutron counting rate with increasing void height, demonstrating a strong linear relationship between these variables. The calibration relationship was verified by detecting the known void height between the thick steel plate (40 mm) and the plain concrete block; the maximum difference between the test result and the actual void height was only 2.1 mm. Additionally, the full-scale model of the Shenzhen–Zhongshan Link immersed tunnel was utilized to devise an on-site detection methodology. This involved conducting void detection and subsequent destructive verification tests. The neutron method detection yielded statistical results. The accuracy rate reached approximately 94% at an allowable error of ± 2.0 mm. This demonstrates a high level of quantitative identification accuracy for the millimeter-level voids at the interface of the steel-shell concrete with a complex structure in the immersed tunnels. This method has been effectively applied in the formal tubes of the Shenzhen–Zhongshan Link immersed tunnel.

1 INTRODUCTION

Steel-shell concrete composite structures are widely adopted in the structural design of immersed tube tunnels (Grantz 1997, Fu 2004), water conservation and hydropower (Wang 2019, Wu et al. 2021, Yang et al. 2018, Wang 2021), bridges (Pan 2018, Zhang 2020, Xu 2021), and other engineering fields owing to their superior properties including high strength, good ductility, fatigue resistance, impact resistance, explosion resistance, and waterproofing, as well as the advantages of labor-saving, material-saving, lightweight erection, and rapid construction (Akimoto et al. 2002, Song and Chen 2005). In the domain of immersed tube tunnels, steel-shell concrete composite structures have evolved from waterproof formwork, which plays a minimal role in structural stress (Gursoy 1995), to steel-shell reinforced concrete structures bearing combined stress (Grantz 1997). The development progressed from stacked stud and channel steel connections (Pryer and Bowerman 1998, Xie and Chapman 2006) to steel–concrete–steel composite structures with longitudinal and transverse partitions (Song

et al. 2019). Further advancements include increasing the contact surface angles between the steel shell and concrete as stiffeners, and integrating welding studs with the concrete to enhance the shear connection of steel plate concrete (Shariati et al. 2013).

However, the complex structural design poses significant challenges to the pouring construction of the concrete. This not only requires a sufficiently good fluidity performance of the concrete paste but the concrete must also be ventilated smoothly (Lyu et al. 2016, Penget et al. 2021). Extensive experimental research and engineering practice data reveal that owing to the densely packed and staggered components such as steel shell longitudinal and transverse partitions and stiffeners, concrete is prone to the formation of voids during the pouring process, particularly near the interfaces of these components with the steel and concrete. Early Japanese steel-shell concrete casting tests revealed that the hollowing areas could constitute up to 5% of the total area (Komon et al. 1995). Notably, hollowing significantly impacts the load-bearing capacity of the joint: a 10 mm hollow can reduce the capacity by

*Corresponding author: hbzhao@nhri.cn

a maximum of 16.5%; at 20 mm, this reduction can reach 37.5% (Tang et al. 2020). Consequently, accurately detecting concrete voids beneath the steel shell surface is vital for maintaining the structural integrity and ensuring project safety. An effective detection method can provide essential guidance for the grouting reinforcement.

At present, the commonly used non-destructive testing techniques for detecting the defects of steel-shell–concrete interface voids include the artificial malleting, ultrasonic (Yang et al. 2012, Wang et al. 2021), impact-echo (Yao et al. 2017, Liu et al. 2021), and impact-imaging methods (Tang and Che 2019, Zhang et al. 2022), which are based on the elastic waves theory; as well as the infrared (Liu et al. 2021), γ -ray (Hua 1981), and neutron methods (Zhang et al. 2017), which are based on the radiographic detection technology.

The artificial malleting method judges the voids by the sound of the mallet hitting the steel shell, which is influenced by the subjective experience of individuals, and therefore often used as a qualitative discrimination method for initial screening in the actual detection. Ultrasonic, impact-echo, and infrared methods can often only qualitatively identify the presence of defects within the structure but cannot identify the height of the void defects. The impact imaging method can provide the distribution range of the height of the voids but cannot be used to determine the exact value. The γ -ray method has considerable external radiation damage. Therefore, the protection requirements are incredibly high and the implementation of engineering applications is challenging. The neutron method uses a neutron source to emit fast neutrons that easily pass through the steel plate and concrete to produce detectable thermal neutrons, according to the counting rate and distribution rule of the thermal neutron, which can be detected out of the region and height of the voids. The neutron method can use low-energy radioactive sources. Therefore, relative to the γ -ray method, the protection requirements are lower. Currently, the neutron method is primarily applied in detecting voids in steel-shell concrete within hydraulic structures, specifically in water diversion and transmission pipelines, runner chambers, and volutes of electric generating units. However, there has been no effective research or application of this method in steel-shell concrete immersed tube tunnels.

This study addresses the challenge of quantitatively detecting millimeter-scale hollowing in concrete under a thick steel shell with a complex structure. The proposed method utilizes the principle of fast neutron slowing to investigate the response relationship between the thermal neutron counting rate and the height of hollowing in a steel-shell concrete composite structure. A technique encompassing both hardware and software equipment has been developed for the quantitative detection of such hollowing. Theoretical foundations for

this technique were established through indoor calibration tests, enabling the quantitative detection of millimeter-scale hollowing in the steel-shell concrete composite structures. The theoretical non-destructive quantitative detection of millimeter-scale hollowing of complex steel-shell concrete structures is achieved by conducting indoor calibration tests. At the same time, combined with the steel-shell concrete immersed tube foot-scale model of the Shenzhen–Zhongshan Link, a blind on-site lid opening verification test is carried out to demonstrate the accuracy of the neutron method in detecting millimeter-avoidance of steel-shell concrete complex structures. This can provide technological support for the high-quality construction of the century-long quality project of the Shenzhen–Zhongshan Link.

2 DETECTION METHOD AND EQUIPMENT

2.1 Introduction of the neutron method

Neutron law quantitative detection of the steel shell concrete interface dehulling is mainly based on the neutron slowing theory, that is, the use of radioactive sources emitted by fast neutrons and the medium atomic nuclei collision, which reduce the energy and decelerate the neutrons, ultimately yielding slow neutrons. The effect of the medium on the fast neutron deceleration and the mass size of atomic nuclei within the medium influence this process. As atomic weight decreases, the deceleration effect strengthens. Hydrogen, with the smallest atomic weight in nature, is the most effective neutron slowing agent. The slowing ability of the hydrogen atoms is 2–3 orders of magnitude larger than that of general soil elements such as oxygen, silicon, aluminum, calcium, magnesium, and iron. Therefore, the slowing and decelerating effect of the medium on the fast neutrons is mainly determined by the amount of hydrogen contained in the medium. Concrete consists of crushed stone, coarse sand, and cement mixed with a specific amount of water. Most of this water reacts with cement to form hydrated water, while a small portion remains in a free state. Both forms of water are uniformly distributed within the concrete. Because concrete is a water-containing material and water molecules contain hydrogen atoms, concrete is a good fast neutron moderator.

Because the fast neutron radiation is easily slowed by “light” but not “heavy,” it can easily penetrate the steel-shell concrete structure of the surface of the steel plate and the concrete material below the interaction. This mainly occurs with the concrete contained in the hydrogen atoms, slowing down the formation of the thermal neutrons. The water content is fixed for a particular proportion of the concrete, which affects the formation of thermal neutron density, that is, the thermal neutron counting rate per unit volume of concrete mass. In areas with void defects, the mass per unit volume of the concrete is noticeably lower than

that in the densely filled areas. Consequently, the thermal neutron counting rate in these hollow regions is lower compared to that in the denser parts. Utilizing a neutron source and thermal neutron detector enables the determination of the thermal neutron counting rate in various parts of the inspected object. This approach allows for pinpointing the location of the hollowing plane and measuring the depth of concrete hollowing beneath the steel plate.

Figure 1. The basic principle diagram of neutron method.

2.2 Detection equipment for the neutron method

The detection equipment for the neutron method comprises a neutron source, thermal neutron detector, integrated circuit, battery, antenna, and an operating computer. The neutron source used in this study is an americium-241-beryllium radioactive source, and the thermal neutron detector is a helium-3 orthogonal gas counting tube; the specific parameters are shown in Table 1.

Table 1. Module parameters of detection equipment for the neutron method.

Module	Type	Property parameter
Neutron source	$^{241}\text{Am-Be}$	Cylindrical shape, diameter 16 mm, height 20 mm, activity $1.48 \text{ E} + 9\text{Bq}$ (40 mCi).
Thermal neutron detector	helium-3 orthogonal gas counting tube	Gas pressure greater than 6 atm; Detection efficiency exceeds 50% for thermal neutrons with wavelengths greater than 1 \AA ; Thermal neutron sensitivity 104 cps/nv .
Battery	Ni-MH	1.2 V, 1200 mAh

2.3 Correlation calibration

According to the basic principle of neutron detection, the size of the thermal neutron counting rate (N) at measurement points is related not only to the height of steel plate evacuation (h) below these points but also to the thickness of the steel plate and the actual water content in the concrete material. Therefore, once the steel plate thickness and concrete material

water content have been established, the deflation height at the measurement points is determined solely by the thermal neutron counting rate at these points. When combined under specific testing conditions, a distinct correlation emerges between the steel plate, concrete, and structure of internal stiffeners of the object being tested. Establishing this correlation requires calibration before the test.

In this test, steel plates with six thicknesses of 14, 18, 24, 30, 36, and 40 mm were selected. Five types of concrete equivalent media with a background moisture content of 117.8, 192.0, 238.7, 354.4, and 598.1 kg/m^3 were used for 30 combinations of the working conditions. The upper surface of the concrete equivalent medium and the steel plate were closely fitted to simulate the non-dehollowing situation, on which five regular defects were formed by lifting the steel plate to varying heights (5.0, 10.0, 20.0, 30.0, and 50.0 mm). The thermal neutron counting rate for each condition was measured by the equipment for different heights of evacuation.

The correlation between the thermal neutron counting rate and the height of deflection was fitted using the least squares method. A quantitative model (Equation (1)) was established by this process. The model relates the thermal neutron counting rate to the height of the de-voids for the combinations of varying steel plate thicknesses and different background moisture contents in the concrete equivalent media.

$$h = f(N) = \sum_{i=0}^2 a_i N^i \quad (1)$$

As an example, the calibration curve for a 40 mm steel plate is shown below.

Figure 2. Calibration curve for 40mm thickness steel plate.

The calibration curves show that when the thickness of the steel plate and the background moisture content of the concrete are known, the thermal neutron counting rate is the highest in the absence of de-voids, and it decreases gradually with an increase in the de-voids. Using the thermal neutron counting rate measured during non-decavitation as a baseline, a decrease in this rate indicates an increase in decavitation. The extent of this decrease is directly

proportional to the decavitation size, a relationship crucial for quantitatively identifying the height of decavitation with this method.

3 PROTOTYPE EXPERIMENT

To further test the validity and accuracy of the neutron method for quantitatively detecting the dehulling of complex structures in the steel-shell concrete, a blind check-open lid validation experiment was carried out based on the foot-scale model of the steel-shell concrete immersed tube tunnel of the Shenzhen–Zhongshan Link.

3.1 Introduction of the full-scale model

The full-scale model was 9.6m long, 54.5m wide, and 10.6m high; the materials and detailed structures, such as cross-section, compartment dimensions, and stiffeners, were consistent with those of the Shenzhen–Zhongshan Link. The model was divided into 51 compartments on the bottom plate, 12 on the wall, and 42 on the top plate. The top planes of the base and the top plates were welded with a mixture of 14 mm and 40 mm steel plates, the pouring holes ($\phi 273 \times 8\text{mm}$) were set in the middle of the top planes of the compartment, and the vent holes ($\phi 89 \times 8\text{mm}$) were set in the corners of the perimeter of the compartments and the T-stiffeners. The C50 high-flow self-compacting concrete was used for the full-scale model and poured without vibration.

Figure 3. Steel-shell structure diagram of full-scale model.

3.2 Measurement points division

The full-scale model test was conducted using each compartment as a test unit, following the final setting of the self-compacting concrete. Variations were observed in the thermal neutron counting rate at the

measurement points. These may be attributed to the use of the same concrete batch but with different thicknesses of the top steel shell, various T-stiffeners, and welding studs on the bottom surface of the steel shell. These variations influenced the concrete content within the test scope. To mitigate the impact of these connectors on the test results, the model was divided into measurement lines, with measurement points deployed according to the arrangement of the T-stiffeners and welding studs.

Considering the standard compartment ($3.5 \text{ m} \times 3.0 \text{ m} \times 1.5 \text{ m}$) as an example; the T-stiffener spacing was 700 mm, and two rows of welding studs were laid between two T-stiffeners. Measurement lines were arranged along the direction of the T-stiffener with a width of 300 mm for the T-stiffener and 200 mm for the welding studs. This was based on a principle involving a 150 mm range on either side of the T-stiffener. Along these lines, the measurement points were placed at 300 mm intervals, following the same layout rules as that for the T-stiffener. This arrangement was also applied to the cross-partition lines at the measurement points. The layout of the measurement points on the top plane of the standard silo grid, along these measurement lines, is illustrated in Figure 4.

Figure 4. Layout plan of detecting line and point on the top of standard compartment.

3.3 Collecting data

Prior to data collection, it was necessary to clean the steel shell surface to remove any debris, including rust, welding slag, and slurry. This step ensured that the surface remained clean, smooth, and free from sand, loose soil, and stagnant water.

A planar model was built in the collection software based on the length, width, and layout of the measurement points; the two-coordinate system was the same, and the equipment was placed in the center of the measurement points of the probe flat, ready for measurement.

The computer was set to a single acquisition time step of 30 s. This setup enabled the activation of specific measurement point positions. By controlling the acquisition button, the thermal neutron counting rate was automatically collected. This process was repeated twice, and the average of these two readings was taken

as the final thermal neutron counting rate measurement value for each measurement point. After the acquisition, the equipment probe was moved to the following measurement point. This was repeated until all the measurement points in the compartment were completed. The above-mentioned three steps were repeated for each compartment.

3.4 Data processing and analysis

After completing point-by-point data collection for each bin, the next step was to process and analyze the collected data, which was also performed on a compartment, including the calculation of the baseline value of the thermal neutron counting rate and the normalization factor for the detection condition.

(1) Reference value of thermal neutron counting rate. The reference value of the thermal neutron counting rate is the value of the thermal neutron counting rate of the concrete in a certain structural (T-stiffeners, welded nail) condition without deflation, i.e., each measurement line in the compartment corresponds to a benchmark value. If there is no point on the line of measurement of deflation, the thermal neutron counting rate of all measurement points should be equal to or similar to the benchmark value (there is a certain degree of fluctuation in the value of the thermal neutron counting rate). Therefore, if there is no significant difference in the data along the measurement line, the average value will be used as the benchmark. However, if individual data points are notably lower than this average, it suggests a potential deflation at the corresponding measurement points. These points should be excluded from the data set before recalculating the average value. The base value of thermal neutron counting rate for neutron method detection under working conditions was calculated according to Equation (2).

$$\bar{n}_j = \frac{\sum_{i=1}^I n_{ij}}{I} \quad (2)$$

where, \bar{n}_j is the reference value of the thermal neutron counting rate for column j of the detection condition (counts per minute (CPM)), n_{ij} is the thermal neutron counting rate in row i and column j of the detection condition (CPM), i and $j = 1, 2, \dots, n$.

(2) Normalization coefficient. In on-site test conditions where the steel plate thickness matches that of the calibration conditions, the reference value for the thermal neutron counting rate in these on-site tests may be lower than that in the calibration settings, owing to the variations in the bottom structures of the steel shell. In this case, it is necessary to normalize the test data before it can be included in the calibration curve of this condition for calculating the void values. Normalization coefficient calculation is given by Equation (3).

$$k_j = \frac{n_0}{n_j} \quad (3)$$

where k_j is the normalization coefficient of the reference value in column j , and n_0 is the reference value for the thermal neutron counting rate of steel plates with the same thickness under the calibration conditions.

The thermal neutron counting rate after normalization of the measurement points can be obtained according to Equation (4).

$$n'_{ij} = k_j n_{ij} \quad (4)$$

where, n'_{ij} is the normalized thermal neutron count rate in row i and column j . This value is introduced in the calibration curve calculation to obtain the value of void height.

(3) Equivalent void height. The void of the calibration experimental design is a regular void defect body formed by continuously improving the steel plate in a state of complete adhesion between the steel plate and the concrete block. Therefore, the void value calculated using the curve is the average of the void values in the measurement points, and we refer to this average value as the equivalent void height. The equivalent void height can be calculated by substituting the normalized thermal neutron count rate into the calibration curve of the corresponding working condition in Section 2.3.

3.5 Radiation safety

The neutron sources used to produce three types of radiation, including alpha particles, gamma Rays (photons), and neutrons, The alpha particles are stopped by the source capsule. Only the gamma and neutron radiation can contribute to any occupational radiation exposure. Under normal conditions a full-time operator of the detection equipment will receive less than 1.5 mSv per year, which is lower than the annual dose limit specified in the "Basic Code for Protection against Ionizing Radiation and Safety of Radiation Sources" (GB18871-2002), taking advantage of all available means to limit radiation exposure is always recommended. The three methods of limiting exposure are: (1) Detection equipment has shielding built into the system which reduces the exposure. (2) Anyone working with or near radioactive materials is subject to the limits of occupational exposure and must complete a radiation safety training course. (3) Keep personnel outside the safety distance of 3~5m from the detection equipment when the detection equipment is working. (4) Keep the time spent by the operator around the radioactive source to a minimum and wear a thermoluminescence dosimeter to monitor the irradiated dose.

4 ANALYSIS OF TEST RESULTS

The consistency of the calculated deflation values with the actual concrete deflation was verified by opening the cover of the steel shell. In the foot-scale model, nine compartments in the bottom plate, three in the wall, and two in the top plate were chosen randomly for verification. In each compartment, six measurement points were selected, giving a total of 84 points. To access these points, covers were opened by cutting a small area of the steel shell at each point using carbon arc gas cutting. This method was employed to avoid damaging the interface between the cover and the bottom surface of the steel shell in contact with the concrete, thus ensuring that the concrete surface morphology remained unchanged after the covers were opened.

4.1 Measurement method for voids

To the top surface of the steel plate as a reference surface for the measurement of the number of defects, the plasticity of the rubber cement to fill the open cover parts so that it is filled with recessed concrete voids, and then a steel ruler to flatten the surface of the rubber cement, so that it is flush with the reference surface, take out the rubber cement, the use of the principle of overflowing method of obtaining the volume of the rubber cement Q , then the actual volume of the defects V can be calculated by Equation (5).

$$V = Q - l_l * l_w * H \quad (5)$$

where l_l is the cutting length of the steel shell at the opening measuring point, l_w is the cutting width of the steel shell at the opening measuring point, and H is the thickness of the steel shell at the opening measuring point.

Then, the relationship between the measured height h of the open lid deflation at the measurement points and the actual defect volume V is described by Equation (6).

$$\bar{h} = \frac{V}{l_l * l_w} \quad (6)$$

4.2 Verification results

The measured void results of 84 open-lid areas were compared with the detection results for validation. We have used the comparison of a typical compartment as an example for illustration.

As shown in Figure 7, #1, #5, and #6 are the open cover positions located on the T-stiffeners structure, #3 and #4 are located on the welded nail structure, and #2 is located on the side of the T-stiffeners leaning on the pouring hole. Among them, the #1 detection result

Figure 5. The results of neutron method.

Figure 6. Opening locations at site.

indicated the presence of 3.8 mm voids, whereas the open cover measurement showed 4.4 mm voids, which aligns closely with the detection results. Specifically, these voids are located on the left side of the T-stiffeners, with the right side appearing dense. For #2 and #3, the detection results indicated a dense structure and the open cover test revealed slight honeycomb formation, which are not classified as voids. Thus, these observations correspond with the results of the respective tests. Furthermore, #4 detection result is dense, and the measured void value of the open cover is 1.8 mm, which is slightly inconsistent with detection result. #5 detection result is dense, and the measured void value of the open cover is 1.8 mm, which is slightly inconsistent. The test for #5 revealed a 2.5 mm voiding, which precisely matches the measured hollowing value on the open cover. This consistency underscores the

Figure 7. Opening condition of steel case Nos. #1 to #6.

fact that the hollowing is predominantly concentrated on the left side of the T-stiffeners, with the right side exhibiting a denser structure. The #6 exhibits denseness accompanied by a minor honeycomb formation observed during the open-cover test. Notably, the honeycomb formation on the left half of the T-stiffeners appears slightly larger than that on the right half. Additionally, it is important to recognize that the upper right corner of the left half experiences open-cover damage, which should not be classified as a part of the void.

Upon verifying the test results of 84 open cover positions and comparing them to the measured void values of the open cover, it can be determined that the compliance rate for void height reaches 94.0% within an error range of ± 2 mm.

5 FORMAL IMMERSED TUBE APPLICATION

The results of the full-scale model cover opening verification test show that the method has met the

requirements of formal immersed tube void detection. Therefore, this method was used to quantitatively detect the void height of the suspected void parts screened on the formal pipe sections, and the quantitative detection results were used as the basis for judging whether the void parts needed to be opened and grouted. According to the requirements of the engineering design, grouting reinforcement is required when the equivalent void height of a single measuring point is greater than 5 mm, and when there are two or more adjacent measuring points with equivalent void heights greater than 3 mm across the T-stiffeners, grouting reinforcement is also required.

Using the neutron method, we have completed the detection of a total of 32 formal pipe sections and nearly 100,000 measurement points. Taking the last immersed tube E24 in the east as an example, 39 suspected void parts were screened out in the bottom plate, and 49 in the top plate. The neutron method was used to detect these 88 parts, a total of 2820 measurement points were detected, and the detection results did not find the parts that need grouting reinforcement, only 25 measurement points had a voiding value between 2.5 and 5.0mm, accounting for approximately 0.16 parts per ten thousand.

6 CONCLUSIONS AND RECOMMENDATIONS

- (1) Based on the theory of fast neutron slowing, the calibration test was carried out by constructing a regular de hollowing defective body. The relationship between the thermal neutron count rate and the de hollowing height of the steel-shell concrete was constructed using the numerical fitting method, which can reach 99% when a steel plate of 40 mm thickness was used, and thus yield a more satisfactory result.
- (2) By integrating the structural design of the steel shell, the intricate steel components located at the base of the shell can utilize the burial rule to systematically arrange the measurement lines for data classification. These lines are then matched with the calibrated thermal neutron count rate benchmark values under normalized working conditions. This approach enables the achievement of millimeter-level non-destructive quantitative detecting of voids at the steel-shell concrete interface, even within complex structural configurations.
- (3) The results of the blind open-cap validation test show that the equivalent height of evacuation detected by the neutron method quantitatively conforms well to the actual situation. The compliance rate of the height of evacuation is calculated to be 94.0% for a margin of error of ± 2 mm.
- (4) The neutron method has been successfully applied to the steel-shell concrete immersed tube tunnel project of the Shenzhen-Zhongshan Link,

completing the test of the critical parts of all 32 official tube sections. The test results not only ensure the quality of the concrete pouring but also serve as important guidelines for the improvement of the structure and the optimization of the construction process.

ABSTRACT: Deep cement mixed (DCM) pile composite foundation was widely used in the immersed tunnels of Shenzhen-Zhongshan Link. The submarine DCM pile composite foundation was characterized by a high replacement rate and large cushion thickness. While there is limited research on the load transfer mechanism and settlement characteristics of DCM pile composite foundation. Based on the field test results, this paper proposed an analytical method which could consider the gravel cushion, DCM pile composite foundation and fully weathered rock layer at the pile base as a co-acting system. Furthermore, the stress and deformation coordination on the contact surfaces between each part of the system was considered. The pile-soil stress ratio and composite foundation settlement calculation equations were derived by analyzing a typical unit body. Finally, the theoretical calculation results were compared with the field test results, and the rationality of the theoretical equations was verified. The proposed theoretical calculation method of submarine DCM pile composite foundation was a theoretical basis for the design of subsequent related projects.

Keywords: Immersed tunnel, Submarine DCM pile composite foundation, Gravel cushion, Load transfer mechanism, Settlement calculation

1 INTRODUCTION

Numerous tunneling projects are emerging with the growing demand for infrastructure construction in China. Currently, Ningbo Yongjiang Tunnel, Ningbo Changhong Tunnel, Shanghai Outer Ring Tunnel, Hong Kong-Zhuhai-Macao Bridge Immersed Tunnel and Shenzhen-Zhongshan Link Immersed Tunnel have been built and are under construction (Yan et al., 2022). The immersed tunnel foundations of the Shenzhen-Zhongshan Link Super Project were the first in China to use large-scale deep cement mixed piles (DCM piles). Previous studies have indicated that excessive settlement or differential settlement in immersed tunnels can affect operational safety (Grantz, 2001). Therefore, it is necessary to investigate the

accurate calculation method of composite foundation settlement.

A number of researches on composite foundation settlement calculations have been conducted. Alamgir et al. (1996) derived analytical equations for the calculation of pile stresses, lateral friction and settlement in composite foundations under flexible foundations. Subsequently, Yang (2000) introduced the concept of 'neutral point' and re-assumed the distribution of pile lateral friction. Lyu et al. (2010) improved the displacement mode proposed by Alamgir et al. (1996), and regarded the foundation, cushion, composite foundation and substratum as a co-acting system, and considered the stress and deformation coordination on the contact surfaces between each part of the system is considered. Smith (2005) established

*Corresponding author: yujianlin72@126.com

a simplified method for settlement calculation of rigid pile reinforced embankment according to the results of numerical analysis, while the calculation mode of pile-soil load sharing is not suitable for mixing pile composite foundation. Luo and Lu (2018) developed a non-uniformly varying pile lateral friction distribution model and derived the analytical equations for the settlement and pile-soil stress ratio of a rigid pile composite foundation. Based on the load transfer method, Yu et al. (2022) investigated the stress characteristics and settlement calculation method of concrete-cored cement-soil pile composite foundation by considering the influence of interface relative displacement on interface side friction.

At present, most of the investigations on composite foundations are based on land area conditions. However, many studies have neglected the settlement of the cushion (Alamgir et al., 1996, Yang, 2000, Lu et al., 2010) and rarely consider the coordination of stresses and deformations of the cushion, the composite foundation, and the substratum (Lu et al., 2010). Compared with the traditional land area conditions, the foundation treatment method of thick cushion and high replacement rate DCM pile was applied in the Shenzhen-Zhongshan Link. The results of the field load plate test indicated that the load transfer mechanism and settlement characteristics of composite foundations were influenced by the cushion thickness and replacement rate (Fu et al., 2021). In this case, the traditional methods for calculating the settlement were not applicable. With the development of cross-sea projects, submarine DCM pile composite foundations have been successfully used in the Busan Immersed Tunnel (Olsen et al., 2022) and the third runway of Hong Kong Airport. The immersed tunnel of the Shenzhen-Zhongshan Link is currently at a critical stage of construction. Therefore, systematic research on the load transfer mechanism and settlement calculation method of DCM pile composite foundation is needed.

Based on the results of field load plate tests, this paper considers the effect of thick cushion on the settlement characteristics and load transfer mechanism of composite foundations. Then, the gravel cushion, the composite foundation and the substratum are considered as a co-acting system. From the coupling relationship between the stress and deformation of the three at the interface, the load transfer law and settlement characteristics of the gravel cushion, pile and foundation soil are analyzed. Finally, the rationality of the settlement calculation formula proposed in this paper is verified by comparing the calculation results with the field measured data. The research results can provide reference for the design and construction of DCM pile composite foundation in future submarine immersed tunnels.

2 PROJECT OVERVIEW

The Shenzhen-Zhongshan Cross-Sea Link (referred to as the Shenzhen-Zhongshan Link) is a super cross-sea project that integrates bridges, islands, tunnels and

underwater interchange hubs. The Shenzhen-Zhongshan Link is about 30 km from the Humen Bridge in the north and 38 km from the Hong Kong-Zhuhai-Macao Bridge in the south. The total length of the tunnel is 6845 m, and the length of the immersed tube is 5035 m (Yan et al., 2022). The project overview of the Shenzhen-Zhongshan Link is shown in Figure 1.

Figure 1. Overview of Shenzhen-Zhongshan Link project.

The DCM method was applied to the immersed tunnel foundations of the Shenzhen-Zhongshan Link. The construction process for this method was as follows: (1) Calculate and set parameters in the DCM construction ship control system according to the design requirements; (2) The cement slurry was stirred and pumped to the front end of the drill bit by using a slurry preparation and transportation equipment; (3) The cement slurry was injected into the foundation soil that had been fully crushed by the drill bit, and a certain strength of cement soil pile was formed after mixing. Photographs of the DCM construction ship and on-site construction are shown in Figure 2.

DCM piles were arranged in the form of single piles. The diameter of the single pile was 1.3 m, the lapping was 0.3 m, four piles were in a cluster, and the equivalent diameter was about 2.3 m. The longitudinal spacing of single piles was 3 m. The horizontal spacing was categorized into 3 m, 4 m and 5 m depending on the magnitude of the upper loads. The comprehensive replacement rate was 41% to 47.4%. The layout of the DCM piles is shown in Figure 3.

(a) DCM construction ship (b) On-site construction photos

Figure 2. Photographs of the DCM construction ship and on-site construction.

Figure 3. Layout of DCM piles.

Field load plate tests were conducted to investigate the settlement deformation behavior of gravel cushion and DCM pile composite foundations. However, the mechanism of the settlement was not clear (Fu et al., 2021). Therefore, it needs to be further studied by theoretical methods.

3 CALCULATION MODEL AND BASIC ASSUMPTIONS

3.1 Derivation of calculation model

The width of the immersed tunnel foundations is large, with a maximum width of more than 55 m. In order to simplify the model, the concentric cylinder formed by a single pile and the soil within its influence range is taken as a typical unit body for analysis. The typical unit body is shown in Figure 4, where a and b are the equivalent radius of a single pile and the soil within its influence range, respectively.

Figure 4. Typical unit body.

It is assumed that the pile and its upper cushion are inner soil columns (radius a), and the soil between adjacent piles and the upper cushion portion above them are outer soil columns (radius b). The b can be obtained by pile arrangement and pile spacing (GB, 2012). The simplified model for the composite foundation of immersed tunnel is shown in Figure 5, where l_c is the thickness below the gravel cushion, and l_p is the thickness of the reinforced area.

Figure 5. Simplified calculation model.

3.2 Basic assumptions

The thickness of the gravel cushion is larger and the compression modulus is smaller. When analyzing the load transfer mechanism, the immersed tunnel foundation can be regarded as a flexible foundation. According to previous studies (Lu et al., 2010), the vertical displacement pattern of soil between adjacent piles can be assumed:

$$w_{si} = w_{pi} + f_{1i}(z)g(r) + f_{2i}(z) \quad (1)$$

$$g(r) = \frac{r}{a} - e^{B(\frac{r}{a}-1)} \quad (2)$$

Where, z is the depth of the calculated point from the gravel cushion; r is the horizontal distance from the calculation point to the center of the pile; w_{si} is the displacement of soil between adjacent piles, which is a function of r and z ; w_{pi} is the pile displacement, which is only a function of z ; $f_{1i}(z)$ and $f_{2i}(z)$ are all the undetermined functions with z as the independent variable; B is an undetermined constant; $i = c, s$, corresponding to the gravel cushion and reinforcement area, respectively.

Correspondingly, the ultimate lateral friction of the pile at i can be calculated by equation (3):

$$\tau_{sui} = \beta_i \sigma'_v = \beta_i \left(\sum_{j=1}^i \gamma'_j z_j + p_s \right) \quad (3)$$

Where, τ_{sui} is the ultimate lateral friction of the pile at i ; β_i is the coefficient of pile lateral friction at i ; σ'_v is the overlying effective stress at the calculated depth; γ'_j and z_j are the effective weights and thicknesses of the material above i ; p_s is the stress of the outer soil column at the gravel cushion.

The degree of pile lateral friction at i is defined as α_i , which can be calculated by equation (4):

$$\alpha_i = \tau_{sai} / \tau_{sui} \quad (4)$$

Where, τ_{sai} is the lateral friction of the pile at i . Based on the previous research (Randolph and Wroth, 1979, Evgin and Fakharian, 1997), Luo and Lu (2018) proposed the ideal elastic-plastic model δ_u . In this paper, the pile-soil interaction at the pile-soil interface adopts the model to determine the relationship between τ and δ . With δ_u as the boundary, in the elastic stage, $\alpha_i = 0 \sim 1$, while in the plastic stage, $\alpha_i = 1$. According to the system load transfer law, the distribution of δ and α_i along the depth is obtained, as shown in Figure 6.

By integrating δ at depths $l_c \sim l_0$ and $l_0 \sim l_p$, respectively, the relative pile-soil displacements at the pile top and pile bottom, Δ_a and Δ_b , respectively, can be obtained as follows:

Figure 6. Distribution of δ and α_i along depth.

$$\Delta_a = \frac{(3l_2 + l_3 - 4l_c)\delta_u}{4} \quad (5)$$

$$\Delta_b = \frac{(4l_p - l_2 - 3l_3)\delta_u}{4} \quad (6)$$

Where, $l_2 + l_3 = 2l_0$

4 DERIVATION OF ANALYTICAL SOLUTION FOR COMPOSITE FOUNDATION SETTLEMENT

4.1 Displacement mode

According to the previous study (Lu et al., 2010), the distribution function of pile lateral friction is $f_{1i}(z)$. To equalize the pile lateral friction of each segment at the interface, the stress coordination constant φ_i is introduced. φ_i satisfies the following relationship:

$$\varphi_c A_c = \varphi_s A_s \quad (7)$$

Where, $A_i = a\beta_i G_{si}^{-1}(1-B)^{-1}$; G_{si} is the shear stiffness of soil between adjacent piles at i .

Let $\varphi_s = 1$, then:

$$\varphi_c = A_s/A_c \quad (8)$$

Similarly, $f_{2i}(z)$ is the slip function at the pile soil interface, which can be obtained by integrating δ along the depth z .

4.2 Stress equilibrium equation of microelement

The cylinder with a thickness of dz is analyzed, and its stress distribution is shown in Figure 7.

From the vertical equilibrium equation of the inner soil column element, it can be obtained:

$$\frac{d\sigma_{pi}}{dz} = -\frac{2}{a}\tau_{sai} \quad (9)$$

Where, σ_{pi} is the vertical stress in the inner soil column at i .

According to the vertical equilibrium equation of the outer soil column element, it can be obtained:

$$\frac{d\sigma_{si}}{dz} = \frac{\tau_{si}}{r} + \frac{\partial\tau_{si}}{\partial r} \quad (10)$$

Where, σ_{si} is the vertical stress in the outer soil column at i .

Substituting equations (1) to (4) into equations (10) and taking two partial derivatives for w_{si} , it can be obtained:

$$\frac{d\sigma_{si}}{dz} = h(r)\varphi_i\alpha_i\beta_i\left(\sum_{j=1}^i\gamma'_j z_j + p\right) \quad (11)$$

Where, $h(r) = \frac{1}{1-B}\left[\frac{1}{r} - B\left(\frac{1}{r} + \frac{B}{a}\right)e^{B\left(\frac{r}{a}-1\right)}\right]$.

Figure 7. Stress analysis of typical unit bodies.

4.3 Stress equation for each section

Substitute equations (3) and (4) into equation (9). Then integrate equations (9) and (11) at each segment. The obtained stress equations for each segment are as follows:

(1) Gravel cushion segment, $z=0\sim l_1$

$$\sigma_{pc} = \frac{\varphi_c\beta_c}{3al_1}(2\gamma'_c z^3 + 3p_s z^2) + M_1 \quad (12)$$

$$\sigma_{sc} = -\frac{h(r)\varphi_c\beta_c}{6l_1}(2\gamma'_c z^3 + 3p_s z^2) + M_2 \quad (13)$$

(2) Gravel cushion segment, $z=l_1\sim l_c$

$$\sigma_{pc} = \frac{\varphi_c\beta_c}{a}(\gamma'_c z^2 + 2p_s z) + M_3 \quad (14)$$

$$\sigma_{sc} = -\frac{h(r)\varphi_c\beta_c}{2}(\gamma'_c z^2 + 2p_s z) + M_4 \quad (15)$$

(3) Reinforced area segment, $z=l_c\sim l_2$

$$\sigma_{ps} = \frac{\varphi_s\beta_s}{a}[\gamma'_s z^2 + 2(\gamma'_c l_c - \gamma'_s l_c + p_s)z] + M_5 \quad (16)$$

$$\sigma_{ss} = -\frac{h(r)\varphi_s\beta_s\gamma'_s z^2}{2} + M_6 - h(r)\varphi_s\beta_s z(\gamma'_c l_c - \gamma'_s l_c + p_s) \quad (17)$$

(4) Reinforced area segment, $z=l_2\sim l_3$

$$\begin{aligned}\sigma_{ps} &= \frac{\varphi_s \beta_s \gamma_s' z^2 (l_2 + l_3)}{a(l_3 - l_2)} + M_7 \\ &+ \frac{2\varphi_s \beta_s z (l_2 + l_3)}{a(l_3 - l_2)} (\gamma_c' l_c - \gamma_s' l_c + p_s) \\ &- \frac{\varphi_s \beta_s z^2}{3a(l_3 - l_2)} [4\gamma_s' z + 6(\gamma_c' l_c - \gamma_s' l_c + p_s)]\end{aligned}\quad (18)$$

$$\begin{aligned}\sigma_{ss} &= \frac{2\gamma_s' h(r) \varphi_s \beta_s z^3}{3(l_3 - l_2)} \\ &- \frac{h(r) \varphi_s \beta_s \gamma_s' z^2 (l_2 + l_3)}{2(l_3 - l_2)} + M_8 \\ &+ \frac{h(r) \varphi_s \beta_s z^2}{(l_3 - l_2)} (\gamma_c' l_c - \gamma_s' l_c + p_s) \\ &- \frac{h(r) \varphi_s \beta_s z (l_2 + l_3)}{(l_3 - l_2)} (\gamma_c' l_c - \gamma_s' l_c + p_s)\end{aligned}\quad (19)$$

(5) Reinforced area segment, $z=l_3\sim l_p$

$$\begin{aligned}\sigma_{ps} &= -\frac{\varphi_s \beta_s \gamma_s' z^2}{a} + M_9 \\ &- \frac{2\varphi_s \beta_s z}{a} (\gamma_c' l_c - \gamma_s' l_c + p_s)\end{aligned}\quad (20)$$

$$\begin{aligned}\sigma_{ss} &= \frac{h(r) \varphi_s \beta_s \gamma_s' z^2}{2} + M_{10} \\ &+ h(r) \varphi_s \beta_s z (\gamma_c' l_c - \gamma_s' l_c + p_s)\end{aligned}\quad (21)$$

Where, M_1 to M_{10} are integration constants, which can be solved based on the stress continuity condition of the inner and outer soil columns at each segment.

4.4 Settlement calculation of substratum

The determination of the additional stress at the top of the substratum is critical to its settlement calculation. Substituting $z=l_p$ into equations (20) and (21), the equations for pile bottom stress and soil stress between adjacent piles at the pile bottom plane are obtained, respectively:

$$\begin{aligned}\sigma_{ps}|_{z=l_p} &= -\frac{\varphi_s \beta_s \gamma_s' z^2}{a} + M_9 \\ &- \frac{2\varphi_s \beta_s l_p}{a} (\gamma_c' l_c - \gamma_s' l_c + p_s)\end{aligned}\quad (22)$$

$$\begin{aligned}\sigma_{ss}|_{z=l_p} &= \frac{h(r) \varphi_s \beta_s \gamma_s' z^2}{2} + M_{10} \\ &+ h(r) \varphi_s \beta_s l_p (\gamma_c' l_c - \gamma_s' l_c + p_s)\end{aligned}\quad (23)$$

According to equation (23), the average additional stress of soil between adjacent piles at the pile bottom plane can be obtained as follows:

$$\bar{\sigma}_{ss}|_{z=l_p} = \frac{b}{a} \frac{\sigma_{ss}|_{z=l_p} 2\pi r dr}{\pi(b^2 - a^2)}\quad (24)$$

According to equations (22) to (24), the additional stresses at the top of the substratum σ_r caused by the

pile stresses and the average stresses in the soil between the adjacent piles can be obtained as (Zhao et al., 2010):

$$\sigma_r = m\sigma_{ps}|_{z=l_p} + (1 - m)\bar{\sigma}_{ss}|_{z=l_p}\quad (25)$$

Where, m is the area replacement rate; $m = a^2/b^2$.

The compression amount of the substratum w_r is calculated by substituting σ_r into the layerwise summation method (GB, 2011), as follows:

$$w_r = \varphi_r \frac{\sigma_r}{E_r} (\bar{\alpha}_i z_i - \bar{\alpha}_{i-1} z_{i-1})\quad (26)$$

Where, φ_r is the empirical coefficient of settlement, which is taken as 0.3 in this paper; z_i and z_{i-1} are the depth of the substratum bottom and top, respectively; $\bar{\alpha}_i$ and $\bar{\alpha}_{i-1}$ are the average additional stress coefficients at the substratum bottom and top, respectively.

5 CALCULATION RESULTS VALIDATION ANALYSIS

5.1 Determination of solution conditions and calculation parameters

The previous literature (Lu et al., 2010, Luo and Lu, 2018) provided a detailed introduction to the solving process of the integral constant M_1 - M_{10} and positional parameters l_1 , l_2 , and l_3 . By substituting the integration constants and positional parameters into each stress and displacement equation, the stresses and settlements in each part of the system can be obtained. The pile-soil stress ratio n is determined by the following equation:

$$n = \frac{\sigma_p|_{z=l_c}}{\bar{\sigma}_s|_{z=l_c}}\quad (27)$$

$$\bar{\sigma}_s|_{z=l_c} = \frac{\int_a^b 2\pi r \sigma_{ss}|_{z=l_c} dr}{\pi(b^2 - a^2)}\quad (28)$$

Where, $\bar{\sigma}_s$ is the average vertical stress in the soil between adjacent piles at the plane of the pile top.

According to the previous in-situ test results (Chen et al., 2010), the height of the equal settlement surface of the gravel cushion is taken as the net pile spacing in this paper. The ultimate lateral friction degree coefficients of the piles in the gravel cushion and the soil are determined by the β -method (GB, 2011) and were 0.3 and 0.2, respectively. δ_{ui} is determined to be 0.15% by the statistical results of Luo and Lu (2018). Based on the field test results and inverse analysis (Fu et al., 2021), the compression modulus of the gravel cushion is 1.8 MPa under the first stage load and 10 MPa

under the subsequent load. Other calculation parameters are shown in Table 1. Note that the soil parameters between adjacent piles are taken as a weighted average of the thickness of each soil layer within the pile length range.

Table 1. Physical and mechanical parameters of materials.

Material name	γ_{sat} / (kN·m ⁻³)	h/m	$E_s/$ MPa	c'/kPa	$\phi'/^\circ$	ν
Gravel cushion	21.0	1.0	10.0	0.1	30.0	0.30
Reinforced area soil	18.4	18.0	5.4	7.9	18.5	0.38
Substratum	20.3	5.0	30.0	18.0	23.9	0.35
CM pile	22.0	18.0	160.0	500.0	30.0	0.25

5.2 Comparison of settlement calculation results

The comparison results of theoretical calculation and measured settlement are shown in Figure 8. As seen in Figure 8, the trend of the theoretical calculation and measured load-displacement curves was consistent, and the settlement values were close under each load. Under the first level load (62.8 kPa), the theoretically calculated and measured settlements were 71.2 mm and 64.9 mm, respectively, with a relative error of 9.7%. Under the second level load (112.2 kPa), the theoretically calculated and measured settlements were 91.4 mm and 84.4 mm, respectively, with a relative error of 8.3%. Under the third level load (161.6 kPa), the theoretically calculated and measured settlements were 104.1 mm and 96.0 mm, respectively, with a relative error of 8.4%. Under the fourth level load (211.1 kPa), the theoretically calculated and measured settlements were 116.4 mm and 107.7 mm, respectively, with a relative error of 8.1%. Overall, the difference between the theoretical calculation and the measured settlement was not large. The error was within 10%, and the calculation accuracy satisfied the engineering requirements. In addition, the relative error tended to

Figure 8. Comparison of settlement calculation results.

decrease as the load increased. Therefore, the settlement calculation method of DCM pile composite foundation proposed by this paper is reliable.

5.3 Comparison of pile-soil stress ratio calculation results

The comparison results of the measured and theoretical calculation of the pile-soil stress ratios are shown in Figure 9.

As seen in Figure 9, both theoretically calculated and measured pile-soil stress ratios increased with increasing

Figure 9. Comparison of pile-soil stress ratio calculation.

load. Under the first level of loading, the theoretically calculated and measured pile-soil stress ratios were 4.4 and 4.6, respectively, with a difference of 4.1%. At the last level of loading, the theoretically calculated and measured pile-soil stress ratios increased to 7.2 and 7.8, respectively, with a difference of 8.5%. The increase in the pile-soil stress ratio gradually decreased. This is because when the load increases, the pile is subjected to more load due to the adjustment of the cushion, resulting in an increase in the pile-soil stress ratio. However, when the load increased to a certain extent, the adjustment effect of the cushion would reach the limit (GB, 2011). In addition, the error between the theoretically calculated and measured pile-soil stress ratios was within 10%. The results of the theoretical calculations can be considered reliable.

6 CONCLUSION

- (1) Based on field load plate tests, the effect of thick cushion and high replacement rate on the load transfer mechanism and settlement characteristics of DCM pile composite foundations were analyzed. Each part co-action of the composite foundation system and the coupling relationship of stress and deformation at the system interfaces were considered. Finally, the analytical solution for the composite foundation settlement

of the immersed tunnel in the Shenzhen-Zhongshan Link was obtained.

- (2) The analytical solution could comprehensively reflect the characteristics of pile-soil interaction, load transfer law and settlement of each part in the composite foundation system with ultra-thick cushion and high replacement rate DCM piles of immersed tunnel. The calculation results of composite foundation settlement and pile-soil stress ratio were similar to the measured results, with relative errors within 10%.
- (3) Submarine immersed tunnel projects have the characteristics of harsh construction environment, large thickness of submarine DCM pile composite foundation cushion and high DCM pile replacement rate. Therefore, the settlement of the cushion and its influence on the deformation coordination of the composite foundation system should be considered in the settlement calculation. To make the calculation results more reliable, the compression modulus of the cushion should be smaller than the design value, and the effective weight as the material weight.

Next generation tunnel waterproofing

Yves Boissonnas*

Sika Services AG, Zurich, Switzerland

ABSTRACT: Sika has been developing a new generation of tunnel waterproofing utilizing sheet membranes, watertight concrete technology, and fully bonded basement waterproofing membranes. This waterproofing concept combines systems well established over the last 50 years with an optimized application. The technology using fully bonded membranes in tunnels was first developed in South Korea and successfully applied in many projects. The fully bonded system, which can also be seen as an improved watertight concrete in accordance with the most advanced tunnel waterproofing standards, offers a reduction of the CO₂ footprint compared to the regular waterproofing membrane by a factor of 2, and an increased reliability compared to the current system. The application is simplified, reducing the work steps but still using the same well-established technique and know-how. The new generation tunnel waterproofing fits the drained tunnels as well as the pressurized systems. It also replaces the waterbars and control sockets needed in the conventional compartment system.

Keywords: waterproofing, fully bonded tunnel membrane, tunnel lining concept

1 INTRODUCTION

Tunnel waterproofing has been a crucial aspect of tunnel construction for many centuries. Ensuring the protection of underground structures from water ingress is vital for their long-term stability and operational safety. The first traces of waterproofing in tunnels go back more than 4'000 years to the Euphrates Tunnel in the city of Babylon where a cut & cover tunnel was then plastered with asphalt. Bitumen only found its way in some cut & cover constructions but is not used anymore in modern tunneling. Over the years, various materials and techniques have been employed to waterproof tunnels and basements. For instance, in South Korea, where the development has led to the adaptation of the fully bonded membrane systems commonly used in basements, and the optimization of the installation process. In this article, we will delve into the worldwide history of tunnel waterproofing using sheet PVC, TPO (FPO) membranes and watertight concrete, explore South Korea's journey towards fully bonded systems, and explain the technique's advantages. Additionally, we will describe the installation process of this waterproofing membrane in a tunnel.

2 HISTORICAL PERSPECTIVES OF PVC, TPO (FPO) MEMBRANES, AND WATERTIGHT CONCRETE

Modern tunnel waterproofing has come a long way since its inception, with the earliest approaches

primarily relying on watertight mortars. Sika was one of the first supplier to develop watertight mortars in 1910. This watertight mortar technology was used 1918 in the old Gotthard railway tunnel opened in 1882, when dripping water had to be controlled to allow the first electrification of the tunnel. Then in the mid-20th century, watertight concrete was a major innovation in tunnel construction, effectively reducing water penetration. However, this method had limitations and was not entirely reliable in providing long-lasting protection against water infiltration. In fact, the constrains of the concrete in

Figure 1. Gei tunnel Switzerland opened in 1967.

*Corresponding author: boissonnas.yves@ch.sika.com

contact with the rock did not allow a concentration of the shrinkage movement in the watertight joints. This leads to cracks within the concrete blocks in-between the dilatation-joints and therefore to water infiltrations.

In the 1970s, the introduction of sheet polyvinyl chloride (PVC) membranes revolutionized tunnel waterproofing practices. The Sika (Sarnafil) membranes were the first to be installed in a tunnel in 1967 to waterproof the Gei Tunnel in Switzerland. PVC membranes offered enhanced impermeability, flexibility, and ease of installation compared to watertight concrete. The flexibility of PVC allowed its adaptation to irregular surfaces and accommodate movements in the tunnel structure, eliminating the risk of cracks leading to leaks.

In the following decades, thermoplastic polyolefin (TPO) membranes emerged as an alternative to PVC. Both PVC and TPO (FPO) membranes contributed significantly to improving waterproofing performance, becoming widely used in tunnel projects around the globe.

These membranes are commonly used in different systems. Firstly, classic drained umbrella waterproofing protecting structure and operation against percolating water and the compartment system widely used in pressurized tunnels. In this system compartments between the membrane and the concrete lining are created by welding waterbars on the membrane to reduce eventual water migration and allow targeted repair injections. Finally, an active control system composed of two membrane layers welded together in compartments and offering the possibility to control the watertightness of the systems by applying a vacuum in the compartment during the construction phase. These compartments can be injected with raisins in case of later water ingress.

3 REASONS FOR TUNNEL WATERPROOFING

There are mainly three reasons to waterproof a tunnel. The most common one is to protect the service from humidity and water. The impact of water on operation can be very diverse like water harming the installations, ice endangering the service, humidity inducing electrical wastage by creeping current and many more. In case of aggressive groundwater, a waterproofing is needed to protect the concrete structure and reinforcement from corrosion. Finally, in some tunnels a waterproofing is needed to prevent any influence of the excavation on the surrounding hydrogeology. Where per example the drainage of the surrounding groundwater leads to settlement at the surface or to protect the phreatic water of tunnel wastewater seeping in the ground.

The waterproofing strategy must meet the needs by installing a pressurized, drained, full round or umbrella waterproofing system. The pressurized system prevents any waterflow in or out of the tunnel

and the full water pressure acts on the tunnel lining. A pressurized tunnel waterproofing is common in urban soft ground. This is the trickiest waterproofing concept as water will find and penetrate any defect. Measures must be foreseen to seal or contain any leaks. Drained systems allow the protection of the structure and operation without the full water pressure acting on the tunnel lining. The water inflow can also be reduced by injecting the ground around the excavation changing its permeability.

4 RISK CONSIDERATION ON THE CHOICE OF WATERPROOFING STRATEGY

The waterproofing strategy should be based on a risk management approach. Water inflow and water damages have a huge impact on a tunnel lifecycle cost and the risk can be reduced by installing an adequate waterproofing system. But no waterproofing layer will be 100% failure free. There can be problems with the materials, the handling, the installation, or the design details. Due to the large size of the surface to be waterproofed in a tunnel, even low remaining risks still have a huge impact on the project. If this remaining risk cannot be accepted and controlled, then mitigation measures and/or limitations of the impact of these leakages on the structure need to be planned.

By installing several lines of defense, the risk can be reduced to an acceptable level. For example, compartmentalization into multiple waterproofing sectors can be treated separately by injections to limit water migration and repair any failure. This is a widely used method to reduce the risk. When a punctured membrane is detected, the compartment is injected with resins and the waterproofing layer restored. As these injection systems can be harmed during concreting or due to challenging application, further measures like double membrane layers are recommended, when a fully dry tunnel is mandatory.

Another approach is to reduce the impact of a risk to the minimum. By using fully bonded systems preventing any water migration between membrane and concrete inner lining, the impact of a failure in the waterproofing layer can be reduced to a very localized spot. In case the lining concrete is not watertight at the same and unique spot as the punctured membrane, then a targeted repair by water-tightening the lining with common concrete injection will lead to an elimination of the risk with a high chance of success.

The same risk approach is needed in TBM tunnels with single shell segmental lining. The huge length of installed gaskets will inevitably lead to localized failures and measures need to be planned. Furthermore, the concrete of the segments is directly exposed to any aggressive groundwater reducing the durability of the lining. Some major owners therefore do not accept single shell segmental linings in critical tunnels due to this remaining risk and the challenging mitigation measures.

Figure 2. Fully bonded membrane ready for concrete application.

5 DURABILITY

Nowadays owners require a low impact on the operation by maintenance work. A common request is limited maintenance guaranty on the tunnel lining in the first 100 years. Therefore, the waterproofing needs to withstand these minimum 100 years, offering a full protection of the tunnel structure and operation.

The client on the New Swiss Alp Transversals (NEAT) decided in the late 20th century to set up an expert group to clearly define objective requirements and tests to replicate the 100 years durability of waterproofing membranes in a tunnel. Since the aging process in the PVC or TPO (FPO) membrane is a chemical reaction and the higher the temperature, the faster a given chemical reaction happens, accelerated aging tests were defined. Membranes are put in a hot aggressive water bath for long periods up to one year and the change on membrane properties, like elongation at break, are measured. The reduction on characteristics can then be extrapolated to determine when the end-of-life level will be reached. The goal is for the membrane to fulfil its waterproofing duties throughout the full life cycle coping with any stresses and movements that can occur on the system. These standardized tests were compiled in major tunnel waterproofing standards like the Austrian ÖBV. So far, only the high-quality PVC and TPO (FPO) membranes fulfil the 100+ years durability tests. Other systems may withstand the aging degradation and prevent any water inflow on the long term, but as long as the aging behavior cannot be proven based on objective standardized tests, a risk remains.

Fact is, that the most widespread reasons for refurbishment and repair of tunnels under operation are water induced damages.

6 FULLY BONDED WATERPROOFING MEMBRANES

The turn of the century witnessed the introduction of a revolutionary technique for waterproofing - the fully bonded waterproofing membrane. This membrane is a multi-layered composite sheet with a carrier layer, and a bonding layer.

Figure 3. Fully bonded waterproofing membrane.

The (mechanical and chemical) bonding layer provides excellent adhesion to the concrete, creating a continuous waterproof seal. The bond occurs when the fresh concrete is poured against the bonding layer creating a strong connection when hardened. Additionally, the carrier layer provides mechanical protection to the bonding layer, enhancing the system's durability and robustness. The carrier layer consists of a fully watertight TPO (FPO) membrane with a proven durability.

Figure 4. Strong bond between membrane and concrete.

This fully bonded system overcomes the limitations of the earlier sheet membrane technique. It prevents water from migrating between the membrane and the tunnel concrete lining. The

EN standards require a bond resisting to 7 bars water pressure to call it a fully bonded membrane. In practice, the effective bond is higher than the required 7 bars.

The system preventing water migration allows a precise location of any damage in the membrane leading to water leaks through the concrete lining. The bond also offers superior resistance of the membrane to ground movement and mechanical impacts, thereby ensuring the longevity of the tunnel structure.

Figure 5. Crack bridging test.

The fully bonded membranes show high flexibility (bi-axial) and excellent crack-bridging capabilities due to the unique combination of high quality membrane with high elasticity and strong bonding resistance.

Typically, fully bonded membranes are used in basement waterproofing. The thickness of the carrier layer varies between 0.8 mm and 1.2 mm. Sika developed fully bonded membrane with up to 2.0 mm carrier layer designed for underground constructions with higher water pressure. The membrane can be welded like the loose laid membrane without a bonding layer. The fully bonded technology saves the need of compartment systems, the waterbars and the control sockets. The first tunnels using this technology are in South Korea. In South Korea typically a 1.0 mm thick carrier layer is used. A first project using the 2.0 mm carrier layer is the Riedberg Tunnel located in Switzerland.

7 EVOLUTION IN SOUTH KOREA

The evolution of tunnel waterproofing in South Korea coincides with its rapid industrialization and infrastructure development. By the 1980s, as South Korea began constructing numerous underground facilities and tunnels, waterproofing became a critical issue.

Early efforts involved conventional waterproofing methods such as the use of watertight concrete and a sheet membrane. However, these techniques had limitations. For instance, the watertight concrete approach did not entirely prevent water leakage in

tunnels, and the sheet membrane method required extensive maintenance due to membrane damage from various construction activities.

By 2015, to overcome these challenges, South Korea started to explore innovative waterproofing solutions and worked towards developing more effective waterproofing systems. This pursuit of excellence led to the introduction of fully bonded systems in tunnel waterproofing. Till today about 4 million m² fully bonded tunnel waterproofing membranes were successfully installed in South Korea.

Figure 6. SikaProof[®]-110.

The fixation of the membrane to the primary rock support was optimized to reduce the work steps and increase ease of application. The membrane including the functional layer can still be hot air welded as in the conventional loose laid membrane system. The quality weld prevents concrete from flowing through poor connections between the different membrane strips when the fresh concrete pushes the membrane into uneven bumps. The fully bonded system addresses issues that plagued older methods, such as the formation of water pathways between sheet membrane and inner lining concrete surface. The blockage of water migration facilitates the localization and repair of leaks as wet spots or dripping cracks coincide with punctured membranes and can easily be fixed with localized concrete injections. Therefore, the system is less sensitive to application quality issues.

The membrane thickness can be reduced to 1.0 mm in comparison to the classic loose laid membrane system, as the membrane works in combination with the inner lining concrete and is not exposed to the same stresses as conventional loose laid membranes. The use of high quality long lasting TPO (FPO) membrane layer allows very long life expectancy of more than 100 years proven by the standardized durability tests.

The system was successfully applied in several South Korean projects among others the Milyang - Ulsan expressway (172'000 m² in 2020), the Kangjin - Kwangju expressway (155'000 m² in 2022) or the Ansong - Sunnam expressway (165'000 m² in 2022).

Figure 7. Tunnel in South Korea with SikaProof®-110.

9 SYSTEM DESCRIPTION

8 POSITIONING IN RELATION TO TUNNEL WATERPROOFING STANDARDS

Most countries, with extensive tunnel projects, have national standards guiding designers regarding tunnel waterproofing. Clients with large tunnel inventory often have their own additional guidance. As an example, in Switzerland the SIA-272 standard regulates the waterproofing and drainage of underground constructions. In addition, the Swiss Federal Railway as well as the national road authorities specify in addition that no single shell segmental lining is acceptable. Only double shell lining including a waterproofing layer and an inner lining are allowed based on their bad experiences on segmental lining watertightness.

Unfortunately, most standards are outdated and reviewing national standards is slow and time consuming. It is therefore important to clearly position new systems in relation to the existing standards.

The fully bonded membrane can be seen as an “upgraded” watertight concrete. Due to the interaction of the membrane and the concrete, the membrane thickness can be diminished, at the same time the crack requirements for the concrete can be loosened and steel content reduced.

The requirements to prove the durability of the carrier waterproofing layer are defined in most tunnel waterproofing standard with the same tests as for the loose laid membranes. Therefore, the fully bonded membrane complies with the usual requirements in the tunnel waterproofing standards/guidelines, even if the system is not yet described in the latest.

The fully bonded membrane also protects the concrete effectively against aggressive ground water, a constraint that was heavily limiting the use of watertight concrete in underground constructions.

 - a. EVA-based waterproofing layer
 - b. Functional layer for full bond
 - c. Geotextile spot-fixed to the waterproofing-layer
 - d. Geotextile strip
5. Inner lining concrete

The waterproofing layer is a fully and permanently bonded, flexible sheet membrane waterproofing system. It consists of an elastic polyolefin (FPO) membrane containing a unique hybrid bonding layer on polyolefin (PO) basis, which bonds permanently with the fresh concrete structure. The membrane is a pre-applied waterproofing system that is designed to be installed before the steel reinforcement (if needed) is fixed and the lining concrete is poured. The concrete is cast directly against the membrane system, where the fresh concrete is embedded completely into the hybrid bonding layer and creates a permanent dual bond both mechanically and adhesively.

The dual bond prevents any lateral water migration between the membrane system and the hardened

concrete. The membrane sheets can be hot air welded together to prevent any fresh concrete flowing behind the membrane between the seams. This is possible in conventional tunnel excavation when the membrane is pushed into uneven bumps when pouring the fresh concrete into the vault formwork.

The geotextile on the backside of the membrane is punctually fixed, allowing the full elasticity of the membrane. Conventional waterproofing membranes with a fully laminated geotextile on their back are losing their elasticity due to the geotextile “reinforcement”. When the fully laminated membrane is exposed to high stress, the geotextile ruptures locally leading to a local over-elongation of the membrane, as all movements occur at this point.

The punctually fixed geotextile on the back of the SikaProof®-110 fully bonded membrane allows simplified fixing and acts as a cushion layer to protect the membrane from rough substrates. The loose geotextile strips can directly be nailed to the substrate holding the membrane in place.

10 WATERPROOFING CONCEPTS

There are two different waterproofing concepts. One is a drained system preventing any water pressure on the tunnel lining and the other is the pressurized system with the full water pressure acting on the lining.

Figure 9. Drained system.

In the drained system the membrane is installed only in the vault like an umbrella. Drainage pipes are placed in the arch-foots and the membrane stretched down to the drainage. A drainage layer needs to be installed outside the membrane to drain the water down to the drainage pipes. The fully bonded membrane will guarantee a water tightness comparable to class “fully dry” and there is no risk of any water migration along the tunnel inside the waterproofing layer.

The other concept is a pressurized watertight construction. The water does not get drained by the tunnel and the full water head acts on the concrete lining. The membrane is installed fully around the circumference of the tunnel.

Figure 10. Pressurized system.

Due to the water pressure the system is exposed to far more stresses than the drained system. Depending on the hydrostatic water pressure, thicker membranes than used in the drained system are recommended. Although due to the system being fully bond, the membrane thickness remains much lower than the loose laid system. A punctured membrane will have the full water pressure acting locally on the concrete lining. In case of crack or poor concrete quality the water will cause a damp to wettish surface. But this water ingress can be easily fixed by localized concrete water-tightening injections.

In shallow pressurized tunnels a 1.0 mm thick fully bonded membrane is installed on the full circumference and welded together. Commonly the invert is installed in a first step and the vault completed in a second step.

Figure 11. Cross passages in TBM tunnels.

Another typical pressurized waterproofing is used in cross passages between two TBM excavated tunnels with a single shell segmental lining. Here

a fully bonded membrane can be connected directly to the segments using a tape. The 2.0 mm membrane is recommended when facing higher water pressure and due to a better weldability to the tape. The Sikaplan® WT Tape-200 is fixed to the segments with epoxy glue. The fully bonded membrane is then hot air welded to the tape offering a watertight connection between the segments and the membrane. This offers a high level of watertightness at low cost.

11 THE INSTALLATION PROCESS

The speed of waterproofing installation can easily be adapted to the general speed of the tunnel lining installation and is never the critical path.

With the geotextile punctually-fixed to the waterproofing SikaProof®-110 membrane, the application is simplified. At the same time, thanks to its spot-fixing, the geotextile does not act as a reinforcement for the membrane and limiting its elasticity. The elongation at break of the membrane remains unchanged.

Figure 12. Scaffolding for membrane installation.

The installation procedure of the waterproofing system depends on the site conditions. As for all tunnels waterproofing, the installation should be performed by skilled and experienced waterproofing contractors, specifically trained in membrane welding and installation. The membrane is delivered to site in 2.0 to 2.1 meter wide rolls with a length adapted to the construction geometry in order to reduce waist. The 2.0 to 2.1 meters are a common size in waterproofing as this allows an appropriate handling in the tunnel and limits the weight of the rolls.

For the installation, only a nailer, hot air welding equipment and a scaffolding adapted to the size of the tunnel are needed.

The substrate needs to comply with the supplier's requirements for waterproofing membrane installation. The roughness of the primary lining shall be

smooth and free of harmful objects like steel fibers and anchor heads. This is to prevent a puncture of the membrane when the membrane is pressed by the fresh concrete against the rock support. A layer of spray concrete without steel fibers and smaller aggregate size is used to reduce the roughness. An evenness of 1:10 (depth D to length L) is needed on the substrate surface. This is to prevent an overextension of the membrane when pushed into bumps by the fresh concrete.

Figure 13. Geometrical substrate requirements.

Due to the fully bonded properties of the membrane the watertightness is less at risk than with loose membranes as the water inflow at a leakage will mostly be blocked by the concrete.

Figure 14. Fixation of the membrane using the geotextile.

The membrane is unrolled, and the attached geotextile fixed with a nail gun to the substrate. First the middle strip (4b, Figure 8) is attached followed by the edges of the geotextile (4c, Figure 8). The next membrane strip can then be fixed parallel with a slide overlap of approximately 10 cm.

Then the two membrane sheets are hot air welded together. Best is the use of an automatic double seam welding equipment. These machines produce two parallel weld seams leaving an air channel in the middle.

This air channel can then be pumped with air and the weld seams checked by controlling the air pressure kept in the channel. Fully bonded membranes can tolerate some insufficient welding due to the restrain of water migration. A quality welding offers

Figure 15. Hot air welding of the membrane.

an additional safety in the system. TPO (FPO) is a thermoplastic, so it can be hot air welded. Combined with the concrete lining the membrane creates a monolithic layer that protects the whole tunnel from water inflow. The welding can also be done manually. The single weld is tested using a screwdriver to control the continuity of the seam.

Figure 16. Test of welding seams.

The tunnel lining formwork can be installed once the waterproofing membrane is completed. The formwork is filled with the fresh concrete and the concrete compacted. Immediately with the pouring of the concrete the functional (bonding) layer starts to interact with the concrete and the bonding takes place. After the concrete has cured the full bonding strength is reached. The gap filling in the crown is recommended after 28 days to prevent any debonding due to injection infiltrating. The gap filling needs to be done with shrinkage compensated mortar to prevent any shrinkage cracks between concrete and mortar.

12 REDUCED INSTALLATION STEPS

This next generation waterproofing for tunnels reduces the work steps for installation from 4 steps to only one step. The installation of the conventional systems needs several work steps. For a pressurized compartment system, in a first step, a cushion layer is installed with the fixation disc, then the membrane is spot welded to the discs and the membrane strips welded together. Finally, waterbars and injection hoses/ports are installed and the waterbars in the crown injected to guarantee the full bedding. Later, any compartment showing water inflow due to a leakage, needs to be injected with raisins.

In drained tunnels with an umbrella waterproofing the drainage layer is attached using the fixation discs. In a second step the membrane is spot welded to the discs and terminated towards the drainage system in the side walls. In a last step the membrane strips are welded, and a protection layer installed where needed.

With the new buildup, the membrane can be installed in one step using the geotextile for fixation. This is a massive reduction of work steps and costs compared to the actual widely used concepts.

13 CONCLUSION

Over the past 60 years, tunnel waterproofing has witnessed significant evolution worldwide. The transition from watertight concrete to sheet PVC and TPO (FPO) membranes marked a substantial improvement in tunnel waterproofing practices. In the last decade only, minor evolutions managed to implement themselves. South Korea's commitment to innovation led to the development and adoption of fully bonded systems, which provide a seamless and reliable barrier against water ingress.

Fully bonded systems offer numerous advantages, including superior watertightness, longevity, and resistance to movement. Their installation process was optimized to reduce the work steps and improve productivity.

The major improvements this new tunnel waterproofing membrane SikaProof[®]-110 offers are:

- Fully-bonded preventing any water migration
- Weldability of the membrane
- Optimized timesaving fixation

As tunnel construction continues to evolve, it is likely that further innovations will emerge, making tunnel waterproofing even more efficient and reliable, ensuring the safety and sustainability of underground infrastructures for generations to come.

Mitigation of the sources of infiltration in the segment sealing gasket

Gustavo Bomben*

FAMA, Zoppola di Pordenone, Italy

ABSTRACT: Tunnel watertightness must be ensured during the construction and operation phases to prevent water infiltration, to minimize maintenance and repair costs, keep operational safety and protect vehicles in transit and mechanical and electrical equipment which are in the tunnel.

In the segmental tunnel lining, watertightness is ensured by each component of the support system, that is the precast concrete tunnel segments with their embedded inserts and gaskets positioned around their sides.

They are different types of infiltrations: Infiltration through cracks in concrete; Infiltration in the interface with embedded inserts; Infiltration of the sealing gasket.

In this paper, we examine the innovative measures introduced to minimize the causes that generate water infiltration in the gasket through the study and experimentation of the measures that reduce the breakage of the segments caused by the gasket and the gasket destabilization during the launch of the segment.

Keywords: Tunnelling, TBM, sealing, connection, infiltration

1 INTRODUCTION

In segmental tunnel lining, watertightness is ensured by each components of the support system, that is the precast concrete tunnel segments with their embedded inserts and gaskets.

There may be infiltrations through cracks in the concrete, in the interface with inserts and in the sealing gasket. In this paper, we are examining the latter.

2 GASKET

It is well known that the performance of the gasket, even if of excellent workmanship, can be endangered during the entire construction cycle. However, it is in particular compromised during the installation of the segment.

During the installation, damages of segment edges and segment corners and the expulsion of the gasket may occur; these are the primary causes of infiltration. Therefore, the aim is to provide gaskets difficult to be removed from their position and with low compression loads. In this condition, repair is not needed.

To reach this aim, gasket geometry engineering has been required, that is made possible thanks to experimental virtualization which allows the assessment of the effects of hydrostatic pressure and to consider the effects on concrete.

The other fundamental element is the size of the gasket.

it must also be acknowledged that a better installation of the segments and rings has been achieved thanks to the widespread use of the dowels instead of the bolts.

Moreover, with the use of 3D modelling of the segments and formwork and the numerical control machining, a greater accuracy of the shapes has been achieved and therefore the coupling of the surfaces between the segments and the rings reaches a much more precise and important result.

Before these innovations, it was quite mandatory to use large size gaskets to compensate for the significant misalignments and openings of the joints.

In this new context, excellent results have been reached with the gasket of medium size, gasket of third generation, 29x14, even in tunnels with diameters exceeding 11 meters and with working pressure exceeding 10 bar.

A further element is represented by the choice of the type of gasket installation to the segment which may be achieved:

- either gluing the gasket;
- or incorporating the gasket into the concrete segment.

2.1 *Glued gasket*

Gluing is a complex process that is strongly influenced by several elements: environmental conditions, the skill and the consistency of the operator.

*Corresponding author: Gustavo.bomben@famaspa.it

In this case, health and environmental aspects should not be underestimated.

Gluing is exposed to the risk of widespread detachments, misalignments and displacement of the gasket.

All these phenomena significantly affect gasket performance.

2.2 Anchored gasket

The anchored gasket is an innovation of recent years and it has replaced the glued solution as its installation is more solid. It also offers several advantages regarding construction, environment and performance.

The anchored gasket, which has brought considerable benefits, has however evidenced critical issues that must be correctly managed to avoid failures.

The anchored gasket, because of its geometry, increases the application arm of the forces generated by its compression, thus augmenting the loads on the concrete.

Therefore, there are:

- increased risk of broken edges;
- increased risk of broken corners.

In particular, there can be hidden breakages, non-visible but that may occur over time. When they are at intrados, they may have important consequences.

Other damages are due to the manufacturing process.

They are classified as follows:

- Tearing;
- Sinking;
- Edge breaking during handling.

Obviously, for each of these aspects repair techniques have been studied and validated.

The effects of the anchored gasket on the concrete require attention to specific aspects that can be summarized as follows:

1. The position from the segment edge which may cause breakage;
2. The filling rate which represents the ratio between the compressible section of the gasket and the groove in which it is contained at full compression.

We must keep always in mind that rubber is flexible but not compressible.

STUVA suggests that the filling rate should not exceed 95% but it also suggests that, under special conditions, it can reach 100%.

These indications are NOT confirmed by ITA which limits the filling rate to 90%.

My personal experience suggests that we should not exceed, when possible, 80%; this is due to the greater loads that the gasket applied to the concrete.

The third point is:

3. The groove of the anchored gasket which is formed by the gasket, whose construction tolerances directly affect its size with significant effects on its hydraulic performance, and on the risk of segment breaking. This risk is reduced when glued gaskets are used because the groove is realized in the formwork that has lower tolerances.

Table 1. Filling rate.

The filling rate is assessed on the gasket section and its groove section, but this represents only one of the aspects. As a matter of fact, the table summarizes several aspects and assessed the filling rate of both the gasket and the linear section in the T-joint and the positive effects of the innovative SOFT CORNER that brings the profile as close as possible to the top and uses sophisticated injection techniques to reduce the infiltration of hollow parts of the profile. It also takes into account the deterioration effects due to the expulsion of the corner that occurs during the installation. At last, it considers the load containment on T-joint due to the position of the variable-geometry gasket that we will discuss later.

The table assesses the use of both glued and anchored gaskets and traditional and SOFT CORNERS, with filling rate ranging from 78% to 95%.

The assessment of STUVA considers only the filling rate represented in the fifth column but not all the other effects which are very important:

- position of the anchored feet in particular in large gaskets and with high compressive force; in this case, asymmetric solutions may represent a mitigation;
- The asymmetric position of the gasket in the joint which protects it from the compression of the TBM jacks.

2.3 T-joint

The T-joint is analyzed according to:

- Compressive force;
- Spalling test.

2.3.1 The compressive force

STUVA has established a procedure for the definition of these loads, using a special equipment.

The test involves compressing the longitudinal joint, represented by the two opposing angular structures, to a gap of 2mm. Next, the gasket linear frame, which represents the circumferential joint, is compressed against the two angular structures up to a gap of 0mm.

Figure 1. Load and displacement test.

The test detects the load and the displacement.

The compression test of the T-joint, as indicated, involves the closure of the longitudinal joint at gap 2mm. However, this does not represent the real

conditions when the longitudinal joints are often closed at gap 0mm.

A different and innovative test establishes a more burdensome procedure with the closure at gap 0mm; moreover, it simulates the expulsion of the gasket in the corner and it measure the consequent loads.

We are now analyzing the variation of the load of the T-joint using both methods.

The test is performed on gaskets of medium size UG018A.

The maximum load measured with STUVA method is 20kN, while using the other method, the load rises to 32kN, an increase of 60%.

Let's now analyze the results with the simulation of the angle expulsion.

During the launch of the segment, in fact, the corners of the gaskets are very often expelled or wrinkled. This creates a concentration of rubber.

The result of this condition is shown in the following graph, where there are also the results of the previous tests.

Table 2. Load deflection test.

It can be observed that the wrinkling of the corner increases the load up to 52kN compared to the 20kN assessed with STUVA method.

In order to reduce the loads generated by the T-joint, an innovative special corner, SOFT. Here follows a comparison, achieved according to STUVA method, of this corner with gasket corners of the same size on the market.

Table 3. Compression load comparison.

The SOFT CORNERS range from 18kN to 28kN while the corners of similar gaskets on the market have loads which exceed 120kN. It is well known that the higher is the load, the higher is the risk of breaking and therefore of infiltration.

2.3.2 Spalling test

The spalling test is performed on concrete blocks having dimensions as illustrated in the following figure, with a characteristic and a determined condition: the blocks have T-joint corners at 90° and, as it occurs with the compression test, the longitudinal joint is closed to a gap of 2mm while the circumferential joint is closed at gap 0mm.

The test is conducted to verify that the edge does not break and the corner does not break.

Figure 2. Spalling test.

The influence of the geometry of the segment corner should be examined.

The mechanical resistance of the acute corners is lower than the mechanical resistance of obtuse and right corners. The experience confirms this thesis. In the following graph, relief of the number of broken corners gives data in tunnel, in particular regarding the breaking of the angles.

96% of broken corners are acute and only 4% are obtuse. The broken corners were actually distributed equally between those facing the direction of excavation and those opposing it.

The test was performed with concrete blocks with right and obtuse corners, according to STUVA, and the corners angles and obtuse, according to the project. The test with concrete blocks with right corner is performed according to the STUVA method. The test performed on the concrete blocks with acute and obtuse corners provides a first step that closes the longitudinal and circumferential joint to gap 0mm. In the second test, to consider the load increases due to the gasket expulsion e al wrinkling of the gasket corner, situation that really occurs, it generates a hyper-closure of the circumferential joint to a gap of -2mm to value the safety margins.

The photos show a spalling test performed according to STUVA and according to the innovative methods. It shows that there is no breaking of the corners and there is no breaking of the edges. It

Table 4. Broken corner.

Figure 3. STUVA spalling test.

should be reiterated that the test performed according to the innovative method is much more burdensome than the one performed according to the STUVA method.

3 INNOVATION

Considering the importance of the phenomena concerning the T-joint, the objective is to study solutions that can contribute to reducing the negative effects.

Figure 4. Innovative spalling test.

To reach this aim, we must first assess the filling rate of the gasket and T-joint. STUVA, as already underlined, describes limits of the filling rate that only concerns the linear part of the gasket and does not deal with T-joint. This approach does not create particular problems with glued gaskets while it becomes decisive for anchored gaskets.

In order to assess the filling rate of the T-joint, the profile section is not taken into account, that is a bidimensional dimension, but the volume, that is a tridimensional value, of the T-joint grooves and the volumes of the gasket linear section and the two angular structures, in open and closed joint conditions, are considered.

When examining the volume of the angular structures of the gaskets, both the compact part of the injected corner and the infiltration of the void parts adjacent to the molded corner were taken into account.

The results of this analysis are shown in the table that compares the filling rate of glued gaskets of different sections with the filling rate of similar anchored gaskets (see Table 1).

4 CONCLUSIONS

The glued gaskets have a filling rate in the T-joint ranging from 89% to 116%.

Similar anchored gaskets with traditional corners have a filling rate ranging from 99% to 141%.

Thanks to the SOFT CORNER, this value passes to 91%-125%.

This highlights the positive effect of the SOFT CORNER compared to the traditional one but the levels of the glued solution are not reached.

Experience has shown that the T-joint with a low filling rate does not create any particular problems as the exceeding rubber is absorbed by longitudinal displacements of the gaskets surrounding the same joint.

On the other hand, when this rate exceeds a determined limit, this contiguous displacement does not occur sufficiently and therefore there is a volume of rubber greater than the volume of the groove that causes the rupture of the system.

In order to minimize the phenomenon above-described, a particular gasket geometry in the T-joint must be studied in order to contain the filling rate within limits more tolerable by the system. This has been achieved by a gradual retreat of the gasket closer to the corner. This approach has given very important results of the T-joint compression.

It passes from 32kN at standard condition to 10kN with variable geometry, compared to 9kN of the linear section of the gasket.

The hydraulic performance of the variable-geometry gasket is comparable to the standard one. Where special sealing performance levels are required, the variable-geometry angle may be unsuitable and the effects of the loads generated in the T-joints should always be verified by spalling test.

The innovation is therefore a gasket with variable geometry that prevents the expulsion of the corners and the loads on the corners of the segments and therefore less infiltrations.

Analysis of cement grout hydraulic erosion in a homogeneous fracture

Hongyu Duan* & Liangchao Zou

Department of Sustainable Development, Environmental Science and Engineering, Royal Institute of Technology, Stockholm, Sweden

ABSTRACT: Cement grouting has been widely used in rock tunneling to reduce groundwater inflow by sealing rock fractures. However, the injected cement grout often encounters hydraulic erosion that affects the safety and sustainability of rock tunnels in the long term. Analysis of the long-term hydraulic erosion effect on cement grout in rock fractures is therefore important for the safety and sustainability development of rock tunnel engineering. In this work, a hydraulic erosion model for analyzing cement grout erosion in a homogeneous fracture is established and used to theoretically investigate the transmissivity evolution of the grouted fracture under long-term hydraulic erosion. In the present model, the fracture seepage characteristics, solid erosion theory and mass conversation for water-solid two-phase flow are considered, and the mathematical model as a set of partial differential equations is established. Based on laboratory tests, the key parameters (e.g., erosion coefficient) are calibrated and the erosion model is validated. Numerical simulations are conducted by numerically resolving the mathematical model. The results show that the erosion phenomenon first occurs in the edge areas of the grouted area near the fracture boundary; the erosion area gradually expands toward the center of the grouted area. The porosity and flow velocity significantly increase in the area with relatively strong erosion effects. During the erosion process, the concentration of cement grout gradually increases along the seepage path until a more uniform distribution of cement particle concentration is achieved. Due to the erosion process, the spatial distribution of hydraulic pressure along the fracture direction transforms from a linear distribution to a nonlinear distribution. The effective fracture transmissivity increases nonlinearly along the erosion process. The presented erosion model and analysis results are potentially useful for the safety and durability assessment of rock tunnels.

Keywords: Hydraulic erosion, Cement grout, Homogeneous fracture, Long-term effect, Effective transmissivity, Two-phase flow

1 INTRODUCTION

Cement grouting is a highly effective method utilized in rock tunnel engineering to ensure the safety and stability of tunnels. When tunnelling in areas with poor geological conditions characterized by highly fractured rock, cement grout could be injected into rock fractures to seal them, thereby reducing the permeability of the rock mass and preventing groundwater inflow into the tunnel. However, the sealing effect of cement grout in rock fractures can gradually decrease over time due to degradation processes (e.g., hydraulic erosion), leading to an increase in fracture permeability that poses a threat to tunnel sustainability. Therefore, it is imperative to investigate the long-term evolution of permeability in grouted rock fracture.

Many studies have been conducted on the long-term permeability of cement grouted areas focused on the impact of cement grout composition and groundwater chemical environment. Laver et al. (2013)

analyzed the samples taken from the grouted area surrounding a tunnel constructed in the early 1900s, and discovered an increase in permeability within grouted area. The degradation of the cement grout was attributed to cement carbonization and the sulfate reaction between the cement grout and groundwater. Lin et al. (2021) conducted experiments to determine the limited hydraulic pressure of cement grouting materials containing different admixtures and predicted the long-term permeability of cement grouts.

However, the aforementioned studies have not taken into account the long-term hydraulic erosion phenomenon, which is in fact a prevalent phenomenon in nature. Under high hydraulic pressure, solid particles within the rock or soil may detach from their mass skeleton and migrate with fluid flow. A similar effect occurs in cement grouted areas under hydraulic erosion, which has been confirmed by laboratory experiment results (Chan 1986) and in-situ observations (Akagi et al. 2010; Liu et al. 2018). Dekker et al.

*Corresponding author: hongyud@kth.se

(2020) developed an analytical solution for groundwater flow and transport within the cement grouting layer, examined the evolution of hydraulic conductivity in the cement grouted area, and quantified the mass flux and dilution ratio of erosion-related components. Liu et al. (2018) developed a hydraulic erosion model for curtain grouting in fully weathered granite, analyzed the overall response of the curtain grouting during hydraulic erosion, and determined the recommended design value for curtain thickness. Liu et al. (Liu 2022) analyzed the permeability evolution law of the cement grouted area under hydraulic erosion, established the damage evolution model of the cement grout, and obtained the relationship between permeability and damage variables.

The permeability evolution of cement grouted area under the action of hydraulic erosion has been studied in the above literature, but the long-term hydraulic erosion in the rock fracture cement grout has not been paid attention to. For the long-term hydraulic erosion of cement grouted area in fractures, it is necessary to consider more complex boundary conditions of hydraulic erosion, and take the non-Darcy seepage and solid-liquid two-phase flow in fractures into consideration. In order to analyze the sustainability of grouted fracture under long-term hydraulic erosion, a hydraulic erosion model of cement grout erosion in a homogeneous fracture is established in this paper. The model is verified by the laboratory tests, and the evolution law of hydraulic characteristics of rock fractures under hydraulic erosion was obtained. The grout erosion model established and the analysis results have certain guiding significance for the safety and durability evaluation of rock tunnels.

2 MODEL ESTABLISHMENT

2.1 Model description

The fracture grout erosion model is illustrated in Figure 1, where x represents the length of the rock fracture, z denotes its width, and a grouted area with a radius of r is positioned at the center of the fracture. The hydraulic pressure on the left side of the rock fracture is p_A , while that on the right side is p_B . Due to hydraulic erosion, fine solid particles in the grouted area migrate from left to right. The seepage area can be partitioned into three zones, namely Zones A, B and C. Owing to the distinct physical phenomena in each zone, diverse forms of governing equations are required to be established. Among them, the analysis of water flow and solid-fluid two-phase flows in rock fractures is required for Zones A and C, respectively, while the hydraulic erosion phenomenon in porous cement grout should be considered for Zone B.

Figure 1. The principle of the hydraulic erosion model for cement grouts.

2.2 Model assumption

The model takes into account the following assumptions:

- The fracture is homogeneous and the surface roughness is not considered.
- In the process of hydraulic erosion, the cement grouted area is saturated, and it is composed of cement grout skeleton, water and fluidized cement grout particles.
- The grouting porosity is the effective porosity, and the disconnected porosity is regarded as a part of the cement skeleton.
- Groundwater and fluidized cement grout particles maintain the same velocity.
- The chemical reactions between water and rock, as well as water and cement, are not taken into consideration.

2.3 Governing equations

For Zone A, according to the cubic law (Zimmerman and Bodvarsson 1996), the permeability k of rock fracture has the following relationship with its aperture e :

$$k = \frac{e^2}{12} \quad (1)$$

According to previous studies, fluid flow in rock mass fractures can be represented by the Forchheimer equation (Zeng and Grigg 2006):

$$-\nabla p = \frac{\mu}{k} u + \rho_w \beta u^2 \quad (2)$$

where p is hydraulic pressure, μ is dynamic viscosity, ρ_w is the density of water, u is the fluid velocity, and β is the non-Darcy factor. In rock fracture, the non-Darcy factor can be calculated by the following empirical equation (Li and Engler 2001).

$$\beta = \frac{1.1 \times 10^{-5}}{k^{1.176}} \quad (3)$$

For Zone B, considering the mass conservation law in the cement grout area during hydraulic erosion, the mass conservation equations for cement grout skeleton (1), water (2) and fluidized cement grout particles (3) are obtained as (Bear 2013):

$$\frac{\partial \rho^{(n)}}{\partial t} + \text{div}(\rho^{(n)} v^{(n)}) = l^{(n)} \quad n = 1, 2, 3 \quad (4)$$

where $v^{(n)}$ is the actual velocity of different phases, according to Assumption D, $v^{(2)} = v^{(3)}$. Since the cement skeleton does not move with the flow, $v^{(1)} = 0$. In addition, there is a relationship between the actual velocity of water and the flow velocity:

$$u = \phi v^{(2)} \quad (5)$$

And $l^{(n)}$ is the mass loss rate of phase n , since all fluidized cement grout particles are derived from cement skeleton, so $l^{(1)} = -l^{(3)} = J$, where J is the mass loss rate of cement skeleton, and $l^{(2)} = 0$. $\rho^{(n)}$ is the partial density of phase n , and it can be expressed by Equation 6.

$$\begin{cases} \rho^{(1)} = \rho_s(1 - \phi) \\ \rho^{(2)} = \rho_w(1 - c)\phi \\ \rho^{(3)} = \rho_s c\phi \end{cases} \quad (6)$$

where ρ_s is the density of cement grout, ϕ is porosity, and c is fluidized cement grout particle concentration. Combine Equations (4)-(6), the mass conservation equations for each phase are obtained:

$$\begin{cases} \frac{\partial \phi}{\partial t} - \frac{J}{\rho_s} = 0 \\ \frac{\partial(1-c)\phi}{\partial t} + \text{div}[(1-c)u] = 0 \\ \frac{\partial c\phi}{\partial t} + \text{div}(cu) + \frac{J}{\rho_s} = 0 \end{cases} \quad (7)$$

For the fluid flow in the grouting area, the following equation is satisfied:

$$-\nabla p = \frac{\mu}{k} u + \bar{\rho} \beta u^2 \quad (8)$$

where $\bar{\rho}$ is the average density of the two-phase fluid, which could be calculated by Equation 9:

$$\bar{\rho} = \rho_w(1 - c) + \rho_s c \quad (9)$$

For the non-Darcy factor in the grouted area, it can be expressed by Equation 10 (Li and Engler 2001):

$$\beta = \frac{1.15 \times 10^{-6}}{k\phi} \quad (10)$$

According to the previous research (Lee et al. 1996), the permeability in porous media has the following relationship with its porosity:

$$k = k_R \frac{\phi^3}{(1 - \phi)^2} \quad (11)$$

where k_R is the permeability parameter. To describe the mass loss rate of cement grout skeleton, there is a constitutive relationship of hydraulic erosion (Vardoulakis et al. 1996).

$$J = \lambda \rho_s (1 - \phi) \left(c - \frac{c^2}{c_{cr}} \right) u \quad (12)$$

where λ is the erosion parameter and c_{cr} is a critical value of particle concentration.

For Zone C, the non-Darcy equation is the same as that in the grouting region (Equations 9 and 10), and the equation of fracture permeability and non-Darcy factor is the same as that in Zone A, as shown in Equations 1 and 3. The mass conservation equation for Zone C can be calculated by the following equation (Bear 2013):

$$\frac{\partial c}{\partial t} + \text{div}(cu) = 0 \quad (13)$$

And the fracture effective transmissivity can be obtained by (Zou et al. 2018):

$$T = \frac{\bar{u}_{out} L}{e \Delta p} \quad (14)$$

where \bar{u}_{out} is the average flow velocity at the outlet boundary of fracture, and Δp is the difference between the inlet pressure and the outlet pressure of the fracture.

2.4 Computational conditions

For the grouted area (Zone B), there are the following initial conditions:

$$\phi(x, y, 0) = \phi_0, \quad c(x, y, 0) = c_0, \quad k(x, y, 0) = k_0 \quad (15)$$

For the initial condition in Zone C, there is:

$$c(x, y, 0) = c_0 \quad (16)$$

Taking the center of the grouting hole as the coordinate origin, the boundary condition for the fluidized grout particle concentration is:

$$c(x_0, y_0, 0) = c_0, \quad \text{where} \begin{cases} x_0^2 + y_0^2 = R^2 \\ x_0 < 0 \end{cases} \quad (17)$$

And the boundary conditions for the hydraulic pressure are:

$$p\left(-\frac{L}{2}, y, t\right) = p_A, \quad p\left(\frac{L}{2}, y, t\right) = p_B \quad (18)$$

3 CALIBRATION AND VALIDATION OF THE MODEL

Table 1 presents the primary parameters of the model, in which initial porosity, permeability parameter, and erosion parameter are obtained from specific measurements or calibration, and the remaining parameters can be established based on previous references (Ma et al. 2023) or research requirements. Initial porosity is determined through nuclear

magnetic resonance technology, while the permeability parameter is calculated using Equation 11 in combination with initial permeability from testing results. The erosion parameter is obtained through cylinder sample test calibration as described by Ma et al. (2022).

The hydraulic erosion equations in the grouted area constitute the core of the proposed model. To simulate cement grout erosion processes in a laboratory setting, an accelerated test method is employed that involves increasing boundary hydraulic pressure and reducing sample size. A cylindrical cylinder was used to conduct tests lasting 50 hours during which changes in sample quality were monitored and porosity evolution curves calculated. Experimental parameters were then input into the proposed hydraulic erosion equation to obtain calculated results for porosity evolution that could be compared with experimental curves using absolute percentage error (APE) and mean absolute percentage error (MAPE) calculations:

$$APE = \left| \frac{\phi_i - \phi_{ci}}{\phi_i} \right| \times 100\% \quad (19)$$

$$MAPE = \frac{1}{n} \sum_{i=1}^n \left| \frac{\phi_i - \phi_{ci}}{\phi_i} \right| \quad (20)$$

where ϕ_i and ϕ_{ci} are testing and calculating the value of porosity at time i ($i=1 \dots n$).

Table 1. Model parameters.

Model parameters	Value
Fracture length of the, L (m)	3
Fracture width of the, W (m)	0.9
Fracture aperture, e (m)	0.001
Radius of grouted area, R (m)	1
Initial concentration of the fluidized particle, c_0	5×10^{-3}
Critical value of concentration, c_{cr}	0.4
Dynamic viscosity of water, μ (m^2s^{-1})	1.01×10^{-3}
Density of water, ρ_f ($\text{kg}\cdot\text{m}^{-3}$)	1000
Density of cement grout, ρ_s ($\text{kg}\cdot\text{m}^{-3}$)	2500
Hydraulic pressure at the left boundary, p_A (MPa)	1
Hydraulic pressure at the right boundary, p_B (MPa)	0
Initial porosity, ϕ_0	0.072
Permeability parameter, k_c (μm^2)	5.12×10^{-10}
Erosion parameter, λ (m^{-1})	2×10^{-5}

Figure 2 Shows the comparison between test and simulation results, demonstrating a high level of agreement between the two. The APE is less than 0.6%, with a MAPE of only 0.28%. These findings indicate that the erosion equations utilized in the

proposed model possess strong applicability when simulating hydraulic erosion within grouted areas.

4 RESULTS AND DISCUSSION

4.1 Evolution of porosity

The porosity evolution law in the grouted area under hydraulic erosion is illustrated in Figure 3. After 2.5 years of continuous hydraulic erosion, a slight increase in porosity can be observed at the inlet and outlet of water flow at the fracture edge, indicating that some fluidized cement particles have started to detach from the grout skeleton due to water flow. At this time, the erosion effect has only caused a minor impact on the area with a maximum porosity increase of 0.09, indicating that the erosion phenomenon is not significant within 2.5 years. However, after five years of hydraulic erosion, the affected area expanded from the fracture edge to the grouting center and resulted in a maximum porosity of 0.13. Furthermore, seven and a half years later, there was further expansion of the erosion area with an increased maximum porosity of up to 0.23. After 10 years, the grouted area exhibited a maximum porosity of 0.43, which was 4.8 times higher than its initial value. At the same time, hydraulic erosion caused the formation of two high-porosity regions at both ends of the grouted area, with the maximum porosity continuously increasing and the growth rate accelerating over time. Specifically, the maximum porosity only increases by 0.02 in the range of 0-2.5 years, whereas it increases by 0.2 in the range of 7.5-10 years.

Figure 2. Evolution of porosity of cement grouted area under hydraulic erosion.

4.2 Evolution of flow velocity

The evolution of velocity magnitude and direction in the fracture is depicted in Figure 4, where the arrow indicates the direction of velocity and its size is positively correlated with the magnitude of velocity. After 2.5 years of hydraulic erosion,

Figure 3. Evolution of porosity of cement grouted area under hydraulic erosion (a) 2.5 years; (b) 5 years; (c) 7.5 years; (d) 10 years.

a high-velocity zone emerged near both ends of the fracture adjacent to grouted areas, where fluid mainly infiltrated or exfiltrated from these zones with a maximum flow rate reaching 0.0086 m/s. At this time, the velocity distribution within the grouted area is relatively homogeneous with no discernible areas of high flow velocity. However, after five years of hydraulic erosion, as this phe-

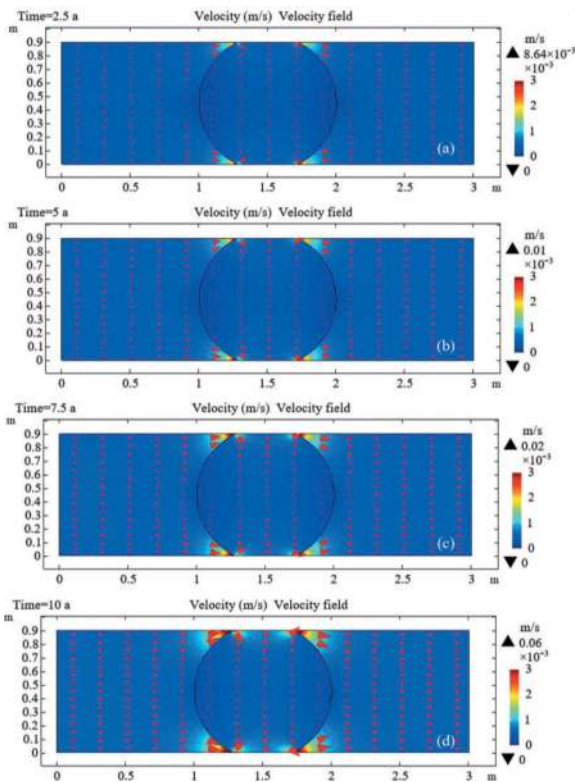

Figure 4. Evolution of flow velocity in the fracture under hydraulic erosion (a) 2.5 years; (b) 5 years; (c) 7.5 years; (d) 10 years.

nomenon gradually intensified, the maximum flow rate increased to 0.01m/s and a small region of elevated flow rates was observed within the grouted area. After 7.5 years of erosion, the maximum flow rate increased to 0.02 m/s and a larger area of high flow rate was observed. Following 10 years of erosion, the maximum flow rate reached 0.06 m/s and a large area of high flow rate can be found in the grouted area. By comparing the magnitudes of vector arrows shown in Figures 4(a) and 4(d), it can be observed that the flow velocity increase significantly both in the grouted area and the rock fracture away from the grouted area. Furthermore, by comparing Figures 3 and 4, it can be inferred that both velocity growth and porosity growth occur at the same location within the grouted area, indicating a significant increase in velocity within areas experiencing hydraulic erosion.

4.3 Evolution of cement particle concentration

The evolution of fluidized cement grout particle concentration under hydraulic erosion is illustrated in Figure 5. After 300 seconds of erosion, a significant increase in grout particle concentration was observed in the rear half of the grouted area, indicating particle aggregation in this region. After 900 seconds, the high grout concentration area migrates towards the fracture, indicating that some cement grout particles have started to exit the grouted area and infiltrate into the rock fracture. A stable grout concentration distribution was observed in the fracture after one year. For the grouted area, the fluidized cement grout particle concentration increased along the seepage path, and the highest concentration was found at the rear of the grouted area. In the fracture area, the concentration is higher in the center than at the boundary. Over a period of 5 years, erosion led to a gradual decrease in grout particle concentration within both the grouted area and fracture, resulting in a more uniform distribution. Throughout this entire process, there was only minimal variation observed in fluidized cement grout particle concentration around 0.005.

Figure 5. Evolution of cement particle concentration in rock fracture (a) 300 seconds; (b) 1000 seconds; (c) 1 year; (d) 5 years.

4.4 Evolution of hydraulic pressure

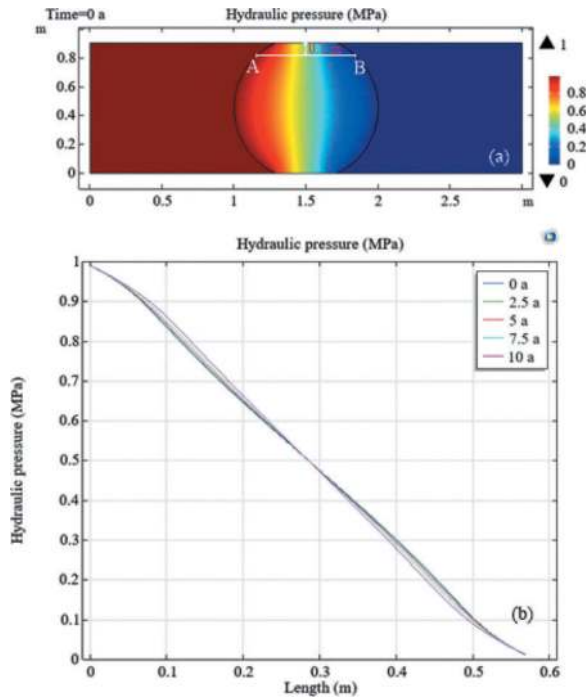

Figure 6. Evolution of hydraulic pressure in grouted area under hydraulic erosion (a) hydraulic pressure distribution in 0 years; (b) evolution curve of hydraulic pressure in line section AB.

Figure 6 (a) illustrates the initial spatial distribution of hydraulic pressure. It can be observed that there is minimal variation in hydraulic pressure within the fracture on both sides due to the fracture's higher permeability compared to that of the grouted area. Meanwhile, the hydraulic pressure gradient is greater at the upper and lower ends of the grouted area near the fracture's edge due to shorter seepage paths, which explains why erosion initially occurs in these areas. In order to further analyze the evolution of hydraulic pressure under hydraulic erosion, taking line segment AB as an example, the evolution curve of hydraulic pressure on this line segment was analyzed (as shown in Figure 6 (b)). It is observed that erosion causes slight changes in hydraulic pressure at each position. In the front half of the grouted area, hydraulic pressure exhibits a time-dependent increase, while in the rear half it shows a decrease. The spatial distribution of hydraulic pressure evolves from linear to nonlinear over time, which can be attributed to erosion effects.

4.5 Evolution of fracture effective transmissivity

The evolution of the effective transmissivity of fractures is depicted in Figure 7, which illustrates a 60% increase in the effective transmissivity of fractures over ten years due to hydraulic erosion. This indicates a significant decrease in the water-proof performance of the grouting body and a non-linear growth trend for the effective transmissivity of the

fracture. After 3 years, the effective transmissivity growth rate of fracture accelerates due to hydraulic erosion and gradually deviates from linearity. Therefore, it is necessary to consider reinforcing the grouted area at this stage to mitigate this growth trend.

Figure 7. Evolution of effective fracture transmissivity under hydraulic erosion.

5 CONCLUSION

In this paper, we establish a hydraulic erosion model for uniform fractures and verify its accuracy through laboratory tests. The evolution law of hydraulic characteristics in grouted fractures under long-term hydraulic erosion is obtained. The main findings are presented as follows.

The model result is consistent with the accelerated test results. During hydraulic erosion, the APE of the erosion model remains within 0.6%. Based on the model calculations, porosity growth is initially observed near the fracture boundary and gradually expands to include grouting holes. Over time, porosity growth in the grouted area accelerates significantly due to hydraulic erosion. In areas experiencing significant hydraulic erosion, a marked increase in velocity can be observed. In the initial stages of hydraulic erosion, fluidized cement grout particles accumulate at the rear end of grouted areas and gradually enter rock fractures. After 5 years of hydraulic erosion, particle concentration slowly decreases throughout all positions while becoming more uniformly distributed across both fractures and grouted areas. Hydraulic pressure changes minimally at each position, and under the influence of hydraulic erosion, the spatial distribution of hydraulic pressure shifts from linear to nonlinear. The effective transmissivity of the fracture increases with erosion, and after three years, the growth of transmissivity deviates gradually from linearity. Therefore, it is necessary to consider reinforcing the grouting area to curb the trend of transmissivity growth.

At present, we only focus on a generic analysis of the impact of cement grout hydraulic erosion in a homogeneous fracture. The more realistic conditions, such as fracture surface roughness and in-situ hydrogeochemical conditions on the evolution of grouted rock fractures' permeability remain important questions for future study.

ABSTRACT: Combined construction with multiple methods is the development trend of underwater tunnels in the future. In the construction process, it is inevitable to encounter the connection problems between different methods. Under high water pressure, it is very important to design the drainage system for the connection parts well. Based on the Zhujiangkou Tunnel of the Shenzhen-Jiangmen Railway, this paper derived the analytical calculation model of seepage considering the drainage system for the connecting section and verified it. It also conducted sensitivity analysis on the main parameters of the drainage system. The results showed that as the circumferential drainage pipe spacing decreased, and the combined parameter of geotextile thickness and permeability coefficient increased, the tunnel seepage flow increased and the lining water pressure decreased. Through the allowable limit water inrush amount, allowable pressure value and economic requirements of the tunnel, the calculation inversion could guide the design of the drainage system for the tunnel connecting section.

Keywords: Underwater tunnel, Combined method, Connecting section, Seepage field, Drainage system

1 INTRODUCTION

Underwater tunnels are transportation channels that expand the urban development space and promote economic development. At present, the construction of underwater tunnels has entered a rapid development stage, and the new development trends are: from single soft soil layer to soil-sand composite layer, from conventional geotechnical to special geotechnical and unfavorable geological conditions, from medium water pressure to high water pressure and ultra-high water pressure, from single method to combination of multiple methods (Li et al., 2017a; Li et al., 2017b). In order to adapt to the new development requirements, more and more underwater tunnels adopt the combined method for construction, and the design and operation process of underwater tunnels have strict requirements on the structural safety and drainage. Excessive water pressure behind the lining and unreasonable drainage structure may cause cracking or damage of the lining, or even sudden water inrush and other safety problems. The traditional seepage law and drainage design of underwater tunnels are no longer applicable to the

connecting sections of the combined method, so it is necessary to study the seepage law and drainage system parameters of the connecting sections.

Regarding the seepage field law and drainage system parameters of underwater tunnels, many scholars have carried out research and achieved certain results by means of theoretical analysis, numerical simulation, field measurement, etc. For the research on the seepage field law of underwater tunnels, Zhang et al. (2020) proposed a method to estimate the amount of water inrush into a tunnel by using the superposition principle based on the Tsingtao subsea tunnel and calculated the tunnel water inrush. Su et al. (2017) based on the numerical analysis results, analyzed the relationship between the groundwater level drop height and the tunnel seepage amount, and improved the seepage prediction accuracy. Li et al. (2022) conducted experiments on grouting rings and initial support under different permeability coefficients, and analyzed the influence of support structures on tunnel seepage and water pressure distribution. El Tani (2003) transformed the relationship between infinite strata and tunnels into two concentric circles through conformal coordinate

*Corresponding author: hukaixun@csu.edu.cn

transformation, thereby optimizing the boundary conditions and making the seepage differential equation easy to solve. Zhu et al. (2019) derived the underground seepage field of double parallel tunnels through conformal transformation. Fu et al. (2021a) extended the conformal mapping technology to calculate the water inrush of tunnel in the fault-affected area, and analyzed the effect of fault on the water inrush. Fu et al. (2021b, 2021c, 2022) analyzed the seepage law and the water inrush of Lianhuashan Tunnel. They considered the relationship between fault and the tunnel position, the influence of surrounding rock permeability coefficient and so on to improve the existed seepage analytical methods. Farhadian et al. (2012) based on Amirkabir Tunnel considering the values of r/h (tunnel radius/water table height above tunnel) to optimize the analytical equations of groundwater seepage into tunnels. Zhang et al. (2022) based on ABAQUS software platform to analyze the seepage control of the diversion tunnel under high external water pressure. Qin et al. (2022) considered the mutual interference in the seepage fields of subsea twin tunnels and proposed an analytical model for the seepage field of subsea twin tunnels. Liu et al. (2023) regarded the seepage law in lining and grouting area as the non-Darcy seepage, and improved the analytical solutions for the subsea tunnel with Hansbo seepage model. For the research on the design of drainage system of underwater tunnels, He et al. (2017) developed a tunnel seepage model experimental system for the construction and operation periods, and explored the relationship between the tunnel drainage system and the groundwater seepage. Arjinoi et al. (2009) revealed the distribution law of seepage around the tunnel under different drainage conditions. Li et al. (2018) constructed a railway tunnel bottom drainage pressure relief system, which includes a horizontal water collection system, a vertical water conduction system, and a bottom-up drainage system. Based on numerical calculations, they verified the performance of the drainage system. Zhu et al. (2022) equivalently treated the drainage system, calculated the distribution law of external water pressure for shallow buried non-circular tunnels, and promoted the development of the design theory of the drainage system.

In summary, the current research on underwater tunnels with combined construction methods including connection sections is still blank, and the parameters of the drainage system of the connection sections have an unclear impact on the seepage of the connection sections. It is urgent to carry out research on the seepage field and drainage system parameters of the connection sections of underwater tunnels with combined construction methods. A seepage model of the tunnel connection section considering the drainage system is constructed, and the corresponding analytical equations are derived. The equations are verified by degeneration test and numerical simulation, and a sensitivity analysis is performed on the parameters of the drainage system that affect seepage, including circumferential drainage pipes spacing, geotextile parameters, initial support parameters, and grouting ring parameters, in order to guide the design of the drainage system of the connection section.

2 ENGINEERING BACKGROUND

The Zhujiangkou Tunnel of Shenzhen-Jiangmen Railway is located in the downstream of the Pearl River waterway, connecting Humen Town in Dongguan and Wanqingsha in Guangzhou. It is designed and built according to the high-speed railway standard with a design speed of 200km/h. It has a single tunnel with two tracks, a total length of 13.69km, a crossing water section length of about 11km, a maximum burial depth of about 115m, and a maximum water pressure of about 1.06MPa. It is currently the underwater tunnel with the largest burial depth and water pressure in China.

The tunnel adopts shield construction method at both ends and mining method in the middle hard rock section. The shield section has a total length of 6.52km, which is divided into two sections, east and west, with lengths of 3.59km and 2.93km respectively. The middle mining method section has a length of 5.52km. The shield tunnel uses two composite slurry balance shields to start from the shield wells in

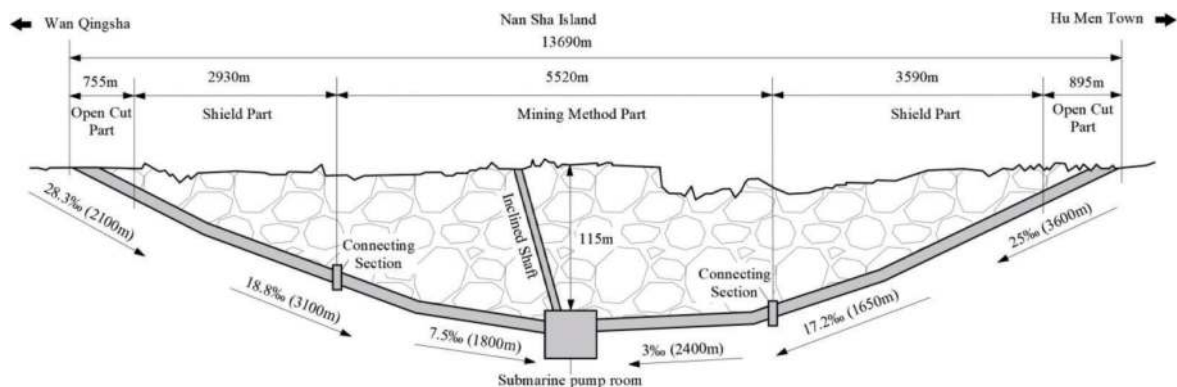

Figure 1. Longitudinal section of the Zhujiangkou Tunnel.

Figure 2. Connecting section structure design diagram.

Humen and Wanqingsha respectively, and disassemble at the boundary of the sea mining method section. The mining method tunnel is constructed through inclined shafts, which are set on the shore of Nansha Island, with a length of 1.16km; the tunnel shore section is mainly constructed by open-cut method, including the ground connection starting point section on the Humen side and the ground connection end point section on the Wanqingsha side, with a total length of about 1.65km. The longitudinal section of the Zhujiangkou Tunnel is shown in Figure 1.

A connecting section is set at the connection position of the shield section and the mining section, which is used to receive and dismantle the shield. The connecting section is built by mining method, and its internal structure and the plug walls on both sides are designed as shown in Figure 2. The construction of the analytical calculation model in the following is based on this design drawing.

3 CALCULATION MODEL

3.1 Simplification of the connecting section model

Generally, the excavation seepage of the tunnel is a three-dimensional flow. For the water flowing into the tunnel along the axial direction, the main source is from the front of the tunnel face. For the transverse and radial directions, it mainly comes from the runoff of the tunnel. When the tunnel is excavated for a certain length, the water flow along the axial direction can be approximately ignored, and only the transverse flow of the tunnel water occurs. Therefore, the cross section of the tunnel is usually selected for analysis, and the two-dimensional plane steady-state seepage is studied. According to the design drawing of the tunnel connecting section, the anisotropic tunnel section of the connecting section is simplified, and the cross section of the connecting section is converted into a circular section for solution by using the equivalent area method (Luo et al., 2017). The

corresponding calculation equation is shown in Equation (1). Therefore, the seepage model of the tunnel connecting section drawn is shown in Figure 3.

$$r = \sqrt{S/\pi} \quad (1)$$

In the equation, r is the equivalent radius of the tunnel obtained by the equivalent area method, and S is the cross-sectional area of the tunnel.

The inner contour area S of the design drawing is 385.6123m^2 , so the derived equivalent radius r is 11.08m.

The following basic assumptions are made for the seepage model of the tunnel connecting section:

- (1) In this seepage model, the seepage path of groundwater starts from the surrounding rock, passes through the grouting ring, initial support, geotextile, and then enters the tunnel through the circumferential drainage pipe. The seepage of groundwater conforms to the mass conservation law, is steady flow, conforms to Darcy's law, and satisfies the seepage continuity equation. That is, the seepage amount of groundwater from the surrounding rock to the grouting ring, initial support, geotextile, and then to the circumferential drainage pipe are equal. All the water entering the tunnel is discharged through the circumferential drainage pipe, and the water leakage effect of possible cracks is ignored.
- (2) The surrounding rock and lining of the tunnel are isotropic and continuous porous media. When it is assumed that the tunnel burial depth is large and the water level is high, the grouting ring and tunnel lining are assumed to be constant head boundaries, and the corresponding boundary head is calculated at the center position of the tunnel.
- (3) The groundwater in the geotextile uniformly infiltrates into the circumferential drainage pipe. In the geotextile, from the middle position of two circumferential drainage pipes to one of them, the head pressure shows a linear distribution. The

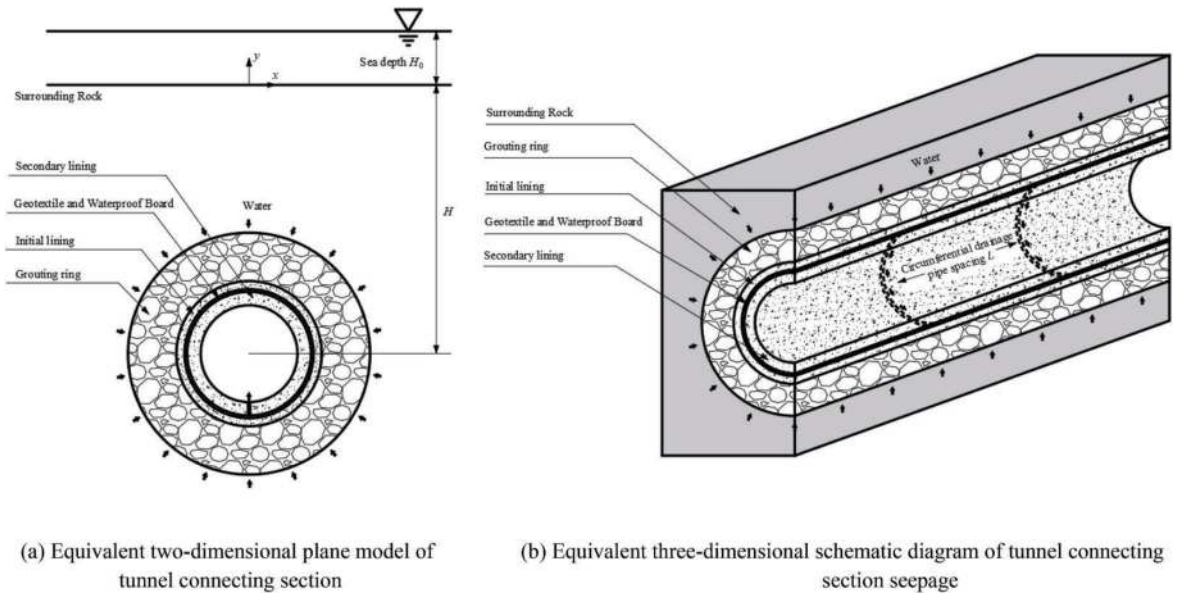

Figure 3. Seepage calculation model diagram of tunnel connecting section.

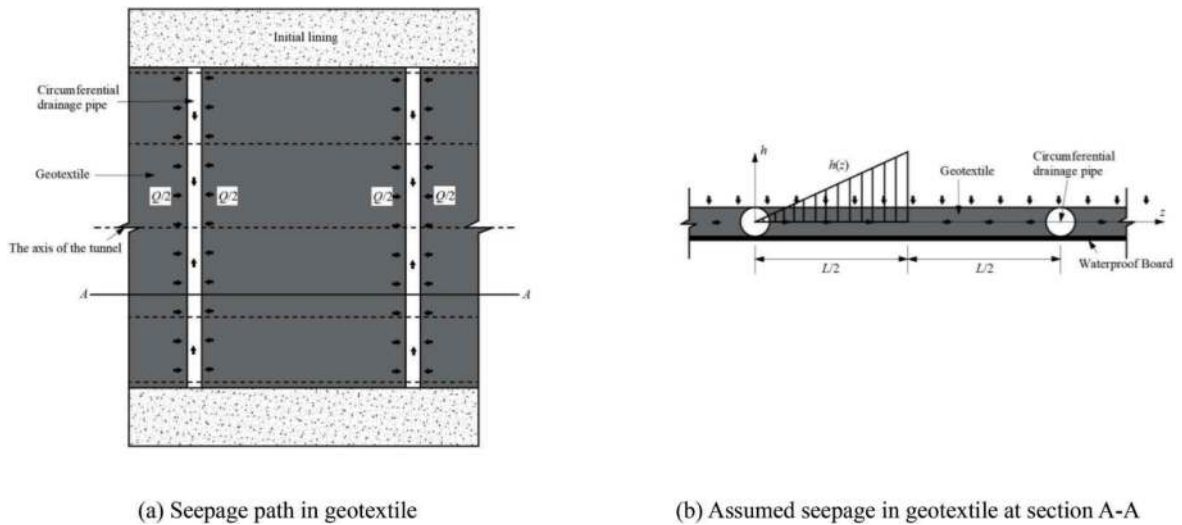

Figure 4. Seepage in geotextile of tunnel connecting section.

inside of the circumferential drainage pipe is a free outflow surface (communicating with the atmosphere), with only position head and zero pressure head. According to this design, it can be seen that the water pressure in the geotextile at the middle position between two circumferential drainage pipes is the largest, as shown in Figure 4.

3.2 Derivation of seepage analytical equation considering the drainage prevention system

Using the mirror method, the tunnel seepage problem in the half-infinite space is transformed into the superposition problem of the seepage field of one source and one sink in the infinite space in the surrounding rock area. As shown in Figure 5.

According to the superposition principle, the head expression of any point $M(x, y)$ in the surrounding rock area is:

$$h = \frac{Q_r}{2\pi k_r} \ln \frac{R_1}{R_2} + C \quad (2)$$

In the equation, R_1 and R_2 are respectively the distances from point M to the center point of the tunnel and the center point of the mirror tunnel, Q_r is the seepage amount, k_r is the permeability coefficient of the surrounding rock, and C is an undetermined coefficient.

According to the boundary condition, when M is located on the ground line, at this time $R_1=R_2$, the total head $p/\gamma+z=H_0$, so substituting into Equation (2), $C=H_0$ can be obtained. Therefore, the function

Figure 5. Solving the tunnel seepage problem in half-infinite space by mirror method.

expression of the head pressure h_g at the outer edge of the grouting ring can be analyzed:

$$h_g = \frac{Q_r}{2\pi k_r} \ln \frac{r_g}{2H} + H_0 \quad (3)$$

In the equation, r_g is the outer radius of the grouting ring, H is the distance from the center point of the tunnel to the ground line, and Q_r is the seepage amount of groundwater flowing into the grouting ring from the surrounding rock.

Therefore, the expression of Q_r , which is the seepage amount flowing into the grouting ring, is:

$$Q_r = \frac{2\pi k_r (H_0 - h_g)}{\ln \frac{2H}{r_g}} \quad (4)$$

The seepage between grouting ring and lining should satisfy seepage continuity equation:

$$\frac{\partial^2 h}{\partial r^2} + \frac{1}{r} \frac{\partial h}{\partial r} + \frac{1}{r^2} \frac{\partial^2 h}{\partial \theta^2} = 0 \quad (5)$$

In equation, h is full head of tunnel, which is sum of position head and pressure head, r is polar coordinate radius, θ is polar coordinate angle.

When the tunnel burial depth is large, the head difference between the tunnel crown and the invert is very small, and it can be assumed that the head on the outside of the entire tunnel is equal, and that the groundwater uniformly radially penetrates through the grouting ring and lining, so it is assumed that $\partial h / \partial \theta = 0$, then Equation (5) is simplified to:

$$\frac{\partial^2 h}{\partial r^2} + \frac{1}{r} \frac{\partial h}{\partial r} = \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial h}{\partial r} \right) = 0 \quad (6)$$

Solving Equation (6), the head equation of any point between the grouting ring and lining can be obtained:

$$h = C_1 \ln r + C_2 \quad (7)$$

Assuming that the head at the outer edge of the initial support is h_2 , and the head at the inner edge is $h(z)$, several boundary conditions that need to be considered for the model equation can be written as:

$$\begin{cases} BC1 : h|_{r=r_g} = h_g \\ BC2 : h|_{r=r_2} = h_2 \\ BC3 : h|_{r=r_1} = h(z) \\ BC4 : h|_{r=r_0} = 0 \end{cases} \quad (8)$$

Therefore, for the seepage inside the grouting ring, considering boundary conditions BC1 and BC2, the head equation and corresponding flow rate Q_g expression of any point inside the grouting ring can be solved:

$$h = \frac{h_g - h_2}{\ln \frac{r_g}{r_2}} \ln \frac{r}{r_g} + h_g \quad (9)$$

$$Q_g = 2\pi k_g \frac{h_g - h_2}{\ln \frac{r_g}{r_2}} \quad (10)$$

In equation, k_g is permeability coefficient of grouting ring, r_2 is outer radius of initial support.

For seepage calculation in initial support, considering basic assumptions (2) and (3) of model, from circumferential drainage pipe to middle position of two circumferential drainage pipes, head follows linear distribution. Assuming that head at middle position of two circumferential drainage pipes is h_z , pressure head at drainage pipe is 0, and total head is position head $-H$, then when $0 < z < L/2$, head loaded on waterproof board is:

$$h(z) = \frac{2z(h_z - H)}{L} \quad (11)$$

Take a micro annulus with axial length dz of initial lining. The seepage amount entering geotextile through micro annulus is:

$$Q_{Li} = 2\pi k_c \frac{h_2 - h(z)}{\ln \frac{r_2}{r_1}} dz = 2\pi k_c \frac{h_2 - \frac{2z(h_z - H)}{L}}{\ln \frac{r_2}{r_1}} dz \quad (12)$$

In equation, k_c is permeability coefficient of initial support, r_1 is inner radius of initial support.

Integrate Equation (12) (boundary $-L/2 < z < L/2$), obtain calculation equation of per meter seepage amount Q_L entering geotextile from initial support:

$$Q_L = \int_{-\frac{L}{2}}^{\frac{L}{2}} 2\pi k_c \frac{h_2 - \frac{2z(h_2-H)}{L}}{\ln \frac{r_2}{r_1} L} dz = \frac{2\pi k_c (h_2 - \frac{h_2-H}{2})}{\ln \frac{r_2}{r_1}} \quad (13)$$

For seepage in geotextile, according to basic assumption (2) and (3) of model, for arc length $d\theta$ and longitudinal width L geotextile micro element, seepage velocity v entering circumferential drainage pipe in micro element (water inlet on both sides of drainage pipe) is:

$$v = 2k_z i = 2k_z t \frac{h_z + H}{L/2} = \frac{4k_z (h_z + H)t}{L} \quad (14)$$

In equation, t is thickness of geotextile, k_z is permeability coefficient of geotextile. Per meter seepage amount Q_t entering circumferential drainage pipe from geotextile is:

$$Q_t = \frac{\int_0^{2\pi} v r_1 d\theta}{L} = \frac{8\pi r_1 k_z (h_z + H)t}{L^2} \quad (15)$$

Because fluid entering grouting ring, lining and tunnel interior satisfies mass conservation law and flow rate equals, derivation can obtain calculation equation for tunnel seepage amount considering drainage prevention system of connecting section:

$$Q = \frac{2\pi(H_0 + H)k_c k_g k_r}{\frac{k_c k_g k_r L^2}{8k_z r_1 t} + k_c k_g \ln \frac{2H}{r_g} + k_g k_r \ln \frac{r_2}{r_1} + k_c k_r \ln \frac{r_g}{r_2}} \quad (16)$$

For tunnel seepage without considering drainage system, water seepage in surrounding rock area and grouting ring satisfies Equation (4) and Equation (10). For seepage calculation in initial support, expression for seepage amount Q_L' is:

$$Q_L' = 2\pi k_c \frac{h_2 + H}{\ln \frac{r_2}{r_1}} \quad (17)$$

Therefore, according to mass conservation law and flow rate equals, combine Equation (4), Equation (10) and Equation (17), derivation can obtain calculation equation for seepage amount without considering drainage prevention system in composite lining:

$$Q' = \frac{2\pi(H_0 + H)k_c k_g k_r}{k_c k_g \ln \frac{2H}{r_g} + k_g k_r \ln \frac{r_2}{r_1} + k_c k_r \ln \frac{r_g}{r_2}} \quad (18)$$

Combine Equation (17) and Equation (18), it can be found that calculation for seepage amount considering drainage prevention system after correction for

situation without consideration. Set correction coefficient as λ , then λ expression is:

$$\lambda = \frac{k_c k_g k_r L^2}{8k_z r_1 t} \quad (19)$$

4 MODEL VERIFICATION

4.1 Model degeneration analysis

The model degeneration method (Ying et al., 2016) is used to verify the correction equation, that is, the limit of the proposed correction equation is first obtained, and the equation is degenerated into a general case without considering these factors, and then compared with the general characteristics considering these factors. When the difference between the two is small, the model equation is confirmed. The correction equation proposed in this paper considers more parameters of drainage pipe and geotextile than conventional equation, and degeneration analysis is required for corresponding parameters.

4.1.1 Circumferential drainage pipe spacing

When the circumferential drainage pipe spacing $L \rightarrow \infty$, that is, it is assumed that no drainage pipe is set between the lining, the correction coefficient Equation (19) and seepage amount Equation (16) degenerate into:

$$\begin{cases} \lim_{L \rightarrow \infty} \lambda = \lim_{L \rightarrow \infty} \frac{k_c k_g k_r L^2}{8k_z r_1 t} = \infty \\ \lim_{\lambda \rightarrow \infty} Q = \lim_{\lambda \rightarrow \infty} \frac{2\pi(H_0 + H)k_c k_g k_r}{\lambda + k_c k_g \ln \frac{2H}{r_g} + k_g k_r \ln \frac{r_2}{r_1} + k_c k_r \ln \frac{r_g}{r_2}} = 0 \end{cases} \quad (20)$$

Equation (20) shows that when the circumferential drainage pipe spacing tends to infinity, the correction coefficient tends to infinity, and the tunnel seepage amount Q tends to 0, which can be considered as impermeable structure of lining. This is consistent with the drainage prevention mechanism of composite lining. When no circumferential drainage pipe is set, it is assumed that the tunnel is a fully enclosed non-drainage full-package structure.

When the circumferential drainage pipe spacing $L \rightarrow 0$, that is, it is assumed that the inner edge of lining can drain to tunnel, the correction coefficient Equation (19) and seepage amount Equation (16) degenerate into:

$$\begin{cases} \lim_{L \rightarrow 0} \lambda = \lim_{L \rightarrow 0} \frac{k_c k_g k_r L^2}{8k_z r_1 t} = 0 \\ \lim_{\lambda \rightarrow 0} Q = \lim_{\lambda \rightarrow 0} \frac{2\pi(H_0 + H)k_c k_g k_r}{\lambda + k_c k_g \ln \frac{2H}{r_g} + k_g k_r \ln \frac{r_2}{r_1} + k_c k_r \ln \frac{r_g}{r_2}} = Q' \end{cases} \quad (21)$$

Equation (21) shows that when the circumferential drainage pipe spacing tends to 0, the correction

coefficient is 0, and the tunnel seepage amount is consistent with the tunnel seepage amount calculation equation without considering the drainage prevention system in composite lining. Groundwater penetrates through lining and enters tunnel directly.

4.1.2 Geotextile permeability coefficient

When geotextile permeability coefficient $k_z \rightarrow \infty$, corresponding correction coefficient and tunnel seepage amount equation are consistent with Equation (21). At this time, geotextile in drainage prevention system is equivalent to extension of drainage pipe and plays role of drainage channel completely. Groundwater enters tunnel directly through lining.

When geotextile permeability coefficient $k_z \rightarrow 0$, corresponding correction coefficient and tunnel seepage amount equation are consistent with Equation (20). It is equivalent to geotextile being impermeable, that is, a water barrier layer is set up, which makes tunnel impermeable. Tunnel is fully enclosed non-drainage full-package structure.

4.2 Numerical simulation verification

ABAQUS software is used to simulate the seepage of the tunnel connecting section. The model construction considers the complete drainage prevention system, including grouting ring, initial support, drainage pipe, geotextile, waterproof board and secondary lining. The model needs to eliminate the influence of size effect, and the size is $150\text{m} \times 30\text{m} \times 200\text{m}$ (length \times width \times height, the left, right and lower boundaries of the surrounding rock are more than 3 times the diameter of the tunnel from the center of the tunnel, and the upper boundary is the actual burial depth). The physical and mechanical parameters of the model calculation process are shown in Table 1.

Table 1. Model parameters.

Item	Value	Item	Value
Sea level height $H_0(\text{m})$	20	Initial support inner diameter $r_1(\text{m})$	11.68
Tunnel burial depth $H(\text{m})$	50	Secondary lining inner diameter $r_0(\text{m})$	11.08
Surrounding rock permeability coefficient $k_r(\text{m/s})$	1.2×10^{-6}	Geotextile thickness $t(\text{m})$	0.003
Grouting ring permeability coefficient $k_g(\text{m/s})$	6×10^{-8}	Geotextile permeability coefficient $k_z(\text{m/s})$	3.5×10^{-4}
Grouting ring outer diameter $r_g(\text{m})$	16.98	Circumferential drainage pipe spacing $L(\text{m})$	5
Initial support outer diameter $r_2(\text{m})$	11.98	Circumferential drainage pipe radius $r_p(\text{m})$	0.075
Initial support permeability coefficient $k_c(\text{m/s})$	6×10^{-10}	Surrounding rock density $\gamma(\text{kN/m}^3)$	20

The boundary conditions of the model are: the bottom and the front and rear hydraulic boundaries are impermeable boundaries, the top boundary is permeable and a constant hydrostatic pressure is applied according to the sea level height, and the left and right hydraulic boundaries are through ditch water and the pore water pressure is linearly distributed. The constructed model is shown in Figure 6.

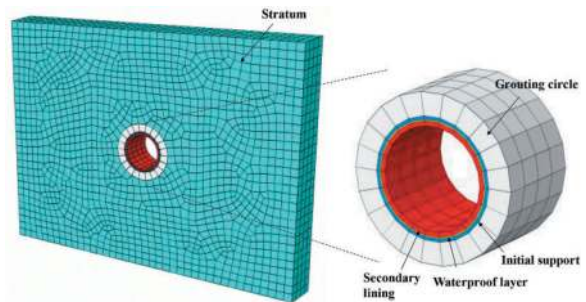

Figure 6. Numerical calculation model of the connecting section.

The calculation verification process considers the change of sea level height, and uses the model to calculate the seepage flow under the sea level heights of 10m, 20m, 30m, 40m, and 50m, and summarizes them with the calculation results of analytical calculation as shown in Table 2.

Table 2. Comparison of analytical solution and numerical solution calculation results.

Sea level height $H_0(\text{m})$	Water inrush $Q/(\text{m}^3 \cdot \text{d}^{-1} \cdot \text{m}^{-1})$		
	Analytical solution	Numerical solution	Error %
10	0.6539	0.6124	6.34
20	0.7629	0.7133	6.50
30	0.8718	0.8141	6.62
40	0.9808	0.9134	6.87
50	1.0898	1.0137	6.98

As can be seen from Table 2, the maximum error between the numerical solution and the analytical solution for the tunnel seepage flow is 6.98%, and the minimum error is 6.34%. The results are consistent, indicating that the analytical results have high accuracy.

5 PARAMETER SENSITIVITY ANALYSIS

For the analysis of the influence of the drainage parameters of the connecting section, the main influencing parameters include the circumferential drainage pipe spacing L , the geotextile parameters k_z and t , the initial support permeability coefficient k_c and

its thickness, and the grouting ring permeability coefficient k_g and its thickness. Therefore, referring to the calculation parameters used in the numerical simulation verification, the control variable method is used to perform the sensitivity analysis of the drainage parameters of the connecting section under multiple factors.

5.1 The influence of drainage pipe spacing

Under the condition that other parameters are consistent with Table 1, considering the change of circumferential drainage pipe spacing L , draw the relationship curve between tunnel seepage flow, water pressure of lining and circumferential drainage pipe spacing, as shown in Figure 7.

Figure 7. The influence curve of circumferential drainage pipe spacing on tunnel seepage flow and water pressure of lining.

It can be analyzed from Figure 7 that as the circumferential drainage pipe spacing increases, the amount of water drained into the tunnel through the drainage pipe decreases, and the water pressure of the lining increases. The slope of both curves gradually increases, reflecting that the rate of change has been increasing. When the circumferential drainage pipe spacing increases from 1m to 15m, the flow rate decreases by $0.0337 \text{m}^3 \cdot \text{d}^{-1} \cdot \text{m}^{-1}$, and the water pressure of the lining increases by 4.5kPa. Figure 7 shows that the drainage pipe plays a role in draining the tunnel seepage water into the tunnel and reducing the water pressure of the lining.

5.2 The influence of geotextile parameters

Under the condition that other parameters are consistent with Table 1, considering the change of geotextile parameter $k_z \cdot t$, draw the relationship curve between tunnel seepage flow, water pressure of lining and geotextile parameter, as shown in Figure 8.

It can be analyzed from Figure 9 that as the geotextile parameter increases, the amount of water flowing into the tunnel increases, and the water pressure of the lining decreases. The slope of both

Figure 8. The influence curve of geotextile parameter on tunnel seepage flow and water pressure of lining.

curves gradually decreases, and this effect will gradually weaken and stabilize. When the geotextile parameter increases from $5 \times 10^{-7} \text{m}^2/\text{s}$ to $3 \times 10^{-6} \text{m}^2/\text{s}$, the flow rate increases by $0.0068 \text{m}^3 \cdot \text{d}^{-1} \cdot \text{m}^{-1}$, and the water pressure of lining decreases by 0.9kPa. Figure 9 shows that improving the permeability performance of geotextile will make more water drain into the tunnel and reduce the water pressure of lining, but this improvement is limited. When the geotextile parameter is greater than $3 \times 10^{-6} \text{m}^2/\text{s}$, the effect can be ignored.

5.3 The influence of initial support parameters

Under the condition that other parameters are consistent with Table 1, considering the change of initial support permeability coefficient k_c and initial support thickness, draw the relationship curve between tunnel seepage flow, water pressure of lining and initial support parameters, as shown in Figure 9.

It can be analyzed from Figure 9 (a) that when initial support permeability coefficient increases from $5 \times 10^{-11} \text{m/s}$ to $1 \times 10^{-9} \text{m/s}$, flow rate increases by $1.081 \text{m}^3 \cdot \text{d}^{-1} \cdot \text{m}^{-1}$, and water pressure decreases by 145.2kPa. Therefore, an increase in the initial support permeability coefficient will result in a decrease in both tunnel seepage flow and water pressure, and the curves show an approximate linear relationship. It can be analyzed from Figure 9 (b) that as initial support thickness increases, both tunnel seepage flow and water pressure decrease. The slope of both curves gradually decreases and stabilizes. When initial support thickness increases from 0.1m to 0.6m, flow rate decreases by $1.3214 \text{m}^3 \cdot \text{d}^{-1} \cdot \text{m}^{-1}$, and water pressure increases by 181.5kPa. Figure 19 shows that improving initial support permeability performance will make more water drain into tunnel and reduce external water pressure; while increasing initial support thickness will extend path for water to pass through initial support which will reduce amount of water flowing into tunnel but increase water pressure accordingly; there is a limit to effect of initial support thickness; when it is greater than 0.6m, effect can be ignored.

(a) Influence curve of initial support permeability coefficient

(b) Influence curve of initial support thickness

Figure 9. The influence curve of initial support parameters on tunnel seepage flow and water pressure of lining.

5.4 The influence of grouting ring parameters

Under the condition that other parameters are consistent with Table 1, considering the change of grouting ring permeability coefficient k_g and grouting ring thickness, draw the relationship curve between tunnel seepage flow, water pressure of lining and grouting ring parameters, as shown in Figure 10.

It can be analyzed from Figure 10 (a) that as the grouting ring permeability coefficient increases, both tunnel seepage flow and water pressure of lining increase. The curves first increase rapidly, there is a turning point at $k_g=1\times 10^{-7}$ m/s, and then maintain a low rate of increase. When the grouting ring permeability coefficient increases from 1×10^{-8} m/s to 5×10^{-7} m/s, the flow rate increases by $0.3684\text{ m}^3\cdot\text{d}^{-1}\cdot\text{m}^{-1}$, and the water pressure of lining increases by 288.6kPa. It can be analyzed from Figure 10 (b) that as the grouting ring thickness increases, both tunnel seepage flow and water pressure of lining decrease. The curves show a linear relationship. When the grouting ring thickness increases from 3m to 6m, the flow rate decreases by $0.0453\text{ m}^3\cdot\text{d}^{-1}\cdot\text{m}^{-1}$, and the water pressure of lining decreases by 35.5kPa. Figure 10 shows that improving the permeability performance of the grouting ring will make more water drain into the tunnel and increase the

(a) Influence curve of grouting ring permeability coefficient

(b) Influence curve of grouting ring thickness

Figure 10. The influence curve of grouting ring parameters on tunnel seepage flow and water pressure of lining.

water pressure of lining. This improvement effect will be limited by its permeability coefficient. When it is greater than a certain value, the effect is not significant. While increasing the grouting ring thickness will extend the path for water to pass through the grouting ring, which will reduce the amount of water flowing into the tunnel and also reduce the water pressure of lining.

The above parameter sensitivity analysis provides the functional relationship between tunnel seepage flow and various parameters. By combining tunnel drainage limit standard and allowable value of water pressure of lining with economic requirements of improved parameters, reverse calculation and comparison can be performed to determine reasonable drainage parameters for tunnel connecting section and guide design.

6 CONCLUSION

Based on the Zhujiangkou Tunnel of the Shenzhen-Jiangmen Railway, this paper studies the drainage system parameters of the underwater tunnel connecting section of the combined method, proposes a tunnel

connecting section seepage equation considering the drainage system, performs degeneration test and numerical simulation verification on the equation, and conducts sensitivity analysis on the parameters affecting seepage, providing reference for the design of the drainage system of the tunnel connecting section.

- (1) The derived seepage equation of the tunnel connecting section considering the drainage system is applicable to the seepage field calculation of underwater irregular section tunnels with large burial depth and high water level, and is also applicable to the seepage field calculation of underwater tunnel connecting sections of the combined method.
- (2) Through degeneration test analysis and numerical simulation verification, the difference between analytical calculation and numerical simulation of tunnel seepage flow and water head pressure of lining is small, and the results are consistent. The degeneration test shows that this equation is essentially a modification of the tunnel calculation equation without considering the drainage structure, making the results more accurate.
- (3) The sensitivity analysis of drainage parameters reveals the influence of circumferential drainage pipe spacing, geotextile parameters, initial support parameters, and grouting ring parameters on the seepage field of tunnel connecting section. Among them, decreasing circumferential drainage pipe spacing, increasing geotextile parameter, increasing initial support or grouting ring permeability coefficient, and decreasing initial support thickness will increase tunnel seepage flow and decrease lining water pressure. It is worth noting that decreasing grouting ring thickness will also lead to simultaneous increase in tunnel seepage flow and water pressure of lining. Combining tunnel drainage allowable value and economic comparison requirements, calculation inversion can be used to guide design of drainage system parameters for tunnel connecting section.

Bahtiyar Ünver

Department of Mining Engineering, Hacettepe University, Ankara, Türkiye

ABSTRACT: The waterproofing methods used in tunneling can be categorized into two main application types namely, the double shell waterproofing method and the sprayed single shell waterproofing method. DSW (double shell waterproofing) method involves a PVC-membrane placed between the primary reinforcement and the final coating concrete. SSW (sprayed single shell waterproofing) method involves a sprayed liquid membrane instead of a PVC membrane and reinforced shotcrete instead of final coating concrete. This paper presents the application methods and material properties of both waterproofing methods. Performance of both methods were analyzed by means of 2D numerical modelling. DSW and SSW methods were also compared in terms of cost, and occupational health and safety. Both methods meet stability criterion. Although the direct cost of SSW method is found to be a little higher, it is superior in terms of labour requirement. Hence the operation is far safer and faster.

Keywords: Waterproofing in Tunneling, Liquid Membrane, Sprayed Single Shell Method, Double Shell Method

1 INTRODUCTION

During tunnel construction, managing surface and underground water challenges necessitates effective waterproofing for long-term viability. There are currently two waterproofing methods used to prevent water problems that may be encountered during tunnel construction. The Double Shell (DSW) and Sprayed Single Shell (SSW) methods offer solutions. DSW utilizes geotextile and PVC-membrane, placed between primary support and final coating concrete, while SSW employs synthetic or steel fiber reinforced shotcrete for primary support, a liquid membrane for waterproofing, and steel fiber reinforced shotcrete as the final lining, creating a rigid structure. This paper discusses the applications, equipment utilization, and material features of the two waterproofing methods. In addition, a 600-meter long tunnel with three different rock classes is considered as a sample tunnel for comparison of these two methods on the basis of cost, stability, and accident types in terms of worker health and safety. Due to high waterproofing performance of methods, no direct waterproofing comparison is made.

The paper guides engineering decisions for sustainable and secure tunnel construction, ensuring longevity and safety of underground infrastructure.

2 TECHNICAL BACKGROUND AND LITERATURE REVIEW

Waterproofing is a critical aspect in the design of long-term tunnel project. Although effective and cost-efficient, the DSW method has drawbacks, including complex and vulnerable workmanship, limited application areas, and troublesome repair works after construction.

The SSW method has been used in tunneling widely in recent years. This method eliminates the use of PVC-membrane, final cast concrete, and steel mesh. Instead, steel fiber reinforced shotcrete is applied as a primary support and final coating consisting of synthetic or steel fiber reinforced shotcrete. The impermeability is ensured by spraying a liquid membrane in between linings. Considering the differences between the two methods, SSW method can be preferred over the traditional method due to its ease of application and speed, under suitable geological conditions. While it has a higher material cost than the traditional method, it offers greater flexibility in application and is advantageous in terms of occupational health and safety. Furthermore, it can be practically repaired during tunnel construction or operation, making it a viable option (Wu et al., 2017).

2.1 The double shell method

The DSW aims to waterproof a tunnel by placing a PVC-membrane between two linings.

PVC-membrane, protection geotextile, and the carrying system are mounted on shotcrete with care to avoid future repair difficulties. The preferred membrane should be made of PVC compound, and plasticized for flexibility and durability. It must possess high elongation and tensile strength and withstand high hydraulic pressure.

To protect the membrane during installation, a geotextile membrane can be applied. In cut-and-cover structures, double-sided geotextile is recommended. In case of damage, a thin signal layer with a distinct color and thickness is added to aid detection. The waterproofing membrane can vary in thickness depending on the water presence (Multiplan, 2016).

Two main waterproofing methods used in traditional tunnel construction are, *the drainage system*, which channels water away, and *the barrier system*, which offers continuous water resistance (Sikaplan, 2017).

2.1.1 Material properties of pvc-membrane

A complex coating system for waterproofing involves integrating main and auxiliary elements with the support system. The primary elements are the membrane, typically made of PVC-P (Plasticized Polyvinyl Chloride) or TPO (Thermoplastic Polyolefin) compounds. PVC-P is a widely used synthetic plastic polymer that can be made more flexible with the addition of a plasticizer. On the other hand, TPO is a modern polymer with a long service life, resistant to various environmental factors, and doesn't require plasticizers during its production. Polyethylene membranes have also been tested and confirmed to have a long service life and durability (Prişcu, 2013). Waterstop tapes, drainage plates and flanges are used as auxiliary waterproofing elements (Multiplan, 2016).

2.2 The sprayed single shell

The SSW method is a more practical alternative method than the DSW method in terms of waterproofing. It involves applying synthetic fiber or steel fiber-reinforced shotcrete to create a stable and rigid structure. After applying the primary support, a liquid membrane is sprayed to form the waterproofing layer. This method provides a smooth appearance to the tunnel lining surface. After the application of liquid membrane, the reinforced shotcrete is reapplied and so the single shell is completed. Using liquid membrane instead of PVC-membrane can speed up the process and reduce the working costs, making it more suitable for challenging surface geometries like T-points (intersections) (Wu et al., 2017).

2.2.1 Application of liquid membrane

The liquid membrane is applied in a similar manner of shotcrete using special equipment (Figure-1).

Also, it should be applied to a dry and clean surface to ensure optimal performance. The liquid membrane should have a minimum thickness of 3 mm and the smoothness of the surface being applied is essential to create an effective waterproofing layer and material savings (Ma, 2011).

Figure 1. Liquid membrane application on the tunnel surface (Bridgepreservation, 2013).

Besides effective shotcrete application is crucial for achieving an efficient and stable single shell method. The surface should be dry before application, as the liquid membrane can be weakened if it comes into contact with water during the curing process (Wu et al., 2017).

2.2.2 Material properties liquid membrane

The liquid membrane used in the SSW is based on a specially formulated EVA (Ethylene Vinyl Acetate) polymer. EVA is chosen for its flexibility, chemical resistance, and high friction coefficient. The degree of elasticity is determined by the amount of vinyl acetate in the chemical formula of EVA. High amount of vinyl acetate decreases hardness of liquid membrane. The material also contains a filling material that contributes to its long-term behavior and curing mechanism, providing long-lasting protection of chemical properties (Wu et al., 2017).

The liquid membrane is designed to create a highly bonded composite support system between the primary and secondary support linings. It adheres firmly to the rough surface of shotcrete. It maintains continuity between the two coatings, regardless of the presence of steel or fiber reinforcement or the use of PVC-membrane. It should eliminate the possibility of mechanical discontinuity and should create a sandwich structure between the outer and inner shotcrete coatings which ensure resistance to rock and water loads (Holter et al., 2014). Unlike PVC, the liquid membrane does not allow water migration between the two sides. It acts as an excellent waterproof barrier, preventing water from passing through the strong polymer chain matrices. The liquid membrane has small pores, allowing water vapor to penetrate and release as steam, avoiding pressure buildup behind the membrane (Wu et al., 2017).

For a leak to occur in single shell system, water must pass through three failure zones: a crack in the primary lining, the liquid membrane, and the

secondary lining. Groundwater cannot migrate over the liquid membrane, making it necessary for all three crack zones to align. In the double shell method, the leak passing through the primary lining is directed to the PVC-membrane and discharged by drainage. Meanwhile, the water pressure on the membrane is carried to the secondary coating concrete.

The strength properties of the liquid membrane are given in Table-1 (Wu et al., 2017):

Table 1. Liquid membrane material and strength properties.

Bond Strength to Concrete	~1.2 MPa
Tensile Strength	1.5 - 3.5 MPa
Elongation	100%
Crack Bridging	>2.5 mm

The liquid membrane can be sprayed directly onto steel inserts or is compatible with coatings using synthetic or steel-fiber reinforced shotcrete on both sides. Its adhesion strength to concrete is 1.2 ± 0.2 MPa, while its bond strength to metals is between 0.5 and 1.2 MPa. These properties also allow liquid membrane as part of hybrid waterproofing applications with traditional membrane when it is necessary (Junwei, 2014).

However, the liquid membrane may not be effective in areas with active water intrusion, as small infiltration rates can lead to increased hydrostatic pressure at the concrete/membrane interface, hindering proper hardening and waterproofing. In such cases, it is recommended to remove the water from the environment before applying the liquid membrane. Fast-curing liquid membranes may also be used to prevent leakage if required (McDonald, 2009).

3 METHODOLOGY

The study compares the stability of tunnels constructed with SSW and DSW methods in a 600-meter sample tunnel having of A2, B2, and C2 rock classes by using the RS² finite element numerical analysis program under static and dynamic conditions. Besides the stability analysis, the cost analysis of tunnels with three different excavation and support systems were performed and the results were compared for two methods. Finally, these two waterproofing methods are examined in terms of occupational health and safety, based on the types of work accidents during construction.

3.1 Stability analysis and comparison

The rock mass parameters of the 600-meter sample tunnel, is divided into three regions having various properties (Table-2). 200- meter long regions were of A2, B2, and C2 classes. The stresses on the shotcrete and on rock bolts are examined respectively, and the tunnel support of these two waterproofing systems is compared by means of 2D numerical modeling. The parameters for the A2 section of the tunnel have the characteristics of the hard rock class.

The rock mass parameters of the medium rock class for B2 and the weak rock class for C2 are also determined. In this direction, parameters such as GSI, uniaxial compressive strength (q_c), Hoek-Brown failure constants m , s and m_i , the density of rock mass (γ), modulus of elasticity of rock mass, and coefficient of disturbance are used. The numerical values of these parameters are given in Table-2.

In addition, the characteristics of the support system and the material parameters of the support units are illustrated in Tables 3 and 4. The finite element model involves 5 stages for the A2 and B2 classes and 6 stages for the C2 class that includes an invert geometry. The tunnel geometry was based on a typical highway tunnel, with a height of approximately 10-meter and a width of 13-meter as the excavation dimensions. It is a double lane, single tube tunnel with an 8-meter platform width (Kartun, 2022).

In the RS² model, the "Initial Loading" is applied as "Gravity Field Stress" since the underground excavation geometry can be modeled with the surface topography. The earthquake acceleration value ($a=0.2$) used in the dynamic analysis is taken from the Turkey Earthquake Map published by AFAD (Kartun, 2022).

Table 2. Rock classifications and material parameters.

	A2	B2	C2
GSI	65	49	27
Depth (m)	100	100	70
q_c (MPa)	83	55	12
m_i	17	15	12
γ (t/m ³)	0.0265	0.0265	0.023
UNDISTURBED ROCK			
E_m (MPa)	18951	14158	405
m	4.871	2.427	0.0035
s	0.0205	0.0035	0.0003
DISTURBED ROCK			
E_m (MPa)	9211	5770	317
m	2.851	1.112	0.442
s	0.0077	0.008	0.0002
Disturbance factor (D)	0.6	0.6	0.2

Results of finite element analysis for each rock class and waterproofing methods reveals that there is no instability problem for support systems of tunnel. Also maximum displacements are in acceptable level in dynamic conditions.

Figures 2 show that total displacements of each rock class in dynamic conditions and maximum displacement is 7.2 cm in C2 class, which is an acceptable value. Also, maximum displacements are 0.7 cm and 0.5 cm for B2 class and A2 class respectively which are quite small.

Table 3. Excavation and support systems.

Support Systems	A2	B2	C2
Rock Bolts Diameter and Type	SN Ø28 cm	SN Ø28 cm	IBO Ø32 cm
Rock Bolts Length and Spacing	Local	4 m Length 2 m X 2 m Spaced	6 m Length 1 m Spaced
Shotcrete Grade and Thickness <i>Single Shell</i>	5 cm C25-30 Steel Reinforced	15 cm C25-30 Steel Reinforced	25 cm C25-30 Steel Reinforced
Shotcrete Grade and Thickness <i>Double Shell</i>	5 cm C25-30 Non- Reinforced	15 cm C25-30 Non- Reinforced	25 cm C25-30 Non- Reinforced
Wire Mesh Type (The Double Shell)	-	Single - Q221/ 221	Double - Q317/ Q317
Steel Arch Type and Spacing	-	I-100 1.75 m Spaced	I-180 1 m Spaced
Forepoling Spacing and Diameter	0.250 m Spaced, 2.5 m Overlaped, 5 m Length	Ø 1.5 Inch Pipes, <i>Forepole application is used only in the C2 excavation and support class.</i>	

Moreover, the axial stresses on the bolts were also examined in Figure 3 for C2 class. As seen, the capacity of bolts is enough for induced stresses.

The most important point that should be emphasized for the comparison of DSW and SSW methods according to the numerical analysis is that, as the quality of the rock mass decreases, the feasibility of the utilization of SSW method also decreases. It can be seen from the displacement values and stresses in C2 class excavation and support system.

Therefore, for weak and extreme weak ground conditions, double shell supporting method and traditional waterproofing should be prioritized.

Table 4. Material parameters of support elements.

Support port Systems	Steel Fiber Reinforced	Non-Reinforced	Bolt		Steel Arch		Wire Mesh		Coating Concrete
	Shotcrete (C20-25)	Shotcrete (C20-25)	SN Ø28 cm	IBO Ø32 cm	I-100	I-180	Q221/221	Q317/317	(C25-30)
E (MPa)	28,500	28,500	210,000	210,000	210,000	210,000	210,000	210,000	30,000
Compressive Strength (MPa)	20	20	400	400	400	400	400	400	25
n Poisson Ratio	0.2	0.2	-	-	-	-	-	-	0.25

Tensile Strength (MPa)	1.50-2.50*	1.00-2.00	0.16 (MN)	0.25 (MN)	-	-	-	-	1.8

* According to experiments, utilization of steel fiber increases the tensile strength of shotcrete with minimum 20% rate, while it has not an important change on the compressive strength of shotcrete (Shende, 2011).

The results of calculations of stresses on shotcrete according to numerical analyses are given in Tables 5-6-7. Based on these stress values and its calculations, both methods ensure the stability of the tunnel without the secondary shell and final coating (Gök, 2021). Tensile stresses (negative values in Table 5) occurred in C2 class have been disappeared after the completion of both waterproofing methods (Table 6). Besides, the cast concrete coating and secondary sprayed lining in both methods are crucial in terms of closing the waterproofing structure and creating an isolated system. Also, it composes a stable shell against dynamic conditions and provides a smooth appearance.

Although the membrane utilized in double shell method can be considered as a discontinuity between shotcrete and coating concrete, it also creates a mobile and flexible structure that is expected to be more stable under dynamic conditions.

3.2 The cost calculations and comparison

The 600-m sample tunnel is divided into 3 rock classes (A2, B2, C2) with 200 meters each to make an accurate and analytical cost comparison.

For both waterproofing methods, each work item is detailed separately, and the cost calculation is made according to the unit price list of the General Directorate of Highways of Turkey. All work items used for this calculation and their descriptions, amounts and application prices are given in Table-8.

Cost calculations are based on 2 main subjects. Such as material and workmanship costs. Material cost includes the amount of shotcrete, metal materials (steel pipe, bolt, reinforcement, etc.), PVC materials (PVC-membrane, drainage pipes, etc.) and coating concrete for DSW method. For the SSW method, steel fiber reinforcement and liquid membrane costs are included. PVC materials, steel mesh and final coating concrete costs are also deducted. The prices used for cost calculations involve both material fees and labor fees of construction.

Figure 2. Total displacement of C2 class single shell method in dynamic conditions (Gök, 2021).

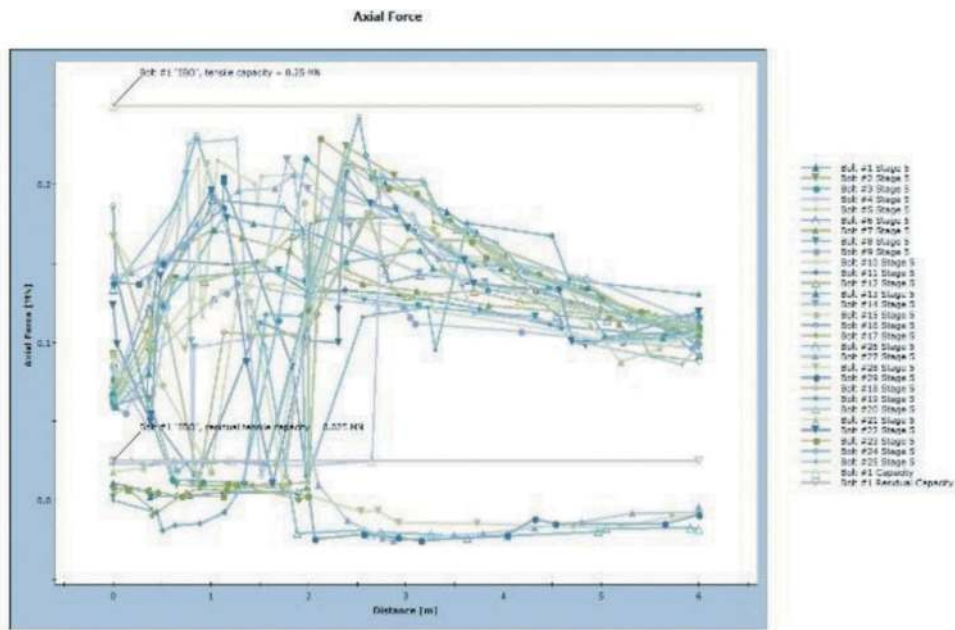

Figure 3. Bolt axial stresses of C2 class single shell method (Gök, 2021).

According to these cost calculations, the 600-meter tunnel constructed with SSW method is found to be costly. However, the financial difference between the two methods remains very low compared to the total cost of the project which is approximately 2.5%. In addition, labor cost savings resulting from the use of steel fiber reinforcement and liquid membrane instead of mesh and PVC membrane applications are not included in the cost calculation. On the other hand, it is expected that tunnel construction will be accelerated by 20-30% thanks to the elimination of mesh and

PVC membrane applications, and this will also directly affect the labor costs (Arioğlu et al, 2008)

3.3 The comparison of two waterproofing methods in terms of occupational health and safety of workers

Occupational health and safety must be prioritized, regardless of the method used during tunnel construction. One of the most significant advantages of the SSW method is the occupational health and safety it offers.

Table 5. Compressive stresses in 3 rock classes for double shell and sprayed single shell without secondary lining (Gök, 2021).

COMPRESSIVE STRESSES				
	The Double Shell (without coating concrete)		The Sprayed Single Shell (without second- ary shell)	
	Maximum (kg/cm ²)	Minimum (kg/cm ²)	Maximum (kg/cm ²)	Minimum (kg/cm ²)
A2	129.12	110.88	129.12	110.88
B2	154.00	79.34	157.33	82.67
C2	214.48	189.52	214.48	189.52
<i>Calculated with Maximum Axial Force Value.</i>				
C2	208.8	-40.80	210.72	-42.72
<i>Calculated with Maximum Bending Moment</i>				

Table 6. Compressive stresses in 3 rock classes for double shell and sprayed single shell with secondary lining (Gök, 2021).

COMPRESSIVE STRESSES				
	The Double Shell (+ 40 cm coating concrete)		The Sprayed Single Shell (+20 cm secondary shell)	
	Maximum (kg/cm ²)	Minimum (kg/cm ²)	Maximum (kg/cm ²)	Minimum (kg/cm ²)
A2	13.44	13.22	24.36	23.64
B2	34.60	29.04	58.29	44.57

workers who work on the platform and/or scaffold during the application of the DSW method.

It is possible to prevent fatal or injury-inducing work accidents that may occur due to falls from the scaffold or platform during the installation of PVC membrane or steel mesh by choosing the SSW method. Moreover, opting for the sprayed SSW method will provide a significant advantage, both in terms of enhancing worker health and safety and in reducing the optimal costs allocated for worker health and safety.

While applying the liquid membrane, there is a risk of injury or even death due to factors such as hearing loss (noise exposure), eye discomfort (eye contact), or potential equipment malfunctions during the spraying process. However, these risks can also be encountered during the application of shotcrete in the DSW method. These accidents are not related to the type of material but to the spraying mechanism.

4 CONCLUSIONS

In this study, two fundamental waterproofing methods used during tunnel construction are examined. A comparison of DSW and SSW methods is given in terms of operational, stability and cost details. To make a more understandable comparison, two waterproofing methods are applied to a 600-meter-long sample tunnel with rock classes A2, B2 and C2. As a result, it is seen that these two methods have their specific solution proposals under appropriate conditions. It also has been concluded that both methods have advantages and disadvantages. Although SSW method is more costly than the traditional method, it has been determined that this innovative method is quite fast and reliable. According to the results of the finite element analysis, compared in terms of stability, these two methods showed almost no difference in terms of performance in the stationary (static) condition. However, it has been determined that DSW method is more stable in the dynamic state. Since the

SSW method is a more mechanized method than the traditional method, accidents that may occur during PVC-membrane application can be avoided. In the liquid membrane construction phase, occupational safety increases as the labor requirement decreases significantly. When the literature studies, analysis studies, and cost calculations for the 600-meter-long sample tunnel with three different rock classes were examined, the following results were obtained;

-Although PVC-membrane has a low cost and effective waterproofing performance, sprayed liquid membrane can be preferred in terms of ease of application and time-saving.

-Although the use of PVC-membrane is advantageous in projects with standard tunnel walls, it was emphasized that the use of a single shell spraying would be a much more effective method in tunnels with complex geometries or corners. Moreover, the tunnel construction time is expected to be reduced by

35% (23% steel mesh additional >10% liquid membrane) thanks to the use of steel fibre and liquid membrane. This acceleration will provide a cost advantage.

-Groundwater must be completely drained for the SSW system to be efficient, otherwise, it will not be possible to achieve the desired performance.

-One of the biggest advantages of the SSW method is to contribute to occupational health by reducing work accidents.

- “Falling from a platform or scaffolding” or “dropping material” are the most common occupational accidents in construction. Such accidents will not occur in the SSW method, since there is no platform established for PVC-membrane application or a welding machine to be used.

-As the quality of the rock mass decreases, the feasibility of the utilization of SSW method also decreases. For weak and extremely weak ground

conditions, double shell supporting method and traditional waterproofing are recommended.

-These two methods could be used as hybrid thanks to the adhesion of the liquid membrane on the PVC-membrane and the traditional method could be preferred if the water drainage is delayed.

ABSTRACT: Ethylene-propylene-diene monomer (EPDM) Rubber gasket, as the key material of waterproof system of shield tunnel joint, will inevitably cause aging damage and reduce waterproof performance with the increase of service time. Moreover, the erosive marine environment will accelerate this damage. Based on the research background of subsea shield tunnel, the accelerated aging test of artificial seawater was carried out, and the attenuation law of tensile properties and the change of micro-morphology of the material were obtained. The constitutive model parameters of the aged rubber material were obtained by fitting, and the accuracy of the results was verified by combining with the finite element model.

Keywords: waterproof performance, shield tunnel, sealing gasket

1 INTRODUCTION

With the rapid development of China's economy and the progress of construction technology, more and more cross-sea and cross-river tunnels are being built. Waterproofing of shield joint is the most critical factor affecting the service safety of shield tunnel. (Ding et al., 2017; Gong et al., 2020) EPDM (Ethylene-propylene-diene monomer) rubber gasket, as the main part of the waterproof system of shield joints, will inevitably cause aging damage with the increase of service time, resulting in leakage accidents. (Shi et al., 2015; Gong et al., 2019) Especially in the erosive marine service environment, the aging of rubber materials will be more significant (Wang et al., 2020).

In order to study the durability of rubber gasket materials, a large number of artificial accelerated aging tests were designed and carried out. Based on thermo-oxidative aging test, unrecoverable damage characteristics (Leng et al., 2021) and molecular structure changes (Li et al., 2020) of gasket rubber materials were analyzed. Based on hydrothermal aging test, mechanical properties (Shi et al., 2015; Johlitz et al., 2020) attenuation law and stress relaxation law (Liu et al., 2022) of rubber materials were studied, and a series of constitutive models were established to analyze mechanical properties changes

of gasket rubber materials under thermo-oxidative aging and hydrothermal aging (Guo et al., 2023; Wang et al., 2023).

In view of the research on the aging properties of rubber gasket materials, the methods of thermal oxygen aging and hydrothermal aging are mainly used, which can not simulate the real Marine service environment. In addition, a large number of studies have focused on the physical and chemical properties of rubber materials after aging, and there is a lack of research on the parameters of the constitutive model of materials after aging in Marine environment.

In this paper, artificial seawater accelerated aging test was designed to simulate the service environment of rubber material in undersea tunnel. Tensile test and scanning electron microscope test were conducted for the rubber material after aging. The constitutive parameters of rubber material after seawater aging were analyzed, and the accuracy of constitutive parameters was verified by finite element model.

2 EXPERIMENTAL METHOD

2.1 Materials

The EPDM rubber sample used in this study is produced by Beijing Oriental Yuhong Waterproof

*Corresponding author: 224812345@csu.edu.cn; geyy@yuhong.com.cn

Technology Co. Ltd., and its main performance indexes are shown in Table 1. The samples were cut into standard dumbbells for tensile and aging tests, as shown in Figure 1. The sample has a thickness of 2mm and a length of 75mm. The width of the drawing section is 4mm, and the drawing gauge distance is 20 mm.

Table 1. Performance indicators of EPDM rubber.

Item	Index
Shore hardness/ H_A	67
Tensile Strength T_s / MPa	≥ 10
Elongation at break E_b / %	≥ 330

Figure 1. Test samples of EPDM.

2.2 Seawater accelerated aging test

For subsea shield tunnel, the gasket is in contact with seawater for a long time. Therefore, the seawater accelerated aging test is designed to simulate its performance changes in the marine service environment. The conditions of seawater accelerated aging test are shown in Table 2. The three aging temperatures are 55°C, 65°C and 75°C respectively, and the five aging times are 24, 48, 72, 96 and 168 h respectively.

Table 2. Aging conditions of EPDM sample.

Aging conditions	Index
Aging temperatures/ °C	55, 65, 75
Aging time/ h	24, 48, 72, 96, 168

Artificial seawater is configured according to ASTM D41141-98(2021). In order to prevent artificial seawater from damaging instruments and equipment, dumbbell samples were put into a high-temperature resistant plastic box filled with artificial seawater, and then the plastic box was put into an SME7000-JY constant temperature water tank for accelerated aging test of samples.

2.3 Tensile test

The tensile property of EPDM rubber gaskets was tested on a CMT4104 universal testing machine by following the standard ASTM D412. In the experiment, extensometer was used to measure the deformation of the stretching section, and the standard distance of extensometer was 20 mm. The maximum range of force sensor is 250N, and the loading rate of tensile test is 500mm/min.

The force-deformation curves, tensile strength T_s and elongation at break E_b of five samples in each group were recorded.

Figure 2. Tensile Test. (a) Universal testing machine. (b) Sample before test. (c) Sample breaking.

2.4 Scanning electron microscope (SEM) analysis

The microstructures of EPDM samples were observed with a Quanta 250 FEG scanning electron microscope (SEM) at the acceleration voltage of 15 kV. The surfaces were ion beam sputter-coated with gold with layer thickness of 1–20 nm.

3 TEST RESULTS AND ANALYSIS

3.1 Mechanical properties

The average tensile strength T_s and elongation at break E_b of five samples after aging are obtained through tensile test as shown in Figures 3 and 4. Results On the surface, at the initial stage of aging, the tensile strength T_s and elongation at break E_b decreased rapidly, which was due to the molecular chain rearrangement caused by rubber molecular chain scission under the action of thermal-seawater environment. With the

extension of aging time, the tensile strength of rubber is improved, mainly due to the hardening of rubber materials caused by aging. However, after a slight increase, the elongation at break E_b generally shows a downward trend, which indicates that with the increase of aging time, the properties of rubber develop to brittleness, and the higher the aging temperature, the more obvious the decrease of elongation at break.

Figure 3. Tensile strength T_s of aged samples.

Figure 4. Elongation at break E_b of aged samples.

3.2 Microscopic surface morphology

The surface morphologies of EPDM samples after seawater ageing were shown in Figure 5. For the unaged EPDM sample, the surface characteristics are smooth and flat (Figure 5 (a)). At the initial stage of aging, the initial defects on the surface of the sample began to expand, forming some larger holes (Figure 5 (b)). With the extension of aging time, the surface of the sample began to become rough, and the number and size of cracks and defects gradually increased (Figure 5 (c),(d)). This phenomenon may be caused by the volatilization of small molecular additives in rubber materials and the interface between inorganic fillers and EPDM substrate during seawater aging. In a word, seawater aging will lead to structural damage of EPDM rubber material, which will affect the mechanical properties of the samples.

4 CONSTITUTIVE MODEL OF SEAWATER AGING RUBBER

4.1 Mooney-Rivlin model parameters

Mooney-Rivlin model, as one of the most widely used rubber constitutive models, is suitable for simulating rubber deformation behavior with strain less than 100%. A large number of scholars obtained the model parameters of Mooney-Rivlin by fitting the experimental data, which verified the accuracy of the model. The expression of Mooney-Rivlin model is as follows:

$$W = C_{10}(I_1 - 3) + C_{01}(I_2 - 3) \quad (1)$$

where W is the strain energy density function, and I_1 and I_2 are the two strain invariants of the Green deformation tensor. C_{10} , C_{01} are the material parameters of the Mooney-Rivlin model.

For uniaxial tensile test, the engineering stress σ has the following relationship with the extension ratio λ (Gent, 2002):

$$\sigma = 2(C_{10} + C_{01}\lambda^{-1})(\lambda - \lambda^{-2}) \quad (2)$$

Where $\lambda=1+\varepsilon$, ε is the strain of tensile test.

Equation (2) can be rewritten as:

$$\frac{\sigma}{2(\lambda - \lambda^{-2})} = C_{10} + C_{01}\lambda^{-1} \quad (3)$$

The stretching curve is converted into the form of equation (3), and linear fitting is carried out by least square method. The slope and intercept of the straight line obtained by fitting are C_{01} and C_{10} .

The calculation of C_{01} and C_{10} values at different aging temperatures and times are shown in Figures 6 and 7.

4.2 Comparison of experimental and simulation results

In order to further verify the rationality of the constitutive parameters obtained from the test, the finite element model of rubber specimen tension is established by ABAQUS. The rubber parts in the model have the same size as the experimental materials, and the element type is C3D8R, which is solved explicitly by dynamic method. The meshing of the model is shown in Figure 8.

The boundary conditions of the model are shown in Figure 9, with fixed constraints at one end of the sample and displacement-controlled loading at the other end. The distance between section A and B in the model is 20mm, which is consistent with the extensometer distance of the tensile test. In the post-processing, the displacement difference between the two sections of A and B is extracted as the deformation of the sample.

The constitutive parameters were obtained by fitting in section 4.1, the unaged sample and the

(a) unaged sample

(b) aged for 24 hours at 75°C

(c) aged for 24 hours at 75°C

(d) aged for 24 hours at 75°C

5 CONCLUSION

In this work, EPDM rubber, as the main waterproof material of subsea shield tunnel, was subjected to the seawater accelerated aging test and the tensile test after aging. The main conclusions are as follows:

1. After aging, the tensile strength of rubber materials decreased rapidly at first, and then increased gradually due to the hardening effect of rubber.

2. With the increase of aging time, the elongation at break of rubber materials generally showed a downward trend.
3. Seawater aging will damage the microstructure of materials, and then reduce the mechanical properties of materials.
4. The Mooney-Rivlin constitutive parameters of the aged rubber material are fitted by the least square method, and the variation law of the constitutive parameters with aging temperature and time is obtained.
5. The finite element modeling is verified by using the fitted constitutive parameters, and the numerical simulation results can well fit the experimental results, with the maximum error of 8.54%.

Research and application of joint waterproofing technology for prefabricated metro station structures

Meiqun Huang, Qi Fan*, Xiuren Yang & Lin Fang

Beijing Urban Construction Design and Development Group Co., Ltd., Beijing, China

National Engineering Research Center for Green & Safe Construction Technology in Urban Rail Transit, Beijing, China

ABSTRACT: The industry has placed significant emphasis on the collective waterproof performance of open-excavated prefabricated station structures. This paper examines the impact and control measures of two significant factors, namely “joint opening” and “gasket dislocation”, which are closely associated with the waterproof performance of prefabricated structures. The multi-line waterproof technologies of “two gaskets + one injection + one embedding” have been thoroughly demonstrated through a combination of experimental research and monitoring results from actual engineering applications. The research and engineering application demonstrate that the waterproofing of prefabricated station structures differs from that of shield tunnels, not only in terms of waterproof structural measures, but also in various control standards. The waterproof sealing gasket, when subjected to an opening amount of 10mm and a dislocation amount of 5mm, is capable of withstanding a water pressure of 1.0MPa. This meets the performance requirements of the station structure, which is buried at a depth of 30m and needs to resist 2-3 times the water pressure. The gaskets exhibit a residual stress value of approximately 67% after a period of 100 years, indicating their ability to withstand long-term water pressure. The double sealing gaskets exhibit a modest enhancement of 20% in performance. The in performance is enhanced by 30% when performance to using a to single sealing gasket. When water leakage occurs in the outer sealing gasket of the lining, the utilization of double sealing gaskets offers notable advantages. According to the current and ongoing projects, the observed maximum joint opening for the station structure and the maximum surface displacement complies with the standards set for controlling the waterproof performance of the joint. There is no evidence of any leakage occurring at the joint, even in the absence of an external waterproof layer.

1 INTRODUCTION

The waterproofing of underground projects, such as subways, has consistently attracted considerable attention from the industry. The subterranean constructions are prone to the extended infiltration of groundwater. If the integrity of the waterproofing system of the structure is compromised, it will not only have a substantial impact on the durability and lifespan of the structure, but also have adverse effects on the functionality of the building and accelerate the corrosion of electrical equipment in the event of groundwater infiltration. Simultaneously, the presence of multiple water leaks can lead to the subsidence of neighbouring layers and have significant implications for the groundwater ecosystem. Numerous engineering projects have provided

substantial evidence of the arduous and costly nature of mitigating leakage in subterranean structures.

The occurrence of water leakage in cast-in-place concrete structures of subway stations is a prevalent issue, which has become a persistent problem. According to Xiao (2021), approximately 90% of cast-in-place concrete stations experience leakage issues. The cost of treating leakage water at each station is estimated to be at least several million, with individual stations incurring costs of nearly 10 million. Upon conducting an investigation into the current state of over a dozen river crossing tunnels constructed in Shanghai, it has been observed that the leakage of the prefabricated tunnel sections, constructed using the shield method, is consistently maintained below 0.1L/m²/d. This leakage rate aligns with the waterproof design specifications for river crossing

*Corresponding author: fanqi@tju.edu.cn

tunnels. Furthermore, the majority of leakage points are concentrated at the joints, grouting holes, and bolt holes. However, in the case of cast-in-place concrete tunnel sections constructed using alternative construction methods, there remains a lack of adequate leakage control. This is primarily attributed to the significant leakage observed at the construction joints and contraction joints that are specific to cast-in-place structures (Wu et al., 2013).

The shield tunnel is considered to be the most exemplary fabricated underground structure. The shield method is extensively employed in the construction of tunnel engineering projects in various sectors such as railways, highways, subways, water conservancy, and municipal infrastructure. This construction method is applicable for both land and underwater construction scenarios, as well as diverse engineering geological and hydrogeological conditions. In recent years, the field of shield tunnel construction in China has experienced significant advancements. Notably, there has been a notable increase in the construction of underwater tunnels with large diameters and high water pressure. For instance, the Qiongzhou Strait Tunnel, which has a diameter of 15.9m and experiences a maximum water pressure of 1.7MPa, presents a formidable challenge for ensuring the waterproofing of shield tunnel segment joints (Chen, 2014).

In China, the construction technology of shield tunnel has undergone significant advancements over the past fifty years, starting with the construction of the Dapu Road River Crossing Tunnel in Shanghai in 1965. During this period, the joint waterproof technology has also experienced continuous development, resulting in notable achievements in waterproof theory, gasket material selection, and setting methods (Zhou, 2004). Zhou (2004) provided a comprehensive analysis of the effectiveness, composition, manufacturing process, cost-effectiveness, and current applications of elastic rubber gaskets, water swelling rubber gaskets, and composite rubber gaskets. The study highlighted the growing complexity and diversity of seal section structures in order to meet the rising requirements for segment joint water pressure, opening, and dislocation. It was noted that the porous elastic gasket, which is primarily made of ethylene propylene diene monomer (EPDM), has emerged as the dominant choice in this field. China's current national standard for shield tunnel engineering includes a provision specifying that the waterproof gasket must be constructed using either EPDM rubber or a composite material consisting of water swelling rubber and EPDM rubber. It is noteworthy that the establishment of a comprehensive set of design and construction methods, as well as technical systems, for the waterproofing of shield tunnel segment joints has been achieved. This includes aspects such as design, construction, and quality control, as outlined in the following standards: GB/T51438-2021 (2021), GB50108-2008 (2008), GB50157-2013 (2013), and GB/T51310-2018 (2018).

Following the successful construction of the initial prefabricated station for the Changchun metro, the presence of numerous connection joints has brought attention to the critical issue of waterproofing in the prefabricated station structure. This matter has garnered significant interest within the industry. Currently, there are six operational prefabricated stations in the Changchun Metro. From the operational data collected at the stations, it has been observed that the maximum groundwater level at the site is approximately 1.5 meters below the surface. The prefabricated station structure exhibits a lack of leakage at the joints in the absence of an external waterproof layer. Water leakage was observed exclusively in the arch of the initial test station, attributed to insufficient sealing measures implemented for the longitudinal tensioning channel of the first ring. After a series of timely improvements in each station during the subsequent period, there was no recurrence of a similar phenomenon. The waterproofing of the prefabricated station structure of Changchun Metro has been found to fully comply with the waterproof technical requirements outlined in the design and specifications, successfully achieving the intended objective (Yang, 2022).

2 DESIGN OF JOINT WATERPROOFING FOR PREFABRICATED STATION

2.1 Prefabricated station joint

The connection method used for the prefabricated station structure is comparable to that of the shield tunnel, as it employs a dry connection process. The connection of prefabricated concrete components involves the direct alignment and interlocking of joint mating surfaces, which can take various forms including mortise joints, flat joints, or lap joints.

As depicted in Figure 1, the grouted mortise joint represents a novel form of dry joint that has been specifically designed for the prefabricated station lining structure. The connection interface of precast concrete components is designed using a tenon and groove system. After the component joints have been aligned and brought into contact, grout is injected into the enclosed gap area created by the waterproof sealing gasket (or isolation rubber) at the joint through the grouting hole. This process ensures that the contact surface of the joint is completely sealed, resulting in

Figure 1. Structure of grouted mortise-tenon joint (single tenon and double tenon).

effective contact. The tenon and groove exhibit complete occlusion, thereby facilitating effective force transmission.

Figure 2 depicts a cross-sectional schematic diagram illustrating the prefabricated station structure of Changchun Metro. The longitudinal joints in the lining structure are formed by 7 internal ring joints. With the exception of the staggered assembly of the arch joint, all other joints are assembled through joints. Among the various joints in the structure, the longitudinal joint of the AB block's bottom plate is secured by applying circumferential prestressed tension. The longitudinal joints of the BC block, CD block, and CE joint on the side wall are primarily compressed by the weight of the components themselves and secured using external bolts. The longitudinal joint of the top arch DE block joint is tightly squeezed through the interaction between the left and right arches, and additional external bolts are employed for locking. The circumferential joints of the station lining structure are formed by inter ring joints, which are assembled through joints and secured by relay type longitudinal prestressed tension.

Figure 2. Structural cross section of Changchun prefabricated station structure.

As a crucial structural measure for the precise positioning control of prefabricated station structure assembly, the installation of positioning pin devices is implemented at all joints within and between the rings of the lining structure. Figure 3 depicts a schematic diagram illustrating the positioning pin device. The positioning pin assumes a critical function in the assembly process by guiding the path of component assembly and ensuring precise assembly accuracy.

Figure 3. Schematic diagram of locating pin rod.

2.2 Technical scheme of joint waterproofing of station lining structure

2.2.1 Joint waterproofing technical scheme

The grouting mortising joint of the assembled station lining structure is designed using the technical scheme of “two gaskets + one injection + one embedding” and includes multiple layers of protection. Figure 4 illustrates the schematic diagram of the joint waterproof structure. Two waterproof gaskets are strategically placed at the joint to effectively provide a sealing mechanism. Grout is introduced into the space between the two gaskets in order to establish a seal that is impervious to water. Additionally, an insert is inserted into the caulking to further enhance its waterproofing capabilities. Among the various components, the waterproof gasket functions as the primary barrier against water infiltration, while grouting and other measures are employed as supplementary methods to enhance waterproofing.

Figure 4. Joint waterproof of grouted mortise-tenon joint.

2.2.2 Waterproof gasket

(1) Materials. The two waterproof sealing gaskets utilize the commonly used EPDM elastic sealing gasket as the primary waterproof material. Additionally, water swelling rubber is incorporated to enhance the waterproofing capability, resulting in a composite porous and multi-groove sealing gasket, as depicted in Figure 5. EPDM rubber exhibits excellent microwave heat vulcanization processing ability, as well as notable durability and cost-effectiveness. The incorporation of composite water swelling rubber improves the waterproof capabilities of the sealing gasket. Additionally, the material used in the composite sealing gasket adheres to the applicable regulations outlined in the current national standards.

(2) Classification of Section Type. The circular hole is chosen for the inner hole of the sealing gasket section, while the bottom hole of the plate is designed with a consistent groove shape. The width of the bottom structure measures 42mm, while the top structure measures 30mm. The rubber material expands by 2mm when in contact with water, and

the overall height after composite is 18mm. The cross-sectional area of the sealing gasket groove should be equal to or greater than the net cross-sectional area of the sealing gasket, with a ratio of 1 to 1.15. This ensures that when the joint opening is 0mm, the sealing gasket can be completely compressed into the groove.

Figure 5. Joint waterproof of grouted mortise-tenon joint.

2.2.3 Analysis of index of joint opening and dislocation

Based on the assumption that the joint utilizes a tenon groove structure and is furnished with a positioning pin device, the variation in component manufacturing precision and the intricate configuration of the structure significantly influences the displacement of the sealing gasket and surface misalignment. The disregard of assembly construction and the neglect of the influence of the structural stress state can have significant consequences. The theoretical dislocation amount of the sealing gasket primarily arises from the positioning deviation of the sealing gasket groove center, which is $\pm 0.5\text{mm}$, and the positioning deviation of the positioning pin rod center, also $\pm 0.5\text{mm}$. Simultaneously, it is imperative to incorporate a reserved gap of 0.5mm for the positioning pin rod, while the theoretical maximum value for dislocation control is 3mm . The theoretical analysis suggests that the extent of surface dislocation in the structure is primarily accounted for by a thickness deviation of -1mm . During the manufacturing process of the component, there is a deviation of $+3\text{mm}$ in the center positioning of the positioning pin rod, with a tolerance of $\pm 0.5\text{mm}$. Additionally, a gap of 0.5mm is reserved for the pin rod. The theoretical maximum value for controlling surface dislocation is 6mm . Among these challenges, controlling the precision of component thickness production proves to be difficult, as the allowable deviation value is relatively large. Consequently, this leads to a greater displacement of its control index when compared to the waterproof sealing gasket. From the empirical observation of the project's assembly process, it is evident that the utilization of the positioning pin rod in the joint has resulted in a highly accurate positioning effect. This has led to a relatively optimal control of surface dislocation in the structure, both longitudinally and circumferentially. The measured values typically range between 0.3mm and 4mm .

The measurement of the waterproof sealing gasket, which is located inside the joint, is not possible directly. Instead, it can only be assessed through the surface dislocation index. Therefore, in practical implementation, the control criterion for surface

dislocation has been suitably elevated, resulting in the attainment of equal values for both parameters. When designing and conducting performance tests on the waterproof sealing gasket, it is recommended to utilize the surface dislocation standard as a means of control. It is advisable to assign a control index value of 5mm for the surface dislocation of the structure.

3 EXPERIMENTAL STUDY ON WATERPROOF PERFORMANCE OF JOINTS

To assess the waterproof capabilities of the chosen waterproof sealing gasket and establish the corresponding performance parameters, a comprehensive set of tests was carried out on a singular composite sealing gasket in Changchun before the construction. These tests encompassed evaluations of temperature adaptability, water pressure resistance, stress relaxation, and compression load. Figure 6 depicts the schematic diagram of the waterproof sealing gasket and testing device. The test utilizes a sealing gasket measuring 200mm in length, in conjunction with a steel structure testing device featuring an end plate. The speed at which the loading displacement occurs is $50\text{mm}/\text{min}$.

Figure 6. Waterproof sealing gasket and experimental device.

3.1 Water pressure resistance test

Based on the above analysis of the control indicators for joint opening and sealing gasket dislocation, in order to study the waterproof performance of sealing gaskets under different splicing conditions, experimental tests were conducted on the waterproof performance of sealing gaskets corresponding to different joint opening amounts under 5 different conditions, including sealing gasket dislocation amounts of 0mm , 5mm , 10mm , 15mm , and 20mm . Figure 7 shows the water pressure resistance curve of a single composite sealing gasket under different opening and dislocation conditions. The analysis of the test results is as follows:

- (1) When the joint is opened by 0mm and misaligned by 0mm , the ultimate water resistance pressure of a single sealing gasket is measured to be 2.6MPa . The experimental observation indicates that the joint is completely sealed at this particular moment. Subsequently, additional pressure testing was carried out, revealing an occurrence of adhesive separation between the sealing gasket and the surface of the steel mold

Figure 7. Water pressure resistance curve of single composite sealing gasket under different opening and dislocation conditions.

base. The adhesive's compressive strength limited its capacity to enhance the water pressure resistance of the sealing gasket.

- (2) When the joint is opened by 10mm and misaligned by 5mm, the ultimate water resistance pressure of a single sealing gasket is 1.0MPa. This opening and dislocation surpass the prescribed maximum control index of 8mm for joint opening and 3mm for sealing gasket dislocation in prefabricated station structures.
- (3) Typically, for underground stations with two or three stories, the depth at which the bottom plate is buried is less than 30m, and the maximum water pressure does not exceed 0.3MPa. According to the test results, it has been determined that the single sealing gasket has the ability to withstand a maximum head pressure of 0.3MPa. When the dislocation reaches 5mm, the permissible opening amount is 16mm. It can withstand twice the maximum head pressure of 0.6MPa. Similarly, when the displacement is 5mm, the allowable opening amount is 13mm. In this case, it can resist three times the maximum head pressure of 0.9MPa. Furthermore, when the displacement is 5mm, the permissible opening amount is approximately 10.6mm.

The influence of the displacement of the sealing gasket on the water pressure performance is less significant compared to the opening of the joint. However, when the displacement reaches 15mm, particularly 20mm, the water pressure performance experiences a notable decline in comparison to other types. This decline is primarily attributed to the width of the sealing gasket. The width of the sealing gasket utilized in the experiment measures 42mm. When the displacement is limited to one-third of the sealing gasket width, the increase in displacement does not have a significant impact on the water pressure resistance performance. However, if the displacement exceeds half of the sealing gasket width, there is a significant decrease in water pressure resistance performance.

According to the pertinent regulations outlined in the current national standards of China, it is

imperative for the sealing gasket to adhere to specific performance criteria. This includes the ability to withstand a water pressure that is 2-3 times greater than the buried water head, taking into consideration the maximum opening and estimated displacement as per the design specifications. Based on the analysis and experimental research conducted on the comprehensive opening and displacement control indicators, a performance standard of 0.6MPa for resistance to water pressure is recommended for prefabricated station structures buried at a depth of 30m.~A pressure of 0.9MPa is necessary. The single composite water-proof sealing gasket demonstrates the ability to withstand water pressure of 1.0MPa, while maintaining an opening of 10mm and a displacement of 5mm, thus satisfying the specified requirements.

3.2 Stress relaxation detection

The durability of elastic sealing gaskets is significantly influenced by the stress relaxation occurring during long-term compression. In order to ensure the long-term effectiveness of the sealing gasket, it is necessary to conduct stress relaxation testing on the gasket. The present study employed the high-temperature accelerated aging technique to examine the long-term compressive residual stress levels of a singular composite sealing gasket under varying service life conditions. Figure 8 depicts the compressive stress relaxation detector along with the schematic diagram illustrating the stress residual curve. From the stress residual curve, it is evident that the stress relaxation of the sealing gasket exhibits a more pronounced effect in the initial phase, but gradually slows down in the subsequent stages. The residual stress ratios of the sealing gasket after 100 and 200 years are 67% and 63%, respectively.

If the station structure is designed with a buried depth of 30m, in accordance with the standard for withstanding a water head of 100m (1.0MPa), it indicates that the sealing gasket's residual resistance capacity after 100 and 200 years is 67m (0.67MPa) and 63m (0.63MPa) respectively. These values still largely satisfy the specifications' requirements. This observation suggests that the sealing gasket utilized in the experiment possesses the capability to fulfil the prolonged water pressure criteria, thereby demonstrating satisfactory water resistance performance.

Figure 8. Compression stress relaxation tester of single composite sealing gasket and stress residual curve.

3.3 Compression load test

The maximum compressive stress index of the sealing gasket serves as the governing criterion for determining the maximum tensile load designed at each tensioning point of the prefabricated station structure. Compression load tests were conducted under various compression and dislocation conditions. Figure 9 presents the schematic diagram illustrating the compression load strain curve of a solitary composite sealing gasket. The experimental results indicate a significant correlation between the compression amount and the compression load. Specifically, as the compression amount increases, the compression load also increases, demonstrating a nearly linear relationship. On the other hand, the displacement has a minimal effect on the compressive load, particularly when the displacement is less than 5mm, as it is not statistically significant. When the displacement exceeds 10mm, there is an inverse relationship between the magnitude of displacement and the compressive load. When the displacement is 0mm and the compression reaches 16mm, the maximum compression load is 38kN/m. Similarly, when the displacement is 5mm and the compression reaches 16mm, the maximum compression load is 36kN/m. The maximum compressive stress index of a single composite sealing gasket should not exceed 40kN/m.

Figure 9. Compression load strain curve of single composite sealing gasket.

3.4 Research on waterproof performance of dual waterproof sealing gasket

The design dimensions of prefabricated station structural components are relatively large, and the joint section is also large. Double waterproof sealing gaskets are recommended for installation at the joints. In order to investigate the waterproof performance characteristics of double sealing gaskets, a novel testing apparatus was specifically developed. Comparative tests were conducted to evaluate the waterproof performance of both double and single sealing gaskets under various operating conditions. Figure 10 depicts the schematic diagram of the test apparatus used to evaluate the waterproof performance of dual sealing gaskets. A pressure gauge is incorporated between the inner and outer channels in order to measure the pressure within the outer channel. The initial measurement is determined using a standardized experimental block of a specific thickness, while the displacement measurement is adjusted through the mutual translation of the mold.

Figure 10. Experimental device of waterproof performance for double sealing gaskets.

The analysis of the test results is presented below:

- (1) Comparative Analysis of Water Pressure Resistance. The comparison test conducted to evaluate the water pressure resistance under various working conditions reveals that the double seal gasket exhibits a slight improvement in water pressure resistance compared to the single seal. The improvement rate ranges from 20% to 30% when considering the same opening and displacement.
- (2) An experiment investigating the correlation between the opening amount and the opening amount. The experiment aims to evaluate the maximum opening capacity by subjecting the system to various working conditions while maintaining consistent water pressure and displacement. Experiments have demonstrated that, when subjected to identical water pressure and displacement conditions, the maximum permissible aperture of a dual sealing gasket can be augmented by approximately 25% in comparison to a single sealing gasket.
- (3) Experiment on the relationship between displacement and distance traveled. In order to conduct the experiment, it is necessary to establish consistent water pressure and opening amounts across multiple working conditions. The objective is to measure the maximum displacement achieved. Experiments have demonstrated that, when subjected to identical water pressure and opening conditions, the maximum permissible displacement of a dual sealing gasket can be enhanced by approximately 30% in comparison to a single sealing gasket.

Based on the aforementioned three sets of test results, it is evident that the dual seal gasket exhibits limited waterproof performance in comparison to the single seal gasket. The improvement rate ranges between 20% and 30%, indicating that the relationship between the two is not simply additive ($1+1=2$). The significance of a dual sealing gasket becomes apparent when there is a local water inrush from the outer sealing gasket of the lining.

4 CONCLUSIONS

The lining structure of the prefabricated station utilizes a grouting tenon joint, which incorporates a waterproof technical approach known as “two gaskets + one injection + one embedding”. The utilization

of double waterproof sealing gaskets involves the application of EPDM elastic sealing gasket as the primary waterproofing component, while composite water expansion rubber serves as the reinforced waterproofing element. The composite expansion rubber sealing gasket functions as the primary defence mechanism for the joint, with grouting and caulking serving as supplementary defence mechanisms for the joint.

Based on an analysis of the characteristics of prefabricated stations' structure, component manufacturing, and construction technology, as well as an examination of the factors influencing opening and dislocation, this study draws conclusions by considering experimental research on the waterproof performance of sealing gaskets and monitoring results from actual engineering applications:

- (1) The waterproofing of prefabricated station structures differs from that of shield tunnels in terms of construction measures and control standards for joint opening and sealing gasket dislocation. Research findings indicate that an initial opening amount of 10mm and a dislocation amount of 5mm serve as appropriate indicators for effectively managing the waterproof performance of joints in prefabricated station structures.
- (2) A solitary waterproof sealing gasket, featuring a 10mm opening and a 5mm displacement, exhibits the ability to withstand a water pressure of 1.0MPa. This performance meets the requirements for a station structure that is buried at a depth of 30m and is designed to resist 2-3 times the water head pressure. After a century of utilization, the material continues to exhibit a residual stress level of approximately 67%. Furthermore, it demonstrates the ability to withstand a water pressure of 0.6MPa and exhibits long-term resistance to water pressure.
- (3) The double channel waterproof sealing gasket exhibits a relatively modest enhancement in waterproof performance when compared to the single channel sealing gasket, with an improvement rate ranging from 20% to 30%. Nevertheless, the significant advantages of the double channel sealing gasket become apparent when there is a local water inrush in the outer channel sealing gasket of the lining.
- (4) The composite porous multi-groove sealing gasket, which exhibits a maximum compressive stress of 40kN/m when fully compressed, can serve as a benchmark for determining the assembled tensile load value of prefabricated structures.
- (5) The influence of the displacement of the sealing gasket on the water pressure performance is comparatively less significant when compared to the joint opening. When the displacement is limited to less than one-third of the sealing gasket width, there is no significant decrease in water pressure performance. However, if the displacement exceeds half of the sealing gasket width, there is a significant reduction in water pressure resistance performance.
- (6) Given that the waterproof sealing gasket is positioned within the joint, the attainment of accurate measurement and monitoring in practical

engineering becomes challenging. When examining the surface dislocation standard that encompasses the dislocation standard of the sealing gasket, the design and performance evaluation of the waterproof sealing gasket can be regulated by considering the surface dislocation.

- (7) From the analysis of the structural engineering of prefabricated stations in China, both those that have been completed and those currently under construction, it is evident that the absence of an external waterproof layer does not result in water leakage at the joints. The majority of longitudinal joints in the measured structure have a maximum opening that is consistently below 5mm. However, the longitudinal joint located on the arch top of the station reaches a maximum opening of 6mm. In terms of the measured circumferential seam, the maximum opening is generally controlled below 7mm, although there are some points that reach 8mm. The measured surface dislocation of the structure can be effectively controlled below 4mm, which demonstrates compliance with the joint waterproofing performance control standard.

Innovative waterproofing system for shallow underground structures

Dmitry S. Konyukhov*, Tengiz E. Kobidze* & Oleg B. Krymov
Mosinzhproekt JSC, Moscow, Russia

ABSTRACT: One of the topical problem of underground construction is the protection of underground structures from water encroachment. The problem is based on the impossibility to apply traditional waterproofing materials for underground constructions (bituminous-polymer rolls, polymer sprayed compositions) on inaccessible exterior insulated surfaces of runway slabs and wall structures constructed in open pits without slots for backfilling. Before the erection of supporting structures, the waterproofing coating is laid on the accessible surfaces of the concrete preparation and “wall in the ground”. This eliminates the adhesion of the waterproofing coating on the outer surface of the protected structures and results in the formation of a gap between the waterproofing and the protected structure. In the case of damage or defect of the waterproofing coating, the seeping ground waters migrate uncontrollably along the formed joint and penetrate into the building. The report presents the results of scientific and practical work performed in the Mosinzhproekt JSC to eliminate the mentioned problem, including the development of design and technological solutions using the methods of voile injection and manufacture of a two-layer seamless waterproofing membrane in the building environment as well as making changes to the effective regulatory and technical documents of the Russian Federation.

1 INTRODUCTION

Among the actual problems of modern tunnelling, an important place is occupied by the prevention or elimination of flooding of underground transport structures during their construction by open and semi-closed methods (hereinafter we will refer to all underground structures as such). In this case, waterproofing protection is completely excluded, which results in the loss of water tightness and maintainability of structures, and violates the conditions of safe operation of such structures.

The reason for this problem is the design limitations in the use of such traditional for underground construction waterproofing materials as bitumen-polymer spreading roll materials and sprayed polymer compositions based on bitumen-polymer composites, polyuria, methylmethacrylate resin – the most widespread and supported by the regulatory framework (CS 120.13330.2012, 2012; CS 122.13330.2012, 2012; PS NOSTROI 2.27.123-2013, 2013).

In accordance with the requirements of the normative document of the Russian Federation (PS NOSTROI 2.27.123-2013, 2013) reliable waterproofing of underground structures is provided by laying a coating of spreading and spraying materials directly on the building envelope from the outside (from the side of

groundwater exposure). But adhesive bonding of these materials is achieved only with the surface of the aged (“old”) concrete structure, which must be available for such an operation. This can only be enclosing walls built with backfill slots and pavement slabs (Figure 1).

In the case of tray slabs of any kind, walls constructed without backfill slots and press walls for load-bearing ‘diaphragm wall’, it is necessary (CS 120.13330.2012, 2012; CS 122.13330.2012, 2012):

Figure 1. Variety of methods of construction of underground structures made of cast reinforced concrete: *a* – cut and cover method with backfill slots; *b* – cut and cover method without backfill slots; *c* – cut and cover and semi-closed-cut method with slab (cover) spacing discs, with a load-bearing ‘diaphragm wall’; 1 – buckle (foundation) slab; 2 – bearing wall; 3 – pressure wall; 4 – excavation wall (in part *b* – bearing structure); 5 – floor slab (cover); 6 – cavities for backfilling; 7 – sliding plane (plane of mutual shift of the walls); 8 – concrete foundation mattress.

*Corresponding author: konuhovds@mosinzhproekt.ru; koba1948@mail.ru

- for the waterproofing of the flume slab, the waterproofing coating shall be placed on the concrete preparation;
- when using the technology of a load-bearing 'diaphragm wall' or without backfill slots, the waterproofing shall be laid on the surface of the 'diaphragm wall', and the 'pressure' or permanent wall shall be tightly pressed against the 'diaphragm wall' to absorb the expected hydrostatic pressure.

In practice, based on the design standards in question, waterproofing protection of building envelopes on the groundwater side is provided. However, due to the lack of adhesive bonding with the insulated surface, the waterproofing coating is not able to localise seeping groundwater within the through damage and prevent uncontrolled migration of groundwater across the entire outer surface of the protected structure in case of even a single filtration damage to the coating or techno-coating. Experience shows that this leads to an unrecoverable emergency situation, in particular:

- to complete watering of the outer surface of the insulated structure and penetration of groundwater into the structure through the filtering defects of concrete and the reinforced concrete structure itself (cracks, voids, weakened and highly porous areas of concrete, technological and expansion joints, etc.) in the form of leaks of different intensity and wet spots on the inner surfaces of the structure (Figure 2);

Figure 2. Example of water penetration in a monolithic reinforced concrete tunnel lining in the case of open works without backfill slots and with waterproofing based on traditional technological schemes and materials of adhesive fixing to the concrete foundation.

- loss of reparability of the protected structure, as sealing of one or several filtration defects (possible at continuous adhesive connection of waterproofing with concrete base) leads to an increase of hydrostatic pressure of groundwater; the consequence of this is activation of

“dormant” filtration defects and appearance of new water spots on other parts of the surface of the watered structure.

To exclude the possibility of such emergency situations, contradictions in the rules of design and construction of waterproofing were eliminated. At the same time, amendments were made to the normative and technical documents of the Russian Federation. These documents establish unified rules for reliable and maintainable waterproofing of underground structures and are based on the need to lay the waterproofing coating by adhesive bonding directly on the outer surface of the protected structures regardless of the availability of access to the isolated surface.

As a result, the use of traditional adhesive bonding materials and technological schemes of their laying for waterproofing of enclosing structures with no access to the external surface remains a possible, but not mandatory technical solution, leading to the arrangement of unreliable and unrepairable waterproofing. In this case, there is an urgent need to introduce into practice waterproofing materials of a new generation that meet the updated regulatory requirements.

2 METHODS AND MATERIALS

The Russian market offers a number of innovative waterproofing materials of domestic and foreign production, providing continuous adhesive bond to freshly laid concrete of protected structures of underground structures without access to the external surface. These are tray slabs, wall structures constructed without slots for backfilling of soil and a pressure wall for a bearing 'diaphragm wall' (Figure 3).

These materials include the following:

1. An original waterproofing system based on the use of an innovative waterproofing composite material developed by the authors (Underground construction, 2015; Underground construction, 2016) and combining the technical properties of two initial materials, which were adopted as:
 - sprayed waterproofing polymer compositions with 'two-sided' adhesion, in particular, ethylene vinyl acetate polymer and bitumen-polymer composite of Flexigum brand, providing normative adhesion (over 0.5 MPa according to CS 120.13330.2012) not only with the base of 'old concrete' covered with a layer of sprayed polymer, but also with the external surface of concrete laid as mortar on the finished waterproofing coating. The ability of durable adhesion of bitumen-polymer waterproofing systems to concrete is confirmed by the traditional character of their use in construction, and EVA-polymer – by many years of experience in the construction of multi-layer monolithic transport tunnels of the closed method of works (Kobidze, 2021);

Figure 3. Waterproofing sheet materials (membranes) with adhesion to freshly laid concrete: a – factory-made waterproofing three-layer roll with self-adhesive edges, with surface adhesion layer, including sand sprinkling; b – two-layer roll based on polyvinylchloride membrane with ‘implanted’ surface layer made of fibre material FiberTex; c – roll based on bitumen-polymer composite (front side with sand sprinkling on the right side); d – seamless two-layer waterproofing coating, produced in construction conditions by applying a surface adhesion layer of sprayed compositions with two-sided adhesion to geotextile reinforcing substrate (base) with an outer polyethylene coating.

- geotextile nonwoven needle-punched material with a density of 250-500 g/m² (GOST R 53225-2008, 2008), used as a reinforcing and strengthening element of the polymer coating, as well as the underlying fabric-base for the manufacture of two-layer seamless waterproofing coating (polymer membrane with a base) in construction conditions by spraying a layer of waterproofing composition with a thickness of 4-6 mm on the ready-made geotextile underlying fabric.

Application of sprayed composition with two-sided adhesion and its modification in the form of a two-layer polymer seamless membrane with reinforcing base, as well as the possibility of directional regulation of physical and mechanical properties of the waterproofing coating with reinforcing fabric depending on the problem to be solved provide:

- the possibility of using the waterproofing coating without a protective layer of fine-grained concrete when binding the reinforcement frame and subsequent concreting of the trough slab by hardening the surface layer of the coating with reinforcing geotextile fabric (Figures 4 and 5);
- speeding up the process of waterproofing works, reducing their cost and guaranteeing a continuous adhesive bond of the waterproofing coating with the inaccessible outer surface of the trough slab;
- adhesive bonding of the sprayed polymer layer of the two-layer sprayed membrane with the hard-to-reach outer surface of the walls of structures built without backfill slots;
- safety of such coating on the wall surface in case of subsidence of the underground structure, achieved as a result of free suspension of the

structures with and without access to the external surface, in accordance with the requirements of CS 120.13330.2012;

- b) local character of water penetrations due to continuous adhesive bonding of waterproofing with concrete base. Under these conditions, groundwater penetration into the underground structure is possible when the location of the through damage to the waterproofing coating or process joint and the filtering defect of the enclosing structure coincide. The low probability of such a coincidence increases the operational reliability and safety of underground structures. However, localisation of groundwater in the zone of coating damage and its migration through the filtering defect of concrete simplifies the establishment of a place for local and relatively low-cost work to restore water tightness of the structure by injecting a sealing compound into the filtering defect of concrete.

Technical characteristics of materials and design and technological solutions for the developed

waterproofing system under construction conditions were confirmed during bench tests and recommended for pilot application at the Moscow Metro facilities.

2. A number of Russian companies act as suppliers of foreign roll waterproofing polymer membranes with the ability to provide adhesive bonding to

the inaccessible external surface of protected structures of underground structures. These materials are a polymer with thickness from 2 to 4.5 mm (depending on the raw material – polyethylene, polyvinyl chloride or bitumen-polymer composite, respectively) with a special thin and hardened surface layer that provides:

- adhesive adhesion (over 0.5 MPa) of the waterproofing coating with the surface of freshly placed concrete of protected reinforced concrete structures erected without access to the external surface;
- refusal to install a protective layer of waterproofing made of fine-grained concrete and performance of works on binding of reinforcing frame with subsequent concreting of the trough slab immediately after laying of the waterproofing sheet.

Waterproofing coating of the above materials is made by laying rolls of 10-15 cm overlap and sealing them with the formation of technological joints (Figure 9).

Factory readiness guarantees the consistency of membrane quality characteristics, significantly accelerates waterproofing and general construction works, as well as reduces labour and material and financial costs for their implementation, but the device of technological joints requires their qualitative

performance to ensure the operational reliability of the waterproofing coating.

Figures 10 and 11 show the schemes of waterproofing for underground structures, created without slots for backfilling and with such slots, respectively, with the use of new generation materials under consideration, characterised by the ability of adhesive bonding with freshly laid concrete.

3 CONCLUSIONS

The application of ‘pre-installed’ waterproofing systems (Kobidze) in underground construction is characterised by the fact that it:

1. has no alternative for the application of adhesion bonded waterproofing coating directly onto insulated exterior surfaces that are not accessible when conventional waterproofing systems are installed;
2. eliminates the need to allocate time for ageing and curing of the concrete base, as well as thorough preparation of its surface for the application of waterproofing coating of adhesive fixing and its protection by a layer of fine-grained concrete before concreting the foundation (trough) slab;
3. accelerates the process and reduces the cost of general construction and waterproofing works, eliminates the possibility of continuous flooding of underground structures, increases the reliability, durability and maintainability of waterproofing coatings and safety of underground structures of open and semi-closed construction methods.

Tunnel drainage system and the possibility of non-destructive remediation

Juraj Ortuta* & Viktor Tóth

Amberg Engineering Slovakia, s.r.o., Bratislava, Slovakia

ABSTRACT: Tunnels are an important part of our infrastructure. The performed inspections and subsequent analysis show that currently a large percentage of roads are damaged and require remediation work. Due to the high increase in mobility and thus the use of road networks, this is associated with potential risk and the possibility of systematic fatigue damage. Faults in the drainage system are often one of the main reasons that can lead to damage to roads and reduced traffic safety. Therefore, preventive measures can improve the quality and durability of these structures in the long run. However, the issue is insufficiently addressed. In the construction sector, there is missing professional literature, proven technologies, and finally a wider market with an offer of remediation work for drainage systems. Tunnels and, in general, all underground structures are costly and time-consuming. The focus of increased attention already during the design on the protection of the tunnel against water and the subsequent design of drainage with the entire drainage system is more than on the spot. The article discusses the possibility of non-destructive remediation measures to ensure the safe drainage of groundwater using the tunnel drainage system.

Keywords: Drainage, Technical design, Underground water

1 INTRODUCTION

Tunnels, and all underground structures in general, are financially and time consuming. Focusing increased attention during the design phase on the water protection of the tunnel and the subsequent design of the drainage with the entire drainage system is more than appropriate. In the event of design errors in the form of unfinished details or imperfect construction work caused by the contractor, negative consequences can arise, the direct impact of which is the remediation work during the actual execution of the work or even during the actual use. During the operation of the work, the defects become more widespread, and the rehabilitation of the drainage system becomes necessary.

Groundwater levels, inflows and water properties in the rock environment are essential input parameters for any tunnel protection design. External requirements such as the degree of protection and, more recently, the requirement not to deplete the water in the rock environment are also crucial at this point.

The design of tunnel drainage needs to address waterproofing, proper drainage system as well as roadway drainage. Their implementation is about achieving a completely impermeable structure, where neither leakage nor a disproportionate increase in hydrostatic pressure is permissible.

The drainage system is used to capture seepage water, groundwater, and water during the implementation of linear constructions. The distribution of drainage profiles along the Višňove tunnel was determined on the basis of the hydrogeological conditions of the massif, which were investigated during the tunnelling.

Currently, the largest works on the Višňové Tunnel are underway in Slovakia and therefore we would like to give a few examples of damage to the drainage system and possible remediation recommendations. We are aware that the situation in this tunnel is very sensitive, but the problem described is far from being related only to this tunnel, but it is a global problem for both completed, historic tunnels and tunnels under construction.

2 WATER AS A (DIS)FRIEND

During the construction, as well as during the actual use of tunnel structures, we very often encounter the problem of water in the structures as an undesirable element. A detailed investigation of the surface and subsurface hydrology should therefore be carried out before and during construction. If the negative effects of water are not of a temporary nature and persist during the lifetime of the tunnel, they become an obstacle to the operation and maintenance of the

*Corresponding author: jortuta@amberg.sk

tunnel itself. In coined tunnels there is the problem of seepage water, which accumulates in faulted tectonic rocks and creates aquifer zones and can also have a buoyancy effect in places.

The transport of seepage water to the tunnel structure is certain and there the water degrades the tunnel lining by its long-term action. The increased pH of groundwater in contact with alkaline substances (monolithic concrete, shotcrete, or cement grouting) can cause lime to be expelled. Contact with water saturated with carbon dioxide (aggressive water) causes calcium hydroxide to leach out of the concrete and calcium supersaturated water to form, which then forms solid deposits in the drainage systems Figure 1. (This effect is more common in old tunnels with outdated drainage systems.)

Another problem is freezing, which occurs at portal points and in winter operations up to a depth of several tens of metres, causing subsequent weathering of the rock and the tunnel structure itself. The impact of water pressure and the cyclic freezing of the tunnel results in a gradual erosion of stability, possibly leading to deformation and even destruction of the structure, which can endanger human lives and cause considerable financial damage to property. The necessary step is then to close the tunnel and undergo rehabilitation of the systems.

Current trends in infrastructure (especially tunnelling) vary from country to country. Some countries have set regulations or have specific regulations and standards in place for tunnel drainage, while others have no regulations.

In Slovakia, TP 04/2015 Protection of tunnels against water and drainage of tunnels and TKP Part 26 Tunnels are currently in force. These documents indicate to some extent the method of implementation of drainage systems but are not intended to address more demanding hydrogeological conditions.

Figure 1. Water seepage through cracks in the lining.

3 TUNNEL VIŠŇOVÉ

In the following sections, however, we would like to focus on the drainage system of the tunnels and their rehabilitation. As mentioned earlier, the

topicality of the topic is not only related to the upcoming tunnels, but also to the historic tunnels and, of course, to tunnels where construction works are in progress and the back drainage has been damaged.

Currently, the largest works on the Višňové Tunnel are underway in Slovakia and therefore we would like to give a few examples of damage to the drainage system and possible remediation recommendations. We are aware that the situation in this tunnel is very sensitive, but the problem described is far from being related only to this tunnel, but it is a global problem for both completed, historic tunnels and tunnels under construction.

The Višňové tunnel is located on the territory of the Little Fatra mountain range. The Little Fatra is a 55km long mountain range in the northwestern part of Slovakia, extending south-east from Zilina, following the main arc of the Western Carpathians. The main ridge runs from southwest to northeast. The centre of the mountain range is divided by the Vah Riverbed. At this place, the river created a 12km long narrow valley known as Strečnianska Tiesňava. The altitude of the mountain range along the route of the tunnel being designed as well as the already built tunnel ranges from 800 to 1300m.

The drainage system is used to capture seepage water, groundwater, and water during the implementation of linear constructions. The distribution of drainage profiles along the Višňové tunnel was determined based on the hydrogeological conditions of the massif, which were investigated during the tunnelling. During the excavation of the exploratory tunnel, the groundwater inflows were stabilised at the interface between the carbonate rocks and the crystalline bedrock (stationing approx. 2400 m) at 10 -20 l/s (in the karst system it depends on the intensity of atmospheric precipitation). After breaching the two sections of the adit, the total amount of water flowing to the eastern portal is 150 -220 l/s. The conditions during tunnelling were mainly influenced by changes in hydrogeological conditions. Given the permanent drainage effect of the exploration tunnel, smaller inflows were expected. The strongest water inflows were expected at the contact of the Mesozoic fault zone between Mesozoic and crystalline rocks. It was calculated that depending on the rate of atmospheric precipitation, inflows of 20-100 l/s would occur. In other parts, short-term and local inflows of 0.2 -0.3 l/s were assumed. However, local, and isolated inflows to open karst systems as well as discontinuities and fault zones that were not registered during the survey were not excluded. In crystalline rocks, large inflows to the tunnel tubes were expected in the range of 10 to 20 l/s in individual sections (Figure2 and 3). The strongest inflows were already in the first phase of coining and decreased over time to the current level.

Figure 2. Water in main collector.

Figure 3. Damming and groundwater pumping. Preparation for reconstruction.

4 DRAINAGE SYSTEM AS A CRITICAL PART OF THE TUNNEL

The drainage system of the tunnel secures removal of seepage water from longitudinal drainage pipes behind the extrados of the lining and from the roadway bed. From the point of view of the drainage system concept, two systems are used, i.e.:

- drainage system without a main collector,
- drainage system using a main collector.

The drainage system without a main collector is used mainly in shorter and less water-yielding tunnels, where designing external drainage pipes with a sufficient capacity, without negative effects on the design of the lining, is not a problem.

The drainage system using a main collector is used for longer tunnels and for heavily water-yielding tunnels, where the use of external side drains is not effective.

If possible, the use of the drainage system without a main collector is preferred. At this system, locations of the origination of defects in the roadway (at shafts and manholes) and subsequently the necessity for regular repairing them are significantly reduced.

The diameter of the drainage pipes is determined by a hydrotechnical calculation taking into consideration the amount of water flowing from the rock massif to the tunnel. The diameter of the tunnel side drainage pipeline in the meaning of current regulations must be 200mm as a minimum for the drainage system using a main collector and 250mm for drainage systems without a main collector. The diameter of the drainage pipeline in the other parts of the construction with smaller profiles, for example in cross passages, must be 150mm as a minimum. The diameter of the linking pipeline (transverse linking of side drains with the main collector) must be 200mm as a minimum. The diameter of the pipeline draining the roadway bed must be 150mm as a minimum.

The diameter of the main collector of seepage water must be designed with respect to the amount of water flowing into the tunnel from the surrounding massif. The main collector can also fulfil the function of the roadway bed drainage.

5 CHANGE IN THE CONCEPT OF THE DRAINAGE SYSTEM

The decision on the change of the function of the original exploratory gallery was made before the start of the construction of the Višňove tunnel proper. The original exploratory gallery was to come to an end by the excavation of the southern tunnel tube. The decision to change the function of the original exploratory gallery to the function of a drainage gallery was made with respect to the permanently high rate of water inflow into the exploratory gallery and the necessity for a design of the drainage system for the Višňove tunnel using a main collector. The drainage gallery assumed the function of the main drainage collector in the space of the tunnel tubes, which fact allowed for excluding the construction of the main drainage collector in the space of the tunnel tubes. As a result of this change, the directional and vertical alignment of both tunnel tubes and the drainage gallery had to be completely redesigned in both portal sections. The alignment of the southern tunnel tube was shifted more southward, so that the original part of the drainage gallery ran approximately in the centre between the tunnel tubes. The vertical alignment of the tunnel tubes was shifted higher, so that the tunnel tubes were located above the drainage gallery along the entire length of the tunnel, and thus the gravity removal of water from the tunnel tubes to the drainage gallery was ensured. After the portal sections of the gallery with the newly designed alignment were broken through, the original portal sections were filled with backfill concrete, or they came to an end by the breakthrough of the southern tunnel tube (Figure 4, 5).

Drainage boreholes ca 300mm in diameter, outfitted with DN 250mm sewerage tubes, in some areas DN 200mm, were carried out for transferring water from the external drainage of the tunnel tubes to the drainage gallery. The drainage boreholes in the

tunnel tubes are in drainage cleaning niches and transverse linking of the cleaning manholes of the drainage under the roadway is carried out in the locations of the boreholes as a standard.

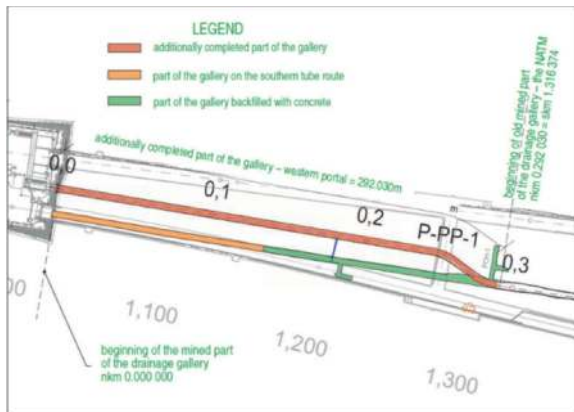

Figure 4. Plan of the portal section of gallery at the western portal.

6 TECHNICAL DESIGN OF THE DRAINAGE GALLERY

The drainage gallery of the Višňove tunnel is located between the northern and southern tunnel tubes along the entire length of the tunnel. It is used as the main collector of the drainage system of the Višňove tunnel and for transferring groundwater from the external side of the drainage of the tunnel tubes to the area of the Višňove tunnel portals. The drainage gallery is formed by four sections, depending on the tunnelling method used and the period in which it the given part was excavated:

- 1) completion of the part of the drainage gallery from the western portal; the NATM method; section 292.03m long,
- 2) the original part of the exploratory gallery; the NATM method; section 2799.78m long,
- 3) the original part of the exploratory gallery; the NATM method; section 3800.22m long,
- 4) the newly built part of the drainage gallery from the eastern portal; the NATM method; section 554.72m long.

Figure 5. Plan of the portal section of gallery at the eastern portal.

The total length of the gallery amounts to 7446.75m. A permanent extraction points for supplying the fire water tank will be provided in the drainage gallery. There are 10 vertical service entrances for the maintenance of the tunnel leading to cross passages passable for vehicles (in the locations of emergency lay-bys) and, in the space of joining the drainage boreholes, drainage niches, in which the drainage boreholes are terminated so that they do not extend into the gallery profile, are carried out.

7 DIRECTIONAL AND GRADIENT RELATED CONDITIONS

In the original part, the gallery roughly follows the horizontal and vertical alignment of the tunnel tubes. In the newly built parts, its horizontal alignment is adapted so that the ends at the portals is between the tunnel tubes and the vertical alignment does not collide with the cross passages located closest to the portals.

The longitudinal gradient of the drainage gallery is variable, from 0.1% to 9%. The longitudinal gradient in a major part of the gallery is ca 2.5%. The highest point of the gallery is at chainage km 0.580 83.

The 1.8m wide and 2.2m high drainage gallery cross-section passable for vehicles is designed. The internal shape varies depending on the tunnelling method as follows:

- a) The original part of the exploratory gallery – section driven using a TBM: circular profile with radius of 1.55m.
- b) The original part of the exploratory gallery – section driven using the NATM: the profile with double-radius (1.75–2.4m).
- c) The newly built part of the drainage gallery – section driven using the NATM (Figure 6); profile with double-radius (1.675–2.325m).

A drainage trough with various profiles, depending on the gallery section along which groundwater is led to the portal areas, lies on the drainage gallery centreline.

Figure 6. Gallery cross-section – portal sections.

7.1 Mined part of the gallery structure

The structure of the mined part of the drainage gallery consists of a double-layer lining with an intermediate drainage and insulation layer. Specifications of the concrete mixtures used differ depending on the period in which the particular part of the structure was built and the standards current in the given period of time. The secondary lining of the drainage gallery is formed by C30/37 grade shotcrete. The secondary lining is applied only in the gallery sections with unfavourable geological conditions and in the newly built portal sections of the gallery. An open waterproofing system is designed for the protection of the drainage gallery against groundwater. The waterproofing consists of a 500mm wide dimpled sheet membrane, which is installed locally, in locations of groundwater inflows through the primary lining. The concentrated groundwater inflows are directed through a short drainage borehole, through a flexible hose to the drainage trough in the gallery bottom.

7.2 Drainage of the gallery

In the centre of the bottom, there is a drainage trough with variable cross-section, depending on the gallery section along which groundwater is directed to the portal areas. There, in the cut-and-cover block of the gallery, it is connected to the tunnel drainage shaft.

Local inflows in the gallery are directed to the drainage trough by a collecting system. This system consists of short drainage boreholes, which are carried out in the locations of concentrated inflows, and flexible hoses, which are installed in the lining and lead through the bottom to the drainage trough.

Drainage niches (Figure 7) are designed for connecting the drainage boreholes collecting water from the external tunnel drainage. The niche is 550mm wide as a minimum (Figure 9). There are 62 boreholes between the tunnel and the gallery carried out from the northern tube and 64 from the southern tube. The net height of the niche is adapted separately to each drainage borehole, depending on the level of the connection of the borehole in the drainage gallery. The minimum net depth of the niches is equal to 590mm in the widest location of the gallery. A back-flap is installed on the borehole mouth. It prevents the overpressure of air to the external tunnel drainage during ventilation of the drainage gallery. A trough made of precast components is in the bottom of the niche. It is covered by a grating with minimum loading class B125 (part of the pre-cast trough), which is connected to the main drainage trough (Figure 8, 10). The niches are marked by serial numbers, the side of the drainage gallery on which the niche is found, and a complementary marking of the tunnel tube block from which the drainage borehole is carried out.

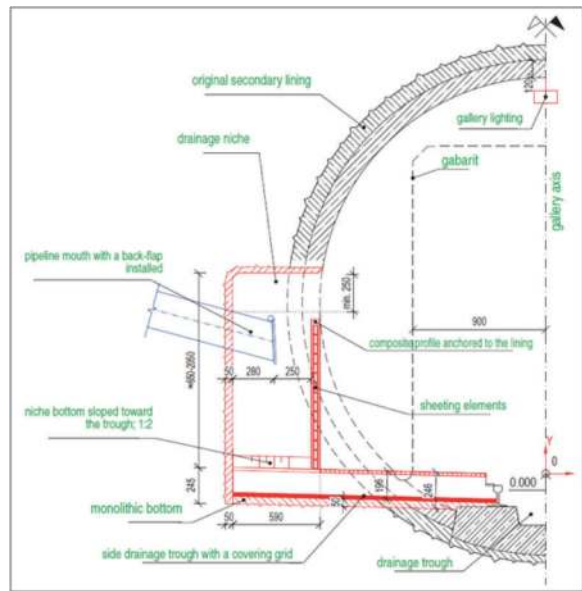

Figure 7. Drainage niche – cross-section.

Figure 8. Drainage niche – side drainage trough in drainage niche.

7.3 Service entrances to cross passages

With respect to the client's requirements, entrances in the form of chimneys passable for persons were designed between cross passages and the drainage gallery. In this way, employees of the operation services will be able to enter the cross passages without the necessity for entering the tunnel tubes (Figure 11).

The net cross-section diameter of the passages is 800mm as a minimum in the part of the cross passage bottom and 1400mm in the section passing through the rock massif and the drainage gallery. They are outfitted with composite pipes providing a sacrificial formwork, and the space between the formwork and the excavation is filled with C30/37

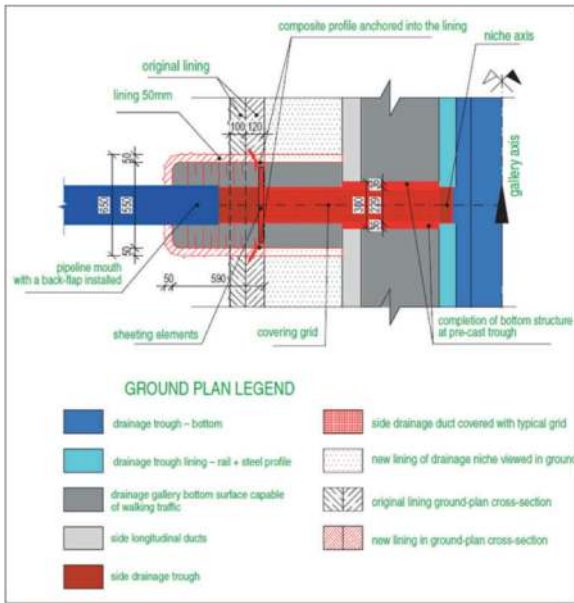

Figure 9. Drainage niche – ground plan.

Figure 10. Completed drainage niche.

Figure 11. Service entrance passable for persons – longitudinal section and cross-section through the gallery in the location of the service entrance passable for persons.

grade concrete. The entrances are equipped with composite ladders and are closed by an airtight, fire resistant cover.

7.4 Closing cross passages and excavation stubs

The cross passages were considered in the original exploratory gallery design as transverse connections between the southern and northern tubes. With respect to the change in the function of the gallery to

the drainage gallery and the changes in the horizontal and vertical alignment of the tunnel tubes, their originally planned function will not be applied, and it will be necessary to close them partially or completely. The cross passages and excavation stubs are closed at the minimum length of 3m from the right-hand wall of the northern tunnel tube (Figure 12).

In the case of a defect of the lining or the bottom of the cross passages, some cross passages were completely closed. The closing involved filling of the space of the cross passages and excavation stubs with cinder cement grout with minimum compressive strength of 10MPa. The unfilled spaces of the cross passages could be used in the future as rooms for storing materials and equipment for the maintenance of the gallery.

Figure 12. Closing of cross passages.

7.5 Intersections with cross passages No. 25, 26 and 27

The vertical alignment of the tunnel route was designed with the aim of minimising possible single-level intersections with cross passages and the existing drainage gallery. A 6.0m difference between the levels of the tunnel alignment and the alignment of the drainage gallery was designed. The level difference H between the bottom of each cross passage and the vault of the drainage gallery depends on the type of the cross passage and its location.

In the case of cross passages No. 25, 26 and 27, the level difference between the cross passage and the drainage gallery is smaller than 2m, therefore it was not possible to use the standard solution to the intersection. For that reason, different solutions were designed for those cases.

In the cases of the cross passages No. 25 and 26, the difference in the levels H was achieved approximately 1.5m from the drainage gallery by increasing the longitudinal gradient of the cross passage up to the maximum value of 10%. For that reason, only local reconstruction of the drainage gallery lining was necessary.

In the case of the cross passage 27, difference between the drainage gallery level while using the maximum gradient reached a value smaller than 0.5m – in the location of the intersection the ground beams of the standard profile extended into the space of the drainage gallery. For that reason it was necessary in the area of the intersection with the cross passage to carry out locally new anchoring of the primary lining of the cross passage using IBO anchors, to reconstruct the lining of the drainage gallery outside the area of the intersection with the cross passage, within the reach of the newly anchored primary lining with IBO anchors and to carry out comprehensive treatment of the drainage gallery lining and foundations of the cross passage in the intersection with the drainage gallery (Figure 13, 14).

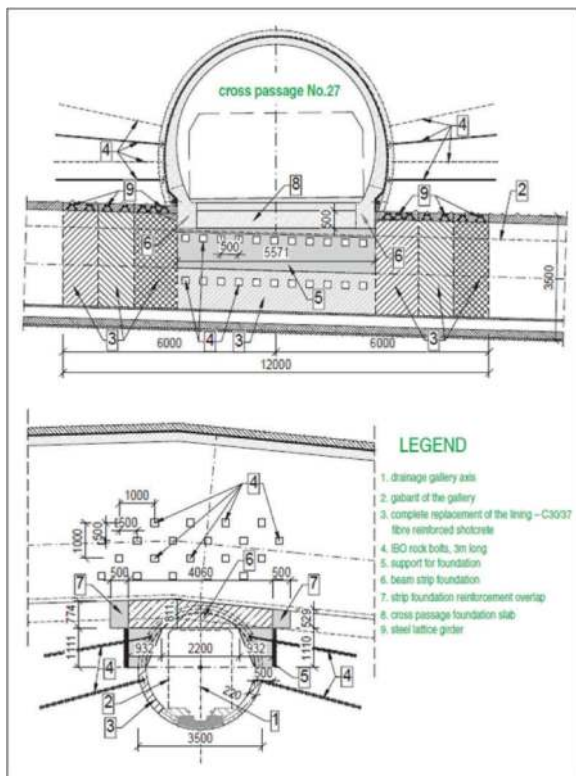

Figure 13. Intersection with cross passage No. 27 – cross-section and longitudinal section through the gallery.

Figure 14. Intersection with cross passage No. 27 – construction phase.

8 CONCLUSION

Changing the main contractor is a rare phenomenon in Slovakia for large infrastructure projects. One of the most important parameters in the selection of a new contractor for the construction of the D1 motorway section Lietavská Lúčka - Višňové - Dubná Skala was the price of the implemented work. The examples presented in this article have also shown that it is often possible to design structures more optimally and with lower investment costs, even without significant negative effects on the safety and durability of the work. In today's economically challenging times, more emphasis should be placed on the use of more efficient designs, which often have fewer negative impacts on the surrounding environment. Unfortunately, investors are often inclined to use less efficient solutions only because fewer contractors have experience with more efficient solutions, and the quality of construction is also problematic for these reasons in such works, but this is often not the fault of the project (although there are quite a few such cases), but the desire of contractors to save in the wrong places, or lack of control by the building supervisor.

Other extremely important factors for designing more optimal solutions are the time available to the designer for design and the reliability of the design inputs. Many times, the designer does not have enough time available to design a particular work and for this reason designs a more massive and expensive structure. Reliability of design inputs is also a frequent problem, given that the results of geotechnical investigations are usually only available in the final stages of design, the area is only sparsely investigated, and the potential variance of design inputs is often too large.

The development of the purpose of the drainage gallery of the Višňove tunnel has undergone dynamic development since its construction, depending on the changing requirements of the client and various designing approaches of the contractor and designing companies. The decision regarding the use of the original exploratory gallery as a permanent object brought an advantage in the exclusion of the main drainage collectors from the tunnel tubes, owing to which the origination of sewerage manholes in the tunnel carriageway was excluded. This decision will have a positive influence on the longevity of the roadway in the tunnel and, at the same time, the necessity for decommissioning this heavily loaded tunnel for the roadway repairs in the future will be excluded, which fact will have significantly positive effect on traffic around Zilina. However, this decision required a design of structural elements which had not been used in Slovak tunnels and the concept of which has not been established in current standards and regulations. In conclusion, it can be stated that it is beneficial that the working, demanding in terms of cost and time, which the original exploratory

undoubtedly is, and the Višňove tunnel will bring indisputable advantages during the operation and maintenance of the tunnel itself.

ABSTRACT: During metro construction, it is likely to cross the stratum with complex water environment. The great difference of geological conditions in China brings great variations to the properties of immersed soil layer, which has a great impact on the metro tunnel structure. Thus, this paper statistically analyses the cases of water gushing accidents in metro tunnels in China and puts forward the failure modes of immersed surrounding rock. Failure can be divided into three modes: flow sand instability failure, fracture expansion failure and collapse failure. Furthermore, based on typical engineering cases, the structural response characteristics of metro tunnel under various failure modes are further analysed and summarized. This study can provide significant reference information and experience for metro tunnel construction.

Keywords: Metro tunnel, Water environment, Statistical analysis, Failure mode, Tunnel structural response

1 INTRODUCTION

With the construction of underground urban space and rail transit, more and more metro tunnels pass through unfavourable geology (Huang et al., 2021; Liu et al., 2018). The great differences in natural conditions of China brings some difficulties to metro construction. Especially in special stratum such as sand, karst and loess, affected by water environment, the nature and structure of immersed soil changes significantly (Mao et al., 2019; Sun et al., 2021; Wang et al., 2018; Zhang et al., 2021). In the dynamic water environment, sand stratum is prone to flow sand, and the stability is completely lost, resulting in pores or cavities around the tunnel. The stratum crossed by Shanghai metro line 18 is mainly sandy soil. Water gushing accident occurs during tunneling, resulting in deformation and damage of tunnel lining (Fan et al., 2018; Zhao et al., 2021). Otherwise, during the construction of Yi wan Railway Tunnel, large-scale karst

stratum is encountered. Under the pressure water environment, the water-rock interaction leads to the expansion of karst fissures and the outburst of tunnel fissure water. Karst stratum with water-rich caves or poor load-bearing capacity may cause water ingress, mud gushing, formation sliding, tunnel structure damage, or even ground collapse, etc. (Qiu et al., 2019, 2020; Wang et al., 2020). The collapsible loess stratum is prone to collapse after water immersion, which will seriously affect the metro tunnel structure.

Therefore, the change of water environment under complex geological conditions brings difficulties and challenges to metro tunnel construction. In view of the lack of a systematic summary on failure mode of immersed surrounding rock and structural response mechanism of metro tunnel. This paper pays more attention to: (1) propose failure mode of immersed surrounding rock, (2) to summarize and analyse the response characteristics of immersed surrounding rock failure to metro tunnel structure.

2 WATER IMMERSION FAILURE MODE OF SURROUNDING ROCK OF METRO TUNNEL

And the common characteristics of the immersion failure of surrounding rock are summarized. Specific statistical analysis is shown in Table 1.

2.1 *Statistical investigation of metro water gushing accidents*

To study failure mode of immersed surrounding rock and structural response mechanism of metro tunnel, the water gushing cases of metro tunnels in China recent years are statistically analysed in this section.

2.2 *Analysis of water gushing accidents in metro tunnel*

2.2.1 *Space analysis*

From the perspective of seven natural geographical divisions in China, the locations of metro

Table 1. Case statistics of water gushing accidents in metro tunnels in China.

Region	Metro name	Cause analysis of surrounding rock failure	Tunnel structure response
Northwest China	Xi'an Metro Line 9	Surrounding rock structure is changed and the strength is reduced after water immersion. Then, the surrounding rock collapse occurs	The arch foot of the tunnel has cracks and large deformation
	Xi'an Metro Line 1		The stress of tunnel sidewall and arch foot increases
	Xi'an Metro Line 2		The stress of tunnel arch bottom increases and deformation occurs
	Xi'an Metro Line 3		The stress on the sidewall of the tunnel increases
	Xi'an Metro Line 4		The bending moment and axial force of tunnel vault increase in the immersion range
	Xi'an Metro Line 2		Tunnel arch foot deformation is large and cracks occur
	Lanzhou Metro Line 1		The stress of tunnel vault and arch foot increases, resulting in deformation
	Xi'an Metro Line 2		The stress on the sidewall of the tunnel increases
	Taiyuan Metro Line 1		Cracks appear at the arch foot of the tunnel, resulting in deformation
	Changsha Metro Line 3		The stress above the tunnel vault is large and uneven deformation occurs
Southwest China	Kunming Metro Line 5	Fracture expansion occurs in surrounding rock under high-water pressure	The stress on the arch foot of the tunnel increases, resulting in cracks
	Guiyang Metro Line 3		Tunnel arch foot damage
	Kunming Metro Line 2		Tunnel arch foot deformation is large and damage occurs
	Guiyang Metro Line 2		The stress on the side wall of the tunnel increases
	Guiyang Metro Line 1		The deformation of tunnel arch bottom is large, and cracks appear at the arch bottom
	Kunming Metro Line 2		The stress on the sidewall of the tunnel increases and the segments produce cracks
Central South Region	Zhengzhou Metro Line 2	Surrounding rock structure is changed and the strength is reduced after water immersion. Then, the surrounding rock collapse occurs	The arch foot of the tunnel has cracks and large deformation
	Zhengzhou Metro Line 3		The stress on the sidewall of the tunnel increases
	Zhengzhou Metro Line 12		The stress on the bottom of tunnel arch gradually increases, and finally the failure occurs

(Continued)

Table 1. (Continued)

Region	Metro name	Cause analysis of surrounding rock failure	Tunnel structure response
East China	Zhengzhou Metro Line 5	Under the action of hydrodynamic force, flow sand occurs in the surrounding rock, resulting in instability failure of surrounding rock	Tunnel arch foot deformation is large and damage occurs
	Wuhan Metro Line 7		The stress above the tunnel vault is large and uneven deformation occurs
	Shenzhen Metro Line 1		Tunnel arch foot damage
	Guangzhou Metro Line 5		The arch foot of the tunnel has cracks and large deformation
	Wuhan Metro Line 3		The stress above the tunnel vault is large and uneven deformation occurs
	Wuhan Metro Line 6		The stress on the side wall of the tunnel increases
	Guangzhou Metro Line 2		The stress of tunnel arch foot increases
	Foshan Metro Line 2		Compared with other parts, the stress of tunnel vault is larger
	Guangzhou Metro Line 3		The stress on the sidewall of the tunnel increases
	Wuhan Metro Line 4		The stress of tunnel arch bottom increases and deformation occurs
	Shanghai Metro Line 11		A cavity is formed at the top of the tunnel and the stress increases
	Qingdao Metro Line 3		The stress above the tunnel vault increases, resulting in the collapse of the vault
	Nanjing Metro Line 3		The stress on the sidewall of the tunnel increases, resulting in cracks
	Nanjing Metro Line 2		The stress above the tunnel vault is large and uneven deformation occurs
	Nanjing Metro Line 4		The stress of tunnel arch foot increases
North China	Hangzhou Metro Line 1	The stress above the tunnel vault is large and uneven deformation occurs	
	Hangzhou Metro Line 4	The stress on the sidewall of the tunnel increases, resulting in cracks	
	Shanghai Metro Line 15	The stress on the top of the tunnel increases, resulting in large-scale cavities	
	Tianjin Metro Line 2	As the stress on the arch foot increases, the bending moment and axial force of the tunnel lining structure increase within the immersion range	
	Beijing Metro Line 10	The stress on the sidewall of the tunnel increases	

water gushing accidents are mostly concentrated in the northwest, southwest, central and eastern regions of China (Figure 1). By consulting Chinese geological data, it is found that the stratum in northwestern China is mostly loess. The middle-south and east China are typical sandy

soil stratum. While the karst stratum in southwestern China is relatively developed, and there are more rifts, grooves and caves. The occurrence of water gushing hazard in the above stratum not only affects project construction, but also causes huge economic losses.

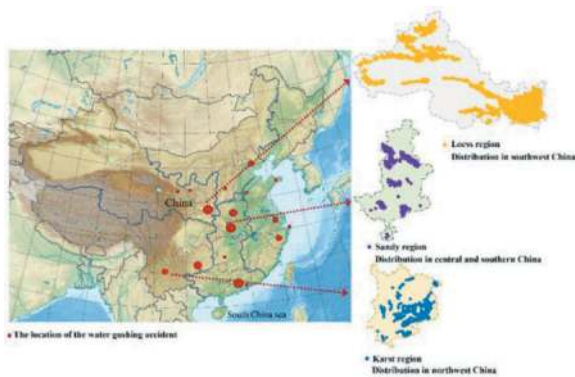

Figure 1. Geographical location of metro water gushing accidents.

2.2.2 Cause analysis

Through analysis and statistics of metro water gushing accidents in China, it can be seen that unstable failure of surrounding rock structure up to 43.6% due to the sand flowing under the action of hydrodynamic force. The instability failure caused by the fracture expansion (FE) of surrounding rock under high water pressure accounts for 17.9%. Collapse failure of surrounding rock after water immersion accounts for 38.5%. Therefore, flow sand instability (FSI), FE and collapse are the main causes of surrounding rock structure damage in water environment.

2.3 Water immersion failure modes

According to the above summary and analysis of the statistical water gushing accident cases, from the surrounding rock classification and the causes of immersion failure, failure of immersed surrounding rock is divided into three modes: FSI failure, FE failure and collapse failure.

2.3.1 Flow sand instability failure

FSI failure means that the surrounding rock produces flowing sand and loses its stability under hydrodynamic action. The most representative stratum in China is the sand stratum of Wuhan area. Sand is a typical loose granular medium. Under stress conditions strain softening and strain localization will occur in sand. If sand is in dynamic water environment, its physical and mechanical properties will be more complex, which is confirmed by a large number of experimental results in the world (Fang et al., 2019; Zhang et al., 2019). During tunnel construction in the sandy stratum, due to the relatively high mobility of sand, the groundwater is replenished quickly. Under the hydrodynamic action, fine sand particles are brought into the tunnel, resulting in the loss of soil particles in the soil around the tunnel. Dominant channels are formed, and pores or cavities are generated around the tunnel (Long and Tan, 2020).

Figure 2. Diagram of earth pressure distribution on tunnel surface (Zhang et al., 2017).

The loss of sand particles changes the soil particle structure in the particle loss area, and changes the distribution of soil pressure on the tunnel surface. The change process of soil pressure distribution is shown in Figure 2. Before seepage erosion, soil pressure is evenly distributed on the tunnel surface. After the loss joint appears on the tunnel surface, the sand particles are lost and the earth pressure at the loss joint is greatly reduced. The large particles around the loss joint form a force arch (particle force chain) to bear the earth pressure outside the loss area (Zhang et al., 2017). This change leads to the original tunnel surface uniform stress state into uneven stress. Seepage erosion generally occurs in the weakest link of tunnel structure, such as ring joint, longitudinal joint and bolt hole. After the width of the loss joint increases, the amount of particle loss will increase, further exacerbating the change of soil pressure around the loss joint, forming a vicious circle to accelerate the process of seepage erosion.

2.3.2 Fracture expansion failure

FE failure refers to the continuous expansion of surrounding rock fractures under the action of water erosion in pressurized water environment. The most representative stratum in China is karst stratum in Guizhou area. The development of karst starts from the dissolution and expansion of the original narrow channel of soluble rock by water flow. The dissolved rock components are continuously taken away through the water flow cycle. The intermittent cracks (voids) of rock mass expand and the connectivity increases, which changes original structure of the rock mass. The increase of permeability further accelerates the seepage of karst water.

Huang et al. (Huang et al., 2021) reported that the overall crack connecting the tunnel and the cave is dominant channel, and the groundwater is transported through the dominant channel. When the water gushing hazard source enters the dominant channel, it is transformed into a hazard body. The formation of dominant channel is essentially the evolution process of solid-liquid-gas coupling of hazard body, which is usually manifested as two failure modes: high-pressure hydraulic fracturing failure and instability failure of filling structure (Li et al., 2017).

Figure 3. High pressure hydraulic fracturing failure process (Lai et al., 2021).

Lai et al. (Lai et al., 2021) studied the process of water gushing hazard in karst tunnel and the seepage characteristics of surrounding rock. The results showed that the essence of seepage failure is the macroscopic result of the initiation, expansion and penetration of surrounding rock cracks under the action of tunnel excavation disturbance and karst water pressure (Figure 3). In the paper reported by Gao et al. (Gao et al., 2021), it is also mentioned that the initiation, expansion and penetration of cracks in surrounding rock are spontaneous, and finally the water gushing channel is formed by cracks.

Wide cracks, faults, karst pipelines and other unfavorable geological structure, their internal filling medium seepage hazard led to the formation of water gushing channel. Subsequently, fault activation water gushing and karst pipeline filling infiltration instability water gushing occur, which is instability failure of filling structure. For the filled karst tunnel, the seepage failure instability process can be divided into three processes (Figure 4) (Lu, et al., 2017, Li et al., 2017):

Figure 4. Filling medium overall instability failure schematic diagram (Lu, et al., 2017).

Moreover, Meng et al. (Meng et al., 2020) studied the seepage characteristics of filling karst tunnel structure, and found that water pressure in filling body gradually decreased along the seepage direction of confined water. With the increase of confined water pressure, the average hydraulic gradient and pore water pressure of filling body gradually increase.

2.3.3 Collapse failure

Collapsibility refers to the property that the internal structure of soil is destroyed under a certain

compressive stress after immersion, and then significant additional subsidence occurs. The most representative stratum in China is loess stratum in Xi'an area. Loess is a kind of special Quaternary sediment formed under dry conditions, which is rich in pores, loose structure, developed vertical joints, and generally has different degrees of collapsibility. The three characteristics of strong water sensitivity, structural plane development and dominant seepage channel of loess determine that loess is prone to collapse after water immersion.

Calcite, clay cementation and silt morphology between loess particles make intact soil metastable under dry condition (Jiang et al., 2012). Collapsibility caused by water immersion is the result of the combined effect of primary and secondary micro-structure characteristics (Garcia et al., 2012). The former is a large number of weakly cemented, unsaturated and porous pure clay and clay-silt mixture aggregates, and the disintegration after immersion leads to the collapse of the overall structure. The latter is composed of high porosity, unstable particle contact and clay coating on silt particles. Their synergistic effect leads to collapsibility. The conceptual model of loess collapsibility mechanism is shown in Figure 5.

Figure 5. Conceptual model of loess collapsibility mechanism (Garcia Giménez et al., 2012).

To further explore the failure mode of surrounding rock of loess tunnel in hydrostatic environment, Li et al. (Li et al., 2019) carried out a long-term large-area static load immersion test on the surface of tunnel crossing strong collapsible loess stratum. The result is shown in Figure 6. It can be seen from the figure that the water in the test pit mainly infiltrates in the vertical direction, while the horizontal infiltration distance is small. Before the seepage front reaches the buried depth of the tunnel, the shape of the seepage area is elliptical. With the increase of

immersion time, the seepage area extends along the vertical direction. Therefore, the area affected by immersion eventually becomes the shape of ‘bulb’. The maximum influence depth of water infiltration is 35 m, and the horizontal diffusion distance is about 5 m. After the immersion test, a detection ditch with a depth of 3m is excavated near the boundary of the foundation pit. The groove shows that the angle between the seepage line and the vertical direction is approximately 45° in the surface layer. After the infiltration front reaches the buried depth of the tunnel, due to the obstruction of the tunnel structure, water infiltrates into the surrounding rock along both sides of the tunnel and continues to move downward.

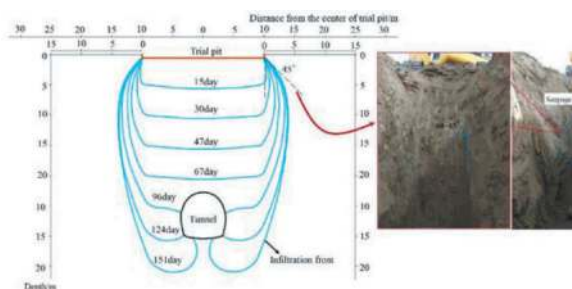

Figure 6. Change process of saturation line in different periods and Form of saturation line in shallow layer (Li et al., 2019).

3 STRUCTURAL RESPONSE CHARACTERISTICS OF METRO TUNNEL UNDER DIFFERENT IMMERSION FAILURE MODES

3.1 Flow sand instability failure

Wuhan located in Hubei Province of China has a huge sand stratum. When the shield tunneling passes through the high-water pressure sand stratum, it is easy to cause water gushing accidents, which may lead to serious secondary accidents, such as excessive surface subsidence, even collapse, tunnel structure deformation and damage (Selmi et al., 2020). Relying on a shield section of Wuhan Metro Line 7 as the research object, Ye et al. (Ye et al., 2017) studied the influence of water gushing on the surface settlement and metro tunnel structure when the earth pressure balance shield was excavated in the sand layer. The metro tunnel is mainly located in the Yangtze River valley area, and the groundwater in the surrounding rock is interlinked with the river water. The phreatic area in the surrounding rock is about 0.5 m-4.2 m away from the surface position. When the tunnel passes through the sandy stratum in the region, it encounters confined water and underground river. Causing water gushing in the tunnel and obvious surface subsidence. The variation of surface subsidence along the horizontal and vertical directions is shown in Figures 7 and 8.

Figure 7. Surface transverse observation axis settlement curve (Ye et al., 2017).

Figure 8. Surface longitudinal observation axis settlement curve (Ye et al., 2017).

According to the distribution of surface lateral settlement, the surface settlement above the tunnel is the largest, which is 4.5 mm, and with the increase of time, the surface settlement is larger, the early settlement amplitude is larger, and the later period is slowly stabilized. For the distribution of longitudinal surface subsidence, the surface subsidence near the water inflow location is large, and the influence range is about 50 m along the longitudinal direction.

According to the construction situation on site and the geological survey of water gushing section, when passing through the sandy stratum with high-water pressure and rich local water content, the hazards such as segment dislocation and cracking occur frequently. By analysing the influence of different seepage velocity on tunnel structure, the variation trend of maximum deformation, maximum tensile stress and maximum compressive stress of tunnel segment with water inflow is shown in Figure 9. With the increase of water inflow, the deformation internal force of the segment shows a nonlinear growth trend. For the segment structure of the

interval tunnel, affected by the water environment, with the increase of segment internal force, the segment lining develops from the initial crack to the late dislocation and damage, further reducing the stability of the overall structure of the tunnel. The risk of tunnel leakage and local collapse is induced. Therefore, when the tunnel passes through the water-rich sandy soil stratum, especially in the environment of confined water and underground river, to prevent excessive surface subsidence and segment structure fracturing by water pressure, effective treatment measures such as grouting should be taken in time to control the water output in a certain range and prevent the further expansion of the accident.

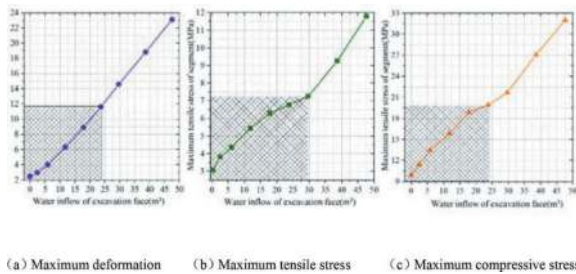

Figure 9. Influence of water inflow on tunnel segment (Ye et al., 2017).

3.2 Fracture expansion failure

The water content in karst area is abundant. In the construction process, due to the excavation of tunnel rock mass, the stability of the original hydraulic circulation system or static water body is destroyed, and it is easy to cause karst collapse, karst leakage, underground water gushing and other adverse geological phenomena. Underground engineering such as metro tunnel has great risks in the construction of such stratum. However, for the tunnel structure that has been used as lining, affected by the water environment such as surface rainfall, the cavity previously existing around the tunnel is filled again. If the pores in the cavity are filled with water, the distance between cavity and tunnel is relatively close, surrounding rock between cavity and tunnel is weak or reinforcement effect is poor. At this time, the high-water pressure in the cavity is easy to have a large bias effect on the tunnel, and even the tunnel lining will be partially destroyed, leading to water gushing accident.

Therefore, taking a karst tunnel with hidden cavity at the bottom as the engineering background, Mo (Mo, Y.C., 2011) analysed the response characteristics of water pressure in karst cavity below the tunnel and the spacing between karst cavity and tunnel to the internal force of tunnel structure.

The influence of water pressure in the cavity on internal force of tunnel lining is shown in Figure 10. With the gradual increase of water pressure in the

cavity, the axial force of tunnel lining gradually increases as a whole (Figure 10(a)). Especially for the tunnel wall foot position, when the water pressure of the cavity is 0.3 MPa, 0.6 MPa, 1.0 MPa and 1.5 MPa, the corresponding axial force of the wall foot lining is -258.2 kN, -511.3 kN, -844.2 kN and -1301 kN.

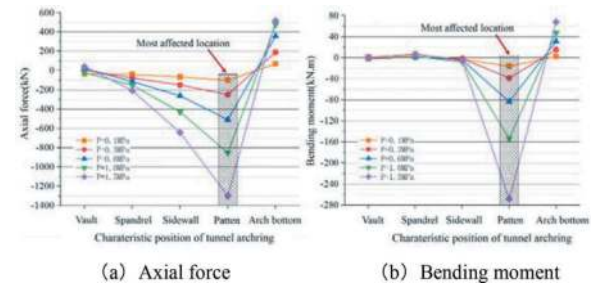

Figure 10. Variation of Internal Force of tunnel lining characteristic position with water pressure in cavity (Mo, Y.C., 2011).

At the same time, the smaller the distance between the tunnel and the solution cavity, the greater the absolute value of the axial force (negative axial force) at the spandrel, side wall and foot of the tunnel, and the greater the absolute value of the axial force (positive axial force) at the top and bottom of the tunnel. The change of the axial force is: foot of the wall > bottom of the tunnel > side wall > arch shoulder > vault. The change of cavity water pressure mainly affects the bending moment of tunnel wall foot, as shown in Figure 10(b), but has little effect on other positions. When the test section is close to the cavity section, the bending moment of the vault and side wall of the tunnel changes little, and the maximum bending moment increment is at the arch foot of the tunnel, followed by the bottom of the tunnel, and the tunnel spandrel is the smallest.

Figure 11 shows the influence law of lining internal force on the variation of cavity spacing between tunnel and karst cave. When the distance between the tunnel and the cavity decreases continuously, the axial force growth law of the tunnel at the characteristic position is different. As shown in Figure 11(a), the axial force of the tunnel wall foot and the side wall increases significantly.

When the distance between the solution cavity and the tunnel is 5.0 m and 3.5 m, the axial force at the wall foot is -844.2 kN and -1053 kN, respectively. Compared with the distance between cavity and tunnel 7.5 m, the axial force increases 1.4 times and 1.8 times respectively. In contrast, the increase of axial force at the bottom, spandrel and vault of the tunnel is small. As shown in Figure 11(b), with the decrease of cavity spacing, the bending moment increment of tunnel wall foot and tunnel bottom is more obvious, among which the bending moment

increment at tunnel bottom is the most obvious, while the bending moment increment at tunnel vault, spandrel and side wall is small. For the tunnel lining with large cavity distance, the bending moment and axial force are less affected by the cavity.

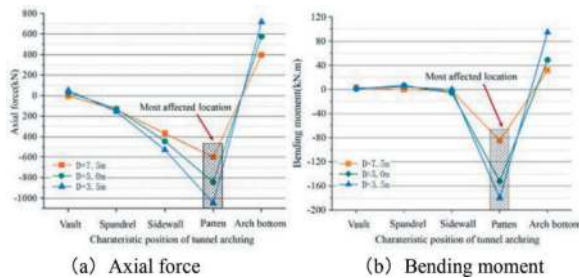

Figure 11. Influence of the distance between water filled cavity and tunnel on the internal force of lining (Mo, Y.C., 2011).

3.3 Collapse failure

In collapsible loess areas, the migration of soil moisture often causes the spatial-temporal discontinuity and spatial heterogeneity of collapsibility, and induces the destruction of tunnel structure (Qiu et al., 2018; Wang et al., 2021). Therefore, to ensure the safety of the loess tunnel structure, Li et al. (Li et al., 2019) revealed the collapsible deformation characteristics of loess tunnel site and its influence on tunnel structure (Figure 12), by measuring and analysing the mechanical response of stratum settlement and tunnel structure during long-term immersion.

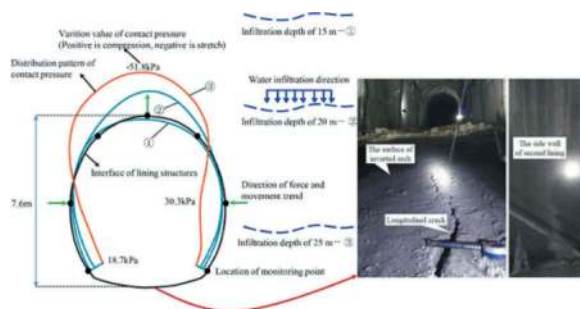

Figure 12. Contact pressure on section XK140 changes with water infiltration depth and Cracks on the tunnel structure (Li et al., 2019).

In the long-term immersion process of the surface above the tunnel, the surface water will infiltrate into the bottom of the tunnel. When the surface water infiltrates near the tunnel depth, the pressure state of the tunnel structure will change due to the collapse of the surrounding loess. The main feature of the change is that the side wall of the tunnel is squeezed laterally by the surrounding loess, and the vault of

the primary lining has the trend of upward movement. Meanwhile, the foundation pressure increased significantly, the tunnel structure collapse, and the inverted arch crack.

With the increase of soil immersion conditions around the tunnel, the adverse impact on the tunnel is also more serious. Weng et al. (Weng et al., 2019) improved the water immersion system (WSS) on the basis of the existing CTE, then it was used to carry out centrifugal model tests on a metro tunnel under full-range and half-range foundation soaking conditions with different soaking depths. The results show that half-range soaking is more harmful to the mechanical properties than full-range foundation soaking. The differential deformation caused by half-range foundation soaking is one of the main reasons for the tunnel cracks.

4 CONCLUSIONS

The failure modes of tunnel surrounding rock after immersion in different water environments are proposed based on the case analysis of water gushing accidents in China's metro tunnels. Combined with typical engineering cases, the structural response characteristics of metro tunnels under various failure modes of surrounding rock are further analysed and summarized. The following conclusions can be drawn:

(1) From the surrounding rock classification and the causes of immersion failure, failure of immersed surrounding rock is divided into three modes: flow sand instability failure, fracture expansion failure and collapse failure. Flow sand instability failure: under the action of hydrodynamic force, the soil particle structure in the particle loss area is changed, which changes the earth pressure distribution on the tunnel surface. Fracture expansion failure: under the interaction of water and rock, the fracture of surrounding rock expands, resulting in the weakening of surrounding rock strength and instability failure. Collapse failure: after the collapsible loess stratum is immersed in water, collapse is attributed to both primary and secondary microstructure features.

(2) Under the influence of immersed surrounding rock, the metro tunnel structure has different response regularities. Flow sand instability failure occurs in surrounding rock, the influence on the tunnel structure is mainly concentrated in the vault. Fracture expansion failure occurs in the surrounding rock, the influence on the tunnel structure is mainly concentrated at the arch bottom. When the surrounding rock collapses, the stress on the side wall and arch foot of the tunnel increases in the large area of static water immersion environment, while in the local pressure water immersion environment, the surrounding rock near the water source occurs local collapse, and the stress increases at the arch foot and arch bottom, resulting in uneven deformation.

ITAtch design guidance chapter for composite Sprayed Concrete Lined (SCL) tunnels waterproofed with sprayed membranes

Jiang Su*

AtkinsRealis, Epsom, UK

ABSTRACT: Composite sprayed concrete lined (SCL) tunnels waterproofed with sprayed membranes have been constructed in major tunnelling projects worldwide. The use of sprayed membranes has the potential to reduce the secondary lining thickness significantly. So far, this potential has yet to be fully realised, mostly due to a lack of detailed design guidance. In response, the author has undertaken the task of developing a design guidance chapter for the ITAtch Lining and Waterproofing Activity Group guidance document.

The design guidance chapter begins by presenting various composite lining configurations and provides a flow chart to aid decision-makers in selecting the most suitable lining configuration based on specific ground conditions and project requirements. It further elucidates the impact of composite action and load sharing on tunnel linings, emphasising their significance in achieving optimal lining structural performance. The stress status of the membrane interface under varying loadings is thoroughly explained. The chapter also recommends analysis stages and verification points based on the membrane interface's life-cycle behaviour within the tunnel to facilitate a comprehensive understanding of the design process. Moreover, the chapter explores various numerical modelling approaches for simulating the membrane interface. Project examples and reference literature will not be listed in this paper due to space limitations.

By focusing on key concepts such as composite action and load sharing, as well as addressing practical considerations such as numerical modelling techniques, this design guidance chapter fills a critical gap in the field. It will serve as a valuable resource for professionals engaged in the design and construction of composite SCL tunnels waterproofed with sprayed membranes, enabling them to make informed decisions and enhance the overall efficiency and effectiveness of such tunnel projects. This paper provides a glimpse of the comprehensive design guidance chapter.

Keywords: ITAtch, Composite Lining, Sprayed concrete, Sprayed membrane

1 INTRODUCTION

Composite sprayed concrete lined (SCL) tunnels waterproofed with sprayed membranes have been constructed for major projects worldwide in various ground conditions. Recent example projects include the Crossrail project in London (Su & Thomas, 2015), REM and Blue Line projects in Montreal (Nasri & Vovou, 2023; Nasri et al., 2023), Gevingas rail tunnel in Norway (Holter, 2013), WestConnex New M5 tunnels in Australia (Aitchison et al., 2018). The ground in which those tunnels were constructed ranges from impermeable stiff clay to permeable weak and hard rocks. The lining configurations range from relatively thick lining working as a passive load-bearing shell structure to an active system with relatively thin lining combined with permanent rock bolts that better utilise

the inherent rock strength. Both drained and undrained (tanked) waterproofing strategies were used. The wide range of applications of composite SCL tunnels waterproofed by sprayed membranes in different geological conditions demonstrates its versatility. However, there is currently no detailed guidance on the design of composite SCL tunnels waterproofed by sprayed membranes. ITAtch Lining and Waterproofing Activity Group published a guidance document in 2013 (ITAtch, 2013), with only two pages covering the high-level design principles. This has left a wide knowledge gap for tunnel designers to efficiently design this innovative lining configuration to achieve acclaimed benefits, such as reduced lining thickness and improved safety records, etc.

With over 15 years of combined academic research, construction supervision, practical design

*Corresponding author: Jiang.su@atkinsrealis.com

and numerical modelling experience on the composite SCL tunnels, the author has been tasked to develop a new design chapter for the next version of the ITatech Lining and Waterproofing Activity Group guidance document. This paper provides a glimpse of this comprehensive design chapter. The author hopes the publication of the paper will encourage the exchange of relevant experience and lessons globally and provide more confidence to adopt this innovative lining configuration among clients and designers. This paper presents the key information in the same order as in the proposed design chapter.

2 LINING CONFIGURATIONS

Table 1 lists typical composite SCL tunnel configurations using a sprayed waterproofing membrane as the main waterproofing measure. For completeness purposes, single shell lining configurations waterproofed with sprayed membranes but without secondary lining are also included. The example lining configurations shown in Figure 1 cover stiff clay (e.g., London Clay) and weak rock (e.g., Breccia and Basalt). The lining configurations can be extended to hard rock ground conditions if rock anchors are installed. It should be noted that this table does not list all possible composite SCL tunnel configurations using a sprayed waterproofing membrane. Instead, it intends to provide tunnel designers with information on selecting the most suitable lining configurations.

Table 1. Typical composite SCL lining configurations.

No.	Name
A-1	Undrained sacrificial primary lining
A-2	Undrained hybrid sacrificial primary lining
A-3	Drained sacrificial primary lining
B-1	Undrained permanent primary lining
B-2	Undrained hybrid permanent primary lining
B-3	Drained permanent primary lining
C-1	Undrained single shell lining
C-2	Drained single shell lining

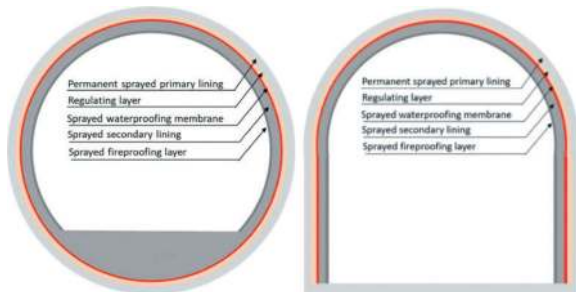

Figure 1. Typical undrained (B-1) and drained permanent (B-3) primary lining configurations.

3 LINING CONFIGURATION SELECTION PROCESS

A lining configuration selection process is shown below in Figure 2. The first column on the left-hand side shows three different levels of watertightness requirements, with the most relaxed requirement on the top and the strictest requirement at the bottom. The second column in the middle asks a key question: With the project ground conditions and local sprayed concrete quality control system, is the permanent primary lining a feasible option? Depending on the answer, the third column on the right-hand side lists suggestions for lining configurations.

It should be noted that temporary water control measures have been introduced to improve the substrate dryness for tunnels constructed on permeable ground with success. (Bedi et al., 2022; Amoushahi et al., 2022). This has greatly expanded the applicable scenarios for the use of sprayed waterproofing membranes, which were only able to be used in relatively dry conditions previously.

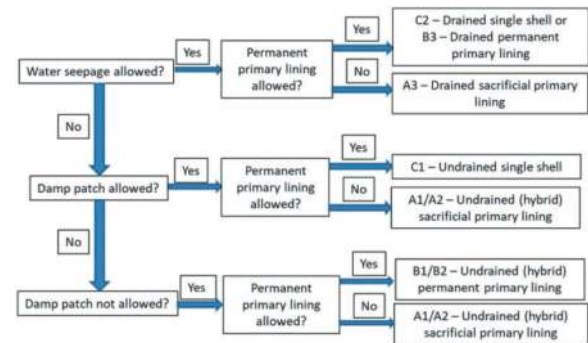

Figure 2. Lining configuration selection process.

4 FUNDAMENTAL ENGINEERING PRINCIPLES

In previous sections, 8no. of lining configurations are introduced. The following section will focus on the B series lining configurations, comprising two layers of permanent linings with sandwiched sprayed waterproofing membranes. This section will first introduce the fundamental engineering principles.

4.1 Functions of the membrane interface

A composite shell lining physically comprises primary and secondary linings with sandwiched sprayed membranes. From a structural perspective, there are two interfaces between the membrane and the concrete linings – the primary-membrane and secondary-membrane interfaces. Conceptually, the sprayed membrane and the two interfaces can be together described as the ‘membrane interface’, which has significantly lower mechanical properties (i.e., strength and stiffness) than the concrete layers on each side

and hence has been the focus of research on the past ten years (Dimmock et al., 2011; Su & Bloodworth, 2014, 2016; Holter, 2016; Diez et al., 2019). The definitions of these terms and the relationships between them are shown in Figure 3. The membrane interface functions on two levels in the composite shell lining, as shown in Figure 4. The first level is to ensure the primary and secondary linings work compositely without failure occurrence at the membrane interface, which is a prerequisite for the second level function. The second level is in the determination of the lining forces (i.e., axial force and bending moment) induced in the primary and secondary linings under various loading conditions as a consequence of the composite action. The following sub-sections will describe the function of the stiffness and strength in both the normal (crossing the membrane) and shear (along the membrane) directions of the membrane interface. The stiffness of the membrane interface follows Hooke's law in this paper.

Figure 3. Definition of technical terms in composite shell lining.

Figure 4. Functions of the membrane interface.

4.1.1 Normal stiffness

The normal stiffness describes how well the membrane can transfer both compression and tension (for bonded interface) and compression only (for unbonded interface) between the primary and secondary lining layers. The higher the normal stiffness, the greater the compression/tension is transferred between the two linings.

4.1.2 Normal strength

The compressive strength of the membrane interface is usually not a concern from design's perspective. There are three different tensile strengths: adhesive tensile strength between the membrane and the two concrete linings and the cohesive tensile strength of the membrane itself. The stress status related to the normal tensile strength at the membrane interface will be explained later in Section 3.3.

4.1.3 Shear stiffness – composite action

Shear stiffness restricts the relative movement between the primary lining by converting part of the global bending moment into a force couple - axial compression and tension in the two linings, depending on the lining deformation curvature. The effect of shear stiffness is also known as “composite action”, which refers to the transfer of shear stress across the membrane interface. The composite action significantly affects the stresses in the primary and secondary linings. Figure 5 (Su & Bloodworth 2018) shows the expected stress distributions in fully composite, partial composite, and no composite beams due to M_{global} , assuming Euler bending and linear elastic behaviour appropriate to the pre-cracked state. The key takeaway is that composite structural action induces a combination of local bending moment M and local axial force N in each layer, as illustrated in Figure 6 (Bloodworth & Su, 2018) for the partial composite case. To design an effective composite lining system, it's important to carefully consider the stress distributions that M_{global} will induce. This requires a thorough understanding of the properties and behaviour of each component layer, including their axial stiffness and Young's modulus.

Figure 5. Composite lining stress due to global bending.

Figure 6. Breakdown of composite lining stresses due to global bending into bending and axial.

4.1.4 Shear strength

It is important to ensure the membrane interface has sufficient shear strength to resist external load-induced shear stress. It is essential that neither cohesive shear failure within the membrane material nor adhesive failure at the concrete-membrane interface should occur if the tunnel is designed as a composite lining.

4.2 Load-sharing effect

This section explains the load-sharing effect in tunnel lining (1) without and (2) with considering the effect of composite action.

4.2.1 No considering the effect of composite action

The load sharing in tunnel linings without considering the effect of composite action can be explained using

Figure 7 (Su & Bloodworth, 2023). The gravity effect and the impact of the membrane shear stiffness (i.e., composite action) are ignored in this example. Only the normal stiffness of the membrane interface is considered. The tunnel has an equal thickness in primary and secondary linings and a 10mm thick sprayed membrane in the middle. When the membrane interface is very stiff, imagined with infinite normal stiffness, it will transfer approximately 50% of the external forces to the secondary lining with effectively zero strain in the membrane. In this case, the deformation of the primary and secondary linings will be the same. The membrane interface will experience the maximum normal stress but the minimum normal strain.

If the membrane's normal stiffness gradually reduces, the primary lining deformation will gradually become greater than the secondary lining. In an extreme case, if the membrane interface has zero normal stiffness (becoming a 10mm air gap between the two linings), the primary lining may take all the external force if its deformation is less than 10mm, and the secondary lining would take none and therefore have no deformation. In this case, the membrane interface will experience the minimum normal stress but the maximum normal strain. This qualitative description is also valid for scenarios where the forces are applied to the sprayed membrane extrados (as would be conceptualised for the groundwater pressure), provided the membrane is still bonded. Besides the normal stiffness of the membrane, the load sharing for a permanent SCL tunnel with a bonded membrane is also affected by the relative lining thickness and the direction of the loading.

Figure 7. Schematic diagram for a composite lining under uniform external loading.

If the membrane is assumed to be unbonded in the long term, based on the pre-construction test of the membrane interface, it can be assumed that the primary lining will resist all the long-term ground loads, and the secondary lining will resist all the long-term groundwater pressure for a fully tanked composite SCL tunnel. This assumption can be used at the preliminary design stage for SCL tunnels constructed in both permeable and impermeable ground. For the latter case, very little long-term consolidation load will be shared by the secondary lining due to the relatively low normal stiffness of the membrane interface when compared to the concrete linings.

4.2.2 Considering the effect of composite action

Composite action leads to different short-term and long-term effects on load sharing in tunnel linings.

In the short term, right after installing the sprayed membrane and secondary lining and before any external ground loads or groundwater pressure is applied, the sprayed membrane is bonded to both lining layers. It will restrict the secondary lining movement from the early-age thermal and shrinkage effects. This will usually lead to tensile stress being generated in the secondary lining. The maximum tensile stress usually occurs at the crown and knee position, as shown below in Figure 8 (Su & Bedi, 2019). This stress at the knee position is usually not a concern due to the design of either a construction joint or a full-moment connection. The maximum tensile stress at the secondary lining crown is usually a main concern. The higher the degree of composite action (e.g., the higher the shear stiffness of the membrane interface), the greater the maximum tensile stress at the secondary lining crown. Hence, the greater the risk of secondary lining cracks.

Figure 8. Secondary lining stress under early-age thermal and shrinkage effect for a composite SCL tunnel.

In the long term, after the long-term ground load and groundwater pressure are shared between the primary and secondary linings, the generated bending moment will be partly converted to axial compression and tension force in the primary and secondary linings, as explained previously. The quantity of this conversion is governed by the shear stiffness of the membrane interface. In addition, to understand how much the bending moment will be converted to axial force, it is also important to understand which lining will take the converted compression and tension. Figure 9 (Su, 2022) shows that the composite action-induced axial compression and tension depend on the tunnel lining deformation shape. If the tunnel is elongating horizontally, axial tension will be generated in the secondary lining at the crown and invert and in the primary lining at the axis level. In comparison, if the tunnel is elongating vertically, axial tension will be generated in the primary lining at the crown and invert and in the secondary lining at the axis level.

4.3 Stress status of the membrane interface

This section explains the stress status of the membrane interface under (1) early-age thermal and shrinkage effect, (2) external water pressure, (3) long-term consolidation loads, (4) other loads and (5) combined effects.

Figure 9. The positions around tunnel lining where composite action-induced tension and compression will occur.

4.3.1 Stress induced by early-age thermal and shrinkage

When the secondary lining is installed on the sprayed waterproofing membrane substrate, its early-age thermal and shrinkage effect will lead to a volume contraction of the lining. Due to the double-bonding nature of the sprayed membrane, tensile stress will be generated at the primary-membrane and secondary-membrane interfaces, as well as the sprayed membrane itself.

4.3.2 Stress induced by groundwater pressure

The stress states of the sprayed membrane under different groundwater pressure application positions are explained in this section. To facilitate the understanding of this topic, a visual representation of the interaction between the primary lining, sprayed membrane, and secondary lining in response to water pressure is shown in Figure 10 (Su & Bloodworth, 2022). The vertical bars represent the axial stiffness of the primary and secondary linings, which generate internal strains and stresses to resist external loading. The hand holding between the people represents the interface between the membrane and two linings.

In case 1, water pressure applied to the primary lining extrados is resisted by both linings and the membrane. In this case, the linings, membrane, and interfaces are in compression in the normal direction.

In case 2, when water pressure applies to the membrane extrados, the membrane, secondary lining, and secondary interface are in compression, but the primary lining and primary interface are in tension. If the magnitude of the water pressure exceeds the tensile strength between the primary lining intrados and the membrane extrados, debonding will occur. It is important to note that the membrane itself will not be in tension.

When short-term ground loading is superposed on the primary lining, its stress state changes from tension to compression. At the tunnel crown area, the membrane and the secondary interface could be in tension due to the self-weight of the secondary lining. As case 2 introduces tension at the primary-membrane interface and is a more conservative design assumption, its stress status will be used in the following discussion.

Figure 10. Holding hand analogy for load effects in membrane interface when water pressure on primary lining extrados (case 1) and membrane extrados (Case 2).

4.3.3 Stress induced by long-term consolidation loads

If composite SCL tunnels are constructed in impermeable stiff clay, the long-term consolidation will apply loads to the primary lining extrados, introducing compression in both interfaces and the sprayed membrane.

4.3.4 Stress induced by other loads

Depending on the individual project requirements and environment, the tunnel lining might experience other types of loads, such as internal downloads loads, etc. This will introduce local tensions in both interfaces and the sprayed membrane.

4.3.5 Final stress status

Therefore, the final stress status of the two interfaces and the membrane itself are subjected to the combined effects of the above-mentioned sources. The effect of the first three loadings is shown below in Table 2, with EAT, GWP, and LTC representing early-age thermal and shrinkage, groundwater pressure and long-term consolidation loads.

5 DESIGN OF COMPOSITE SCL TUNNELS

This section first presents the behaviour of the sprayed membrane within a composite tunnel through its whole life cycle, followed by recommended analysis stages. The suggested sprayed membrane properties for numerical analysis are provided as well.

Table 2. Stress status of membrane interface under different loadings.

	EAT	GWP	LTC
Primary interface	Tension	Tension	Compression
Sprayed membrane	Tension	Compression	Compression
Secondary interface	Tension	Compression	Compression

5.1 Membrane behaviour in composite SCL tunnels

To ensure optimal performance of the composite lining, the sprayed membrane must remain firmly bonded to both primary and secondary linings under the individual or combined action of compression, tension, and shear. This requirement applies to both short- and long-term scenarios and dry and wet conditions. Dry conditions refer to ambient temperature sprayed membranes with no direct water exposure or low moisture content. Wet conditions refer to sprayed membranes at ambient temperature, either directly exposed to water or with high moisture content.

To achieve this, it is crucial to understand the timeline behaviour of sprayed membranes within composite SCL tunnels. A simplified explanation of membrane behaviour in low-permeability stiff clay or high-permeable weak rock can be found in Figure 11 (Su & Bloodworth, 2023) and the accompanying bullet points. It is important to note that this does not consider the freeze and thaw effects on sprayed membranes. The behaviour of the sprayed membrane can be split into two stages – stage 1 is the loading stage, and stage 2 is the relaxation stage.

Stage 1 starts with installing the membrane and secondary lining with zero membrane shear stress and shear displacement (point a). After this point, the early-age thermal and shrinkage effect occurs, leading to certain stress generated in the membrane. After that, the long-term consolidation effect begins if the tunnel is constructed in impermeable stiff clay. For tunnels constructed in the permeable ground, the dewatering/depressurisation commissioned during the ground excavation and primary lining construction stops. Hence, the membrane interface's normal and shear stress and displacement start to increase.

Stage 1 ends at point b when long-term consolidation is completed for tunnels constructed in stiff clay, and dewatering/depressurisation effects disappear for tunnels in permeable ground. The membrane is still dry and without any creep within stage 1. At this point, the normal and shear stresses are the greatest throughout their lifetime. It should be noted that a certain degree of creep should occur, and the membrane gradually becomes wet during stage 1. However, this figure neglects these effects for demonstration purposes to ensure the maximum interface stresses are obtained.

After point b, creep and moisture movement into the membrane begins. They will reduce the

membrane's stiffness, reducing normal and shear stress and increasing normal and shear displacement. These effects continue and, in theory, could finish at either point c or d.

At point c, a small amount of normal and shear stresses is maintained within the membrane, and the normal and shear displacement of the membrane is greater than at point b.

In the theoretical maximum case point d, very little normal or shear stress is maintained within the membrane, and the normal and shear displacement reaches the theoretical maximum value.

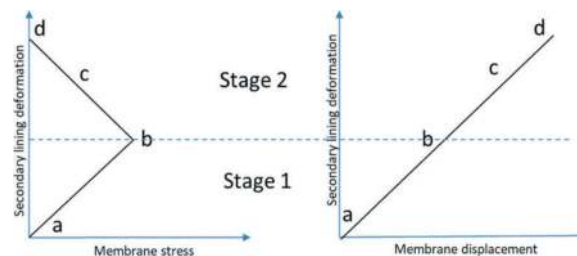

Figure 11. Timeline behaviour of sprayed membrane within a composite SCL tunnel.

5.2 Recommended analysis stages

Based on the description of the timeline behaviour of the sprayed membrane above, three stages are suggested to be analysed, and lining and membrane performance are to be checked according to Figure 11.

At point a, check the interface robustness for water pressure on the primary lining extrados. The secondary lining is only resisting its own self-weight and early-age thermal and shrinkage-induced stresses.

At point b, with the dry membrane properties, the membrane interface normal and shear stresses are greatest and should be checked against short-term dry membrane interface tensile/shear strain and stress limits. The interface robustness should be checked by assuming water pressure on the primary lining extrados. Note that this is a theoretical point for the maximum membrane interface stress in an SCL tunnel with a permanent primary lining.

At point c, with the wet membrane properties, the normal and shear strain (displacement) of the membrane interface is the greatest and should be checked against long-term wet membrane interface tensile/shear strain and stress limits. The interface robustness should be checked for water pressure on the membrane extrados. The primary and secondary lining capacity should be checked at each of the above stages. The capacity of the tunnel linings should be checked following the relevant concrete design standard or industry guidance, which will not be expanded here.

5.3 Selection of interface parameters

Su and Bloodworth (2016) carried out a comprehensive laboratory testing programme on element specimens cut from composite SCL panels (with

sandwiched EVA-based sprayed membrane) with different primary lining substrate surface preparations and membrane thicknesses, loaded in compression, tension and shear under ambient laboratory climate conditions (e.g., 15-20°C temperature and 40-60% relative humidity) under immediate short-term loading.

The variation in moisture content of the EVA-based membrane observed in field measurements can affect its mechanical properties, as suggested by Holter (2016) and confirmed by Diez et al. (2019). Table 3 provides a range of key mechanical interface parameters for EVA-based membranes in dry and wet conditions. However, it should be noted that the limiting tensile and shear strains under long-term loadings at different stress levels have not yet been determined, and this is an important area for future research. Table 3 lists recommended interface parameters for the sprayed membrane interface, adopting the option 1 modelling approach as mentioned in the next section.

Table 3. Recommended membrane interface parameters.

	Unit	Dry membrane	Wet membrane
Normal stiffness (Kn)	GPa/m	4-8	0.55-0.85
Shear stiffness (Ks)	GPa/m	2-4	0.30-0.35
Tensile strength	MPa	0.8	0.35-1.00
Shear strength	MPa	2.0	Not reported*

* A value of 0.5MPa can be used for modelling purposes, subjected to project testing verification

6 MODELLING COMPOSITE SCL TUNNELS

To effectively simulate composite action in a sprayed membrane interface, commercially available finite element or finite difference software can be used. Closed-form analytical solutions are generally avoided due to the complexity of SCL design, the construction sequence, and non-circular tunnel profiles. “Beam and Spring” models are typically used to simulate the secondary lining behaviour. However, these models cannot realistically simulate the stage construction of the primary lining and complex soil-structure interaction. In more complex situations, such as junctions and caverns with multiple side galleries, 3D models may be used.

For the routine design of SCL tunnels, 2D plane strain modelling is the most common and stress relief factors obtained from detailed 3D modelling experience can be applied. A list of key considerations for simulating composite SCL tunnels is provided in the full design guidance document, which is not included in this paper due to paper length limitations. The following sections will introduce the three key topics in the numerical modelling of composite SCL tunnels: (1) simulation of composite action, (2) simulation of the membrane interface, (3) simulation of groundwater pressure on the membrane, and (4) simulation of early-age thermal and shrinkage effect.

6.1 Simulation of composite action

When designing an SCL tunnel with composite action, it’s important to use appropriate modelling techniques to simulate the interaction between the primary and secondary lining layers. Traditional 2D beam or 3D shell elements should be avoided as they cannot realistically model the stress distribution through the depth of the linings. Hence, no composite action will be simulated using two beam elements (representing two layers of concrete linings) and one layer of membrane interface. Instead, 2D zones or 3D volume elements should be used for the linings and interface elements for the sprayed concrete-sprayed membrane interface to simulate composite action accurately. It’s also important to ensure that sufficient elements are present through the thickness of the linings to model the flexural behaviour and any potential cracking.

When using 2D zones or 3D volume elements to model primary and secondary linings in SCL tunnel analysis, the output is stresses rather than internal force resultants such as axial force and bending moment, which are required for thrust-moment capacity curves used in design verification. To obtain these internal force resultants, 2D beam or 3D shell elements can be attached to the centroidal axis of each lining layer, with negligible stiffness, to follow their deformation. This is known as the “dummy beam” approach. To ensure accurate analysis, it is important to appropriately scale the output of axial force and bending moment during post-processing. Another option is to use built-in functions in some finite element programs to calculate lining forces automatically based on the stresses.

6.2 Simulation of membrane interfaces

To effectively simulate composite action in SCL tunnels, the interface used in the numerical analyses must be capable of transferring compressive, tensile, and shear stresses between the two layers of zones or volume elements. Option 1, which uses interface elements, is typically the most suitable for simulating the membrane interface in the composite SCL tunnel. This is because the thickness of the membrane is relatively small compared to the lining thickness. To implement Option 1, normal (cross the membrane) and shear (along the membrane) springs with tension and shear strength cut-offs can be utilised to create interface elements. Figure 12 (Su & Bloodworth, 2019) provides a schematic example of this approach.

Figure 12. Interface element approach (option 1).

On the other hand, when carrying out numerical calibration against composite beam tests, neither adhesion nor cohesion failure is usually a concern. Instead, the membrane thickness is significant compared with the total lining thickness (e.g., >5% of total thickness), and if ignored, predicted results will differ significantly from laboratory test results. In this case, Option 2 should be adopted with the sprayed membrane simulated with 2D zones or 3D volume elements, as shown in Figure 13 (Su & Bloodworth, 2019). Option 3 is the most comprehensive method to simulate composite action in situations where both the membrane thickness effect and adhesion and cohesion failure mechanisms need to be considered. In this approach, the 2D zones or 3D volume elements representing the membrane are assigned actual material parameters, and the appropriate interface parameters are assigned to each interface element, as shown in Figure 14 (Su & Bloodworth, 2019).

Figure 13. Zone or volume element approach (option 2).

Figure 14. Hybrid approach (option 3).

6.3 Simulation of groundwater pressure

The application of groundwater pressure to the extrados of the primary lining was achieved by assigning groundwater within the ground, resulting in the groundwater pressure being applied to the extrados of the primary lining. To move the application of groundwater pressure to the extrados of the membrane interface, a pair of mechanical loads should be applied to the model, as shown in Figure 15 (Su & Bloodworth, 2022). These loads consisted of outward forces that cancelled out the groundwater pressure applied from the soil and inward forces that applied the groundwater pressure at the desired location. The magnitudes of these forces should be automatically calculated as a function of their depth below the phreatic surface in the model. The effect of groundwater pressure-induced membrane interface debonding is not discussed here but can be referred to Su (2023).

6.4 Simulation of early-age thermal and shrinkage

The early-age thermal and shrinkage effect of the concrete lining can be simulated by assigning compressive strains with age-dependent concrete

Figure 15. Simulation of groundwater pressure application for bonded membrane using mechanical forces.

Young's modulus in a stepwise approach. Alternatively, an equivalent total strain can be assigned to the matured concrete Young's modulus in a one-step approach to achieve the same effect. The compressive strain is derived from the concrete mix specification and testing performance requirement. Combined with the restraint effect of the membrane substrate, tensile stress at the membrane-concrete interface and the membrane itself, as well as in the concrete lining hoop direction, will be developed, as shown in Figure 8.

7 CONCLUSIONS

This paper provides a glimpse of the updated design chapter for the next version of the ITAtech Lining and Waterproofing Activity Group design guidance document. This design chapter is still under development and review. Hence, new information might be added. Notwithstanding, it is hoped that this paper will serve as a valuable resource for professionals engaged in the design and construction of composite SCL tunnels, enabling them to make informed decisions and enhance the overall efficiency of such tunnel projects. Last but not least, long-term stress and strain monitoring data for composite linings are sought to verify the engineering principles and proposed design approaches.

Self healing materials for preventing tunnel crystalline damage: Anti-calcium leaching, mechanical performance, self-healing mechanism

Yueping Tong, Fei Ye, Chongming Tian, Yin Jiang, Junyuan Zhang, Han Wang, Bowen Wu & Xingbo Han

Chang'an university, Xi'an, China

ABSTRACT: The crystalline blockage disease in tunnel drainage systems is closely linked to the calcium leaching process of shotcrete, especially in water-rich tunnels. Groundwater infiltrates the initial support shotcrete through cracks, continuously transporting calcium material from the hydration products of cement into the drainage system. This leads to a significant reduction in the tunnel's drainage capacity and a notable increase in safety and operational risks to the lining structure. In order to reduce the generation of calcium crystallization within the tunnel from the source, this paper employs a deionized water immersion test method. Through the determination of parameters such as the pH value of the leaching solution, calcium ion concentration, mechanical strength, variation rate of crack length, and relative strength recovery, as well as microstructure analysis, it investigates the effectiveness of self-healing materials in improving the resistance of shotcrete to calcium leaching and their applicability in tunnels. The research findings indicate that self-healing materials can effectively enhance the resistance of shotcrete to calcium leaching. The calcium ion concentration in the leaching solution is significantly lower than that of ordinary shotcrete, with a reduction rate of up to 80.72%. Self-healing materials enable the shotcrete to withstand significantly higher bending loads, and they also contribute to substantial improvements in flexural strength and ductility. These materials also exhibit good repair effects on pre-existing cracks in the mortar, with a relative compressive strength recovery rate of up to 88%. Microscopic observations reveal the growth of insoluble micro-crystallizations within the self-healing shotcrete. These micro-crystallizations fill the capillaries and interface cracks in the shotcrete, reducing the seepage pathways between groundwater and shotcrete. This suggests a certain potential for resisting calcium leaching.

1 INTRODUCTION

In recent years, a significant number of tunnels worldwide have experienced the phenomenon of crystalline blockage in their drainage systems (Jung et al., 2013; Ye et al., 2021). Due to the fact that these drainage systems are concealed within the tunnel structure, addressing this issue has proven to be a challenging task, causing substantial concerns for tunnel operators and maintenance personnel. The blockage of tunnel drainage systems results in a substantial reduction in the tunnel's drainage capacity. If left uncleared, the water pressure acting on the lining continuously increases, exacerbating pre-existing issues in the tunnel, such as cracks and water infiltration. As the water pressure continues to rise, it may even lead to structural damage, including deformation and cracking of the lining. This poses

a significant risk to both the operational and structural safety of the tunnel (Xu et al., 2022).

The crystalline substances found within tunnel drainage pipes are primarily composed of calcium carbonate, often mixed with sediments, cement particles, and other particulate matter. Initially, these substances are relatively loose in texture and can be easily flushed away by water. However, over time, these crystalline materials become more compact, adhering to the interior surface of the drainage pipes, forming a hard and high-strength plate-like structure that is difficult to remove. The main source of crystallization in tunnel drains is the Ca^{2+} leaching process of the shotcrete, and mountain tunnels are subject to seepage fields that allow water from within the mountain to continuously converge into the tunnel. Before groundwater can enter the tunnel drainage system, it must first pass through the

tunnel's initial support shotcrete, a process that is actually the root cause of the crystalline clogging problem in tunnels. As groundwater continuously permeates the shotcrete, calcium-rich hydration products in the shotcrete, such as $\text{Ca}(\text{OH})_2$ and C-S-H, undergo dissolution-diffusion processes: $\text{Ca}(\text{OH})_2 (\text{s}) \rightarrow \text{Ca}^{2+} + 2 \text{OH}^-$, $\text{C-S-H} (\text{s}) \rightarrow x \text{Ca}^{2+} + 2x \text{OH}^- + \text{SiO}_2 \cdot n \text{H}_2\text{O}$ (Lu et al., 2021). This leads to a substantial influx of Ca^{2+} into the tunnel drainage system. When these Ca^{2+} come into contact with the air, they react to precipitate calcium carbonate: $\text{CO}_2 + \text{Ca}(\text{OH})_2 \rightarrow \text{CaCO}_3 \downarrow + \text{H}_2\text{O}$, $\text{CO}_3^{2-} + \text{Ca}^{2+} \rightarrow \text{CaCO}_3 \downarrow$, $\text{HCO}_3^- + \text{Ca}^{2+} + \text{OH}^- \rightarrow \text{CaCO}_3 \downarrow + \text{H}_2\text{O}$. The accumulation of calcium carbonate crystals gradually leads to the blockage of the tunnel drainage pipes.

To address the issue of crystalline blockage in tunnel drainage systems, many researchers have suggested that the solution should start with the concrete itself, considering it as the source of the problem (Dietzel et al., 2022; Tian et al., 2020; Galan et al., 2019). Currently, commonly used approaches primarily involve enhancing the compactness of concrete through the addition of mineral admixtures to improve its resistance to calcium leaching. As shown by Thurmann et al. (2015) investigated the anti-leaching effects of various concrete mixtures and proposed that replacing 30% of cement with materials such as fly ash or slag can reduce calcium leaching by 35%, while substituting 15% of cement with higher-activity volcanic ash can reduce it by 55%. Jiang et al. (2023) studied the impact of different levels of glass powder on concrete's resistance to leaching and found that adding 10% of glass powder led to the least calcium ion precipitation and the densest microstructure in concrete. Harer (2017) suggested that using materials such as fly ash and 7% aluminum sulfate accelerant can significantly reduce the calcium leaching in concrete, leading to a reduction of about 65% in calcium ion release. Tang et al. (2016) employed an accelerated calcium leaching test method to study the effect of slag on the calcium leaching process in cement slurry and determined that a slag content of 40% to 50% reflected the optimal resistance to calcium leaching.

However, as tunnel operations continue for longer durations, the incidence of water infiltration and cracking in tunnels increases. To meet the demand for enhanced durability, some scholars have proposed the application of self-healing materials to cement-based materials to achieve self-repair effects in concrete (Ghosh et al., 2009; Van et al., 2011). As shown by Kim (2011) introduced a self-healing technique for post-cracked concrete performance by embedding polyurethane healing agents in mortar. The results demonstrated that the mortar could recover over 50% of its original strength and stiffness after self-repair. Additionally, due to autonomous crack healing, permeability was reduced by factors ranging from 102 to 104. Tran et al. (2009) explored the effectiveness of developing a self-repair system in ordinary concrete using single-component epoxy resin as the healing

agent and hollow tubes as the storage system. The research revealed that repeated self-healing was achievable, with strength partially recovered after four days of healing and fully restored after seven days, with an increase of approximately 30% over the initial values. The post-healing crack strength also exceeded that of standard specimens by 32%. Ahn et al. (2010) investigated the self-healing effect of concrete with mineral admixtures through a recrystallization method in practical applications. The results indicated that concrete cracks autonomously healed after three days, with crack widths decreasing from 0.22mm to 0.16mm after seven days of curing. By day 33, nearly complete self-healing had occurred, presenting a viable method for repairing concrete cracks in tunnels.

In summary, self-healing materials offer excellent durability and crack repair capabilities. However, existing research has predominantly focused on the crack repair and strength enhancement aspects of self-healing concrete, with limited attention given to its resistance to calcium leaching. Therefore, this paper, by incorporating self-healing materials into shotcrete, investigates the variations in calcium leaching resistance, compressive strength, flexural strength, and crack development. Microscopic analysis is employed to validate the optimization mechanisms. The research findings present a novel approach to address crystalline blockage in tunnels and leakage-related cracks in linings.

2 MATERIALS AND METHODS

2.1 Materials

The cement used is White Dragon brand cement with a grade of P·O 42.5. The coarse aggregate sourced from the Mahu Stone Factory, while the fine aggregate Hanjiang River sand. Local groundwater is supplied for mixing, and a high-performance water-reducing agent with a 40% water-reducing rate is used. The accelerator selected is a non-alkaline liquid accelerator from Shanxi Budongquan Building Materials Co., Ltd., meeting the GB/T35159-2017 standard. The specific performance characteristics of the HZC-1B non-alkaline liquid accelerator provided in Tables 1 and 2.

The self-healing permeable crystalline material (SHM) is provided by Nanjing Paniel Technology Industrial Co., Ltd. The substance's composition was tested using a PANalytical Axios X-ray fluorescence spectrometer, with the test results shown in Table 3. Performance parameters of the SHM were evaluated

2.2 Mix proportion

Large panels of shotcrete were prepared on-site at the Shuang Feng Tunnel in Shaanxi for experimental purposes. The control group utilized regular shotcrete, denoted as “OS,” while the experimental group used shotcrete with internally incorporated self-healing material, referred to as “SHS.” In this mixture, the sand content was 50%, the water-reducing agent dosage was 1% of the cementitious material content, the accelerator dosage was 4% of the cementitious material content, and the self-healing material was internally incorporated at 3%

of the cementitious material content. The shotcrete mix proportions are provided in Table 5.

Table 5. Shotcrete mix proportions/(kg/m³).

No.	Cement	Sand	Stone	Water	SHM	Sp.	Acc.
OS	410	868	843	183	0	4.1	16.4
SHS	397.7	868	843	183	12.3	4.1	16.4

2.3 Specimens procedures

In accordance with GB50086-2001 “Technical Specification for Soil and Rock Anchor and Shotcrete Support,” wet shotcrete large panels were produced using the wet-spray method at the tunnel site. The dimensions of the large panel were 450 mm × 350 mm × 120 mm. Before spraying the shotcrete, the large panel test molds were positioned against the wall at a 75° angle with the ground. The nozzle was positioned vertically to the test mold, with a distance between 0.95 m to 1.20 m. After 1 day of forming the large panel, it was demolded, and a multifunctional cutting machine was used to cut the large panel into cubes measuring 100 mm × 100 mm × 100 mm and prisms measuring 100 mm × 100 mm × 400 mm. These specimens were then used for immersion testing. The immersion tank dimensions were 40 cm × 50 cm × 22 cm, and each tank was filled with 19.5 L of deionized water to fully submerge the test specimens, simulating the calcium leaching process of shotcrete. The test process is depicted in Figure 1.

2.4 Testing method

2.4.1 Calcium dissolution test

At 1 day, 3 days, 7 days, and 28 days of immersion, 1000 mL of leaching solution was collected for analysis. A PXSJ-226 ion meter was employed to

Figure 1. The forming process of shotcrete slab and soaking process.

Figure 2. Macroscopic test of the shotcrete specimen (a) Calcium dissolution test (b) Compressive strength (c) Four-point bend strength test (d) Mortar compressive strength tester.

conduct Ca^{2+} and pH tests on the leaching solution. Each test was performed six times, and after each test, the electrodes were rinsed with deionized water and dried to minimize errors. The average values were then calculated. The testing procedure is illustrated in Figure 2(a).

2.4.2 Compressive strength and four-point bend test

After immersing the specimens for 1 day, 3 days, 7 days, and 28 days, the specimens were removed for compressive strength and four-point bending tests conducted in accordance with the GB/T 50081-2009 standard. For the compressive strength test (Figure 2(b)), the specimen was tested using the servo-hydraulic loading device, and the compressive strength value was calculated based on Equation (1). For the four-point bending test (Figure 2(c)), the DYW-2000 universal material testing machine was used. The flexural strength of the specimens was calculated using Equation (2). Three specimens were tested for each group, and the arithmetic average was determined.

$$f = \frac{\frac{1}{3} \sum_{i=1}^3 F_i}{A} \quad (1)$$

Where, f is the compressive strength (MPa); F_i is the peak load of the three specimens (KN); A is the cross-sectional area (mm^2).

$$f_i = \frac{Fl}{bh^2} \quad (2)$$

Where, f_i is the flexural strength (MPa); F is the peak load of the specimen (KN); l is the distance between the bottom supports of the specimen (mm); b is the width of the specimen (mm); h is the height of the specimen (mm).

2.4.3 Self-healing crack test

The testing procedure for evaluating the self-healing effect of self-healing shotcrete cracks is as follows: 1) Prepare mortar specimens measuring $70 \text{ mm} \times 70 \text{ mm} \times 70 \text{ mm}$; 2) After curing for 7 days, apply compressive force to the mortar specimens until cracks appear, as shown in Figure 2(d), and record the compressive strength as the initial compressive strength of the mortar, denoted as I_0 ; 3) Place the cracked specimens in deionized water and observe the crack healing process. After 28 days, conduct a second compressive strength test, and calculate the relative strength recovery rate using Equation (3).

$$K_I = \frac{I_R}{I_0} \times 100\% \quad (3)$$

Where, I_0 is the initial compressive strength, I_R is the secondary compressive strength after the crack healing process, K_I is the relative strength recovery rate.

2.4.4 SEM test

After the specified leaching time, the shotcrete specimens to be tested are cut into small pieces of approximately 0.5 mm in size. Subsequently, these pieces are dried in a drying oven for 24 hours. The dried, electrically conductive samples are then prepared for testing, and their microscopic appearance is observed. The testing equipment used is the Tescan Mira4 scanning electron microscope (SEM).

3 RESULTS AND DISCUSSION

3.1 Anti-calcium ion leaching of shotcrete

Based on the pH change curves in Figure 3, it can be observed that both ordinary shotcrete and self-healing shotcrete exhibit relatively high pH values within the first 7 days of leaching, with minor variations. The pH value of ordinary shotcrete is around 11.8, while that of self-healing shotcrete is above 11.4. As the leaching process progresses, the hydration reactions in the shotcrete become more extensive, and secondary hydration reactions occur, consuming a significant amount of alkaline compounds. By the end of the 28-day leaching period, the pH values for ordinary shotcrete and self-healing shotcrete have decreased to 10.3 and 9.9, respectively.

Figure 4. illustrates the changes in Ca^{2+} concentration in the shotcrete. The data indicate that as the leaching time increases, the Ca^{2+} leaching efficiency in self-healing shotcrete gradually decreases. The Ca^{2+} concentration in self-healing shotcrete is significantly lower than in ordinary shotcrete, with a reduction rate of up to 34.69% to 80.72%. Self-healing materials contain a substantial amount of hydrophilic crystalline growth factors. Under conditions of water infiltration, these growth factors move through the internal moisture of the shotcrete,

Figure 3. The pH change of the leaching solution.

triggering secondary cement hydration reactions and continuously generating insoluble micro-crystallizations. These micro-crystallizations serve two main purposes: 1) They can penetrate into the capillary cracks within the shotcrete, thereby enhancing the shotcrete's resistance to water permeation; 2) They can fill the pre-existing cracks in the shotcrete or new cracks formed due to leaching, thus cutting off the flow pathways between groundwater and the shotcrete lining. This significantly improves the shotcrete's resistance to calcium leaching, and this process is referred to as the self-healing process, as depicted in the schematic diagram in Figure 5.

Figure 4. Variation of calcium ion concentration in shotcrete.

3.2 Compressive strength of shotcrete

The compressive strength variation of shotcrete is shown in Figure 6. After 1 day of leaching, the compressive strength of self-healing shotcrete and ordinary shotcrete is essentially similar. At 3 days of leaching, the compressive strength of shotcrete increases significantly. By 7 days of leaching, the change in compressive strength is minimal. After leaching for 28 days,

Figure 5. Crystal growth factor healing mechanism.

the compressive strength of ordinary shotcrete and self-healing shotcrete is 31.190 MPa and 30.163 MPa, respectively. Overall, the inclusion of self-healing materials has resulted in a slight reduction in the compressive strength of shotcrete. This outcome may be due to the relatively high content of self-healing materials, which tend to aggregate within the shotcrete, leading to poor homogeneity and limited improvement in the compressive strength of shotcrete.

Figure 6. Compressive strength of shotcrete.

3.3 Bending property of shotcrete of shotcrete

3.3.1 Failure pattern

The fracture morphology of the two types of shotcrete after 28 days of leaching is shown in Figure 7. From the figure, it can be observed that the ordinary shotcrete instantly fractures from the middle portion when it reaches the ultimate load, resulting in an incomplete form. In contrast, the shotcrete containing self-healing materials exhibits a distinct difference in the mode of failure. Before reaching the maximum load, fine cracks appear in the lower middle section

of the specimen and continue to expand, but they do not completely split. Moreover, it is evident that the loading time for self-healing shotcrete is longer, and the appearance of cracks is delayed.

Figure 7. Cracking pattern of (a) ordinary shotcrete and (b) self-healing shotcrete.

3.3.2 Calculating crack width

Due to the varying crack failure patterns observed in the shotcrete, it is necessary to quantitatively assess the changes in crack length using Equation (4). Figure 8 illustrates the curve displaying the rate of change in cracks in the shotcrete. In comparison, self-healing shotcrete exhibits a higher rate of change in crack length. This results in longer and more intricate cracks, with the rate of change in crack length increasing by 13.8% to 52.2%. This observation suggests that self-healing shotcrete can accommodate more significant deformations and is characterized by a ductile failure mode. In contrast, ordinary shotcrete exhibits brittle failure, with a smaller load-carrying capacity when subjected to larger crack openings.

$$R_L = \frac{L_1 - L_0}{L_0} \times 100\% \quad (4)$$

Where, R_L is the percentage change in crack length, (%); L_1 is the crack length, (mm); L_0 is the initial specimen height, $L_0=100$ mm.

Figure 8. Rate of crack length change of shotcrete at different time.

3.3.3 Flexural strength

The variation in the flexural strength of shotcrete is depicted in Figure 9. Both types of shotcrete show

an increasing trend in flexural strength as leaching time progresses. However, in comparison, the self-healing material proves to be more conducive to enhancing the flexural strength of shotcrete. At 28 days, there is an 8.3% increase in strength, with the most significant increase occurring at 3 days, reaching 10%. This underscores the fact that the self-healing shotcrete contains a substantial quantity of micro-crystallizations that serve as bridges, reinforcing its toughness and enabling it to withstand higher bending loads, resulting in improved flexural strength (Diego et al., 2023).

Figure 9. Flexural strength of shotcrete.

3.4 Self-healing property

3.4.1 Crack healing morphology

The morphology of ordinary mortar and self-healing mortar after prefabricated cracks is shown in Figure 10(a) and (c). When the ordinary specimen is compressed to 88.1 kN, severe damage is evident with large cracks and corner detachment, resulting in poor integrity. In contrast, for the self-healing sample, when subjected to a load of 131.0 kN, only a small crack and a few micro-cracks are observed. After 28 days of immersion, the crack-healing morphology of ordinary mortar and self-healing mortar is presented in Figure 10(b), (d). In the ordinary sample, the original cracks are still clearly visible, showing no healing effect. Conversely, in the self-healing sample, the original cracks and fissures are no longer observable at their initial locations, and large cracks are hardly visible on the surface and sides.

Due to the possibility that micro-crystallizations generated by self-healing materials may form within the shotcrete, assessing the self-healing effect of these materials based solely on changes in surface crack width is not comprehensive (Zeng et al., 2015). Furthermore, the relationship between external changes in crack appearance and the internal self-healing state

Figure 10. Mortar crack morphology comparison before healing and 28 days healing.

may not necessarily be straightforward. Therefore, the next section provides a more comprehensive evaluation by considering the restoration of mechanical performance.

3.4.2 Compressive strength of mortar

Figure 11 illustrates a comparison of compressive strength before and after healing for the mortar. It is evident that the compressive strength of both the damaged self-healing mortar and the ordinary mortar decreases after 28 days of leaching. However, the self-healing mortar exhibits a smaller reduction in compressive strength, with a post-healing compressive strength that is 3.5 times that of the ordinary mortar. The relative strength recovery rates are 59% for the ordinary mortar and 88% for the self-healing mortar. This indicates that self-healing materials not only facilitate crack healing but also contribute to the restoration of mechanical performance to some extent. This outcome is mainly associated with the inherent characteristics of the healing materials.

Figure 11. Initial and second compressive strength of specimens.

The self-healing mortar undergo a process of “dehydration-dormancy” to “hydration-activation-crystallization” before and after the creation of cracks. After 28 days, the cracks are substantially healed, resulting in a relatively high compressive strength recovery rate (Victor et al., 1998). This suggests that when groundwater infiltrates the shotcrete in tunnels, self-healing materials play a role in repairing leaching fissures and larger cracks, filling voids created by cracks and defects with generated micro-crystallizations, sealing the cracks, and reducing the risk of calcium leaching (Qian et al., 2010; Yang et al., 2010).

3.5 SEM analysis

Figure 12 presents SEM images of ordinary shotcrete and self-healing shotcrete at 1, 7, and 28 days, respectively. In the early stages, both ordinary and self-healing specimens exhibit plate-like calcium hydroxide and unhydrated cement particles. The ordinary specimen’s interface regions show pre-existing cracks, whereas the self-healing specimen’s interface is denser. After 7 days of leaching, it is observable that at the crack interfaces of ordinary specimens, cracks are more pronounced, and calcium hydroxide is still present. In contrast, the self-healing specimens have grown a substantial network of micro-crystallizations at the interface, and noticeable cracks are not visible. By the 28th day, the internal structure of the ordinary specimens exhibits short rod-shaped ettringite and C-S-H gel. In contrast, the self-healing specimens primarily consist of fibrous gel. With increasing leaching time, the self-healing specimens shift from localized micro-crystallizations to a substantial quantity of micro-crystallizations. These micro-crystallizations deposit at the surface or interfaces of the paste, forming a network structure (Reinhardt et al., 2003; Chu et al., 2014). This network structure fills the capillaries within the paste and serves as a bridge in the transition zones between interfaces. The internal

Figure 12. Mortar crack morphology comparison before healing and 28 days healing.

structure of the self-healing specimens appears relatively dense, predominantly filled with a significant number of fine micro-crystallizations generated during different stages (plastic and hardening). Therefore, self-healing materials not only repair early cracks but also inhibit the development of later cracks in shotcrete, ultimately achieving the desired effect of “no cracks, no leakage” (Mihashi et al., 2000).

4 CONCLUSIONS

This paper employed a deionized water immersion method to investigate the effects of self-healing materials on shotcrete, focusing on improvements in calcium leaching resistance, mechanical properties, and crack repair. The main conclusions are as follows:

- 1) The pH difference between the leaching solutions of ordinary shotcrete and self-healing shotcrete was small. After 28 days of leaching, their pH values decreased to approximately 10.3 and 9.9, respectively. The self-healing shotcrete exhibited significantly lower Ca^{2+} concentrations in the leaching solution, with reduction rates of up to 80.72%.
- 2) Self-healing materials had a limited impact on improving the compressive strength of shotcrete but enhanced its deformability. Self-healing shotcrete displayed a more ductile failure mode, with crack length changes higher by 13.8% to 52.2%, and a maximum increase in flexural strength of 10% compared to ordinary shotcrete.
- 3) The incorporation of self-healing materials resulted in the effective repair of native cracks in mortar or concrete and controlled the development of cracks. Self-healing specimens achieved

a relative compressive strength recovery rate of 88%.

- 4) Microscopic analysis indicates that self-healing materials contain a significant amount of hydrophilic crystalline growth factors. These factors lead to the formation of insoluble micro-crystallizations that fill the micro-cracks and interfacial cracks within the shotcrete, resulting in a network structure. The internal structure becomes denser, suggesting that self-healing materials hold potential as a means to resist calcium leaching.

Analysis of viscous fingering between water and cement-based grout in tunnels

Suihan Zhang*, Fredrik Johansson & Liangchao Zou
KTH- Royal Institute of Technology, Stockholm, Sweden

ABSTRACT: Rock grouting is a common measure to reduce the seepage through conductive fractures in the rock mass around tunnels. Two types of grouting are normally carried, pre-excavation grouting and post-excavation grouting. Pre-grouting, commonly applied in Scandinavian tunnels, is used to seal the conductive fractures around the tunnel before the excavation of tunnel sections. In post-excavation grouting, which is dedicated to seal the remaining leakage in the excavated tunnel sections, the injected grout often encounters large seepage in rock fractures. Previous experiments have shown that the grout can be washed out easily when the grout is fresh even though the injected grout has initially sealed the fracture. One of the most significant phenomena for the water to “break up” the grout is viscous fingering. Viscous fingering occurs when certain conditions enable interface instability between the water and the cement-based grout. In this paper, the authors aim to evaluate if viscous fingering can be avoided under pre- and post-grouting conditions. For this purpose, computational fluid dynamics (CFD) simulations using the software Ansys Fluent is carried out. The simulation results demonstrating viscous fingering between water and cement-based grout are analyzed and discussed. Based on the results, suggestions on the grouting strategy with respect to pre- and post-grouting are provided to deal with the potential issues related to viscous fingering.

Keywords: Rock grouting, Rock tunnelling, Viscous fingering, Yield stress, CFD analysis

1 INTRODUCTION

Excessive water seepage through rock fractures can cause significant problems in rock tunnels in both construction and operation phases. To deal with the excessive water seepage, one of the common measures is to seal the rock mass around the tunnel using cement-based grouting. For instance, pre-excavation grouting (pre-grouting) is commonly applied in Scandinavian tunnels to seal conductive fractures around the tunnel before excavation of tunnel sections. It aims to form a tight zone around the tunnel that ensures the water ingress into the tunnel is within requirements (NFF 2011; Stille 2015). Another common type of tunnel grouting, post-excavation grouting (post-grouting), mainly serves as a remedial measure to seal the remaining leakage after the excavation of tunnel sections.

The pre-grouting in tunnels is usually carried out under the assumption of hydrostatic pore pressure conditions with no seepage flow occurring in the rock fractures (Stille 2015). This implies that the injected grout is not likely to be disturbed by the

flowing water in the fractures if the rock fractures are not well connected. However, once the grouted fracture is connected to the excavated tunnel, e.g. via new boreholes, a pressure gradient may build up in the grouted areas causing seepage flow in the rock fractures that can disturb the injected grout. Post-grouting work, on the contrary, often encounters unfavorable hydraulic conditions. The excavated tunnel functions as a well in the rock mass. Therefore, the pressure gradient can be high close to the tunnel, especially if the tunnel is at great depth under the groundwater level. The grout for post-grouting is often injected into fractures or zones with strong water flow and high pressure gradient. This unfavorable environment affects the penetration length of the grout during the injection since erosion constantly occurs (Axelsson 2009; Guo et al. 2020). Even if the fractures were sealed during the injection, the high pressure gradient may still drive the water to disturb the grouted area afterwards.

One of the mechanisms that could potentially disturb the injected grout when pressure gradient exists in the grouted fracture is viscous fingering. Viscous

fingering describes a type of interface instability between two fluids when the less viscous fluids is displacing the more viscous fluid (Homsy 1987). This instability, which is also called the Saffman-Taylor instability (Saffman and Taylor 1958) occurs due to the difference in viscosities and presents itself in the shape of fingers in the more viscous fluid. In the context of rock grouting, the groundwater (Newtonian fluid) behaves as the less viscous fluid which can displace the more viscous fluid, i.e. the grout (yield-stress fluid for cement-based grout) after the injection. Coussot (1999) and Lindner et al. (2000) studied the viscous fingering between a Newtonian fluid and a yield-stress fluid in a Hele-Shaw cell (parallel plates similar to a homogeneous fracture replica), but these studies was not performed in the context of water-grout interaction. Funehag (2017) described the risk of viscous fingering after grouting with leaking boreholes penetrating the grouted area. From the observation of an unpublished experimental attempt by the authors to visualize water-grout interaction, viscous fingering initiated in the grout and then developed rapidly until the water penetrated into the grouted area. Significant grout erosion followed up and reduced the grouted area. Apart from Funehag (2017) and this experimental attempt, the viscous fingering between water and cement-based grout has not been specifically investigated elsewhere.

The present study aims to investigate the interaction between water and cement-based grout from perspectives of potential risks for viscous fingering in tunnel grouting. The focus is given to the time window after the injection is finished (grouting pressure relieved). This is the time when viscous fingering is most likely to occur. If viscous fingering is not initiated, the cement-based grout has the time and the space to grow its strength through hardening and thus ensure a satisfactory grouting outcome.

The study is performed through two-phase computational fluid dynamics (CFD) simulations. A sensitivity analysis is performed of the parameters describing the rheological properties as well as the influence from the boundary conditions. The outcome of the present study is to suggest principles for a design strategy to prevent or minimize the effect of viscous fingering between groundwater and cement-based grout with consideration of the rheological properties of the grout.

2 METHODOLOGY

2.1 Analytical limit state for viscous fingering

For a typical yield stress fluid, the shear stress in the fluid needs to overcome the yield stress for this fluid to start flowing. The fluid will remain static if the shear stress is lower than the yield stress. Based on this property of a yield stress fluid, groundwater may not be able to displace the fresh grout if the pressure gradient is insufficient. As described in the previous chapter, one of the prerequisites for viscous fingering to occur is one fluid displacing another. Therefore, a limit state where viscous fingering is just to be initiated may exist between water and cement-based grout. This limit state coincides with the limit state for the cement-based grout to start flowing. Based on the work by Coussot (1999), in the context of flow between two parallel plates, the limit state can be written in a simple analytical form as:

$$\frac{\partial P}{\partial x} > \frac{2\tau_0}{b}, \quad (1)$$

where P is the pressure at the interface, x is the flow direction of the displacing fluid, τ_0 is the yield stress of the displaced fluid and b is the aperture between the parallel plates. This limit state will be evaluated

Figure 1. Conceptual model for the risk of viscous fingering after the completion of pre-grouting (right) and post-grouting (left).

against the numerical studies to test whether it can be used to control viscous fingering behavior in cement-based grout.

2.2 Conceptual model

Risk of viscous fingering can occur both in pre-grouting and in post-grouting conditions in tunnel constructions. In this study, both scenarios are taken into consideration. The conceptual model for pre- and post-grouting conditions with respects to viscous fingering are illustrated in Figure 1.

Pre-grouting from a tunnel face is commonly carried out in sequences. In difficult grouting conditions where the requirements are higher, multiple rounds of borehole drillings are required including: probe holes to measure the conductivity of the rock mass, additional grout holes to perform grouting and control holes to measure the sealing results. Among these boreholes, the grout holes and the control holes can be drilled after some of the grouting in other holes are finished. The drilling of these boreholes, if they intersects the grouted fractures, will expose the grout to a low pressure, meaning that the groundwater pressure from the inside of the fracture will create a pressure gradient in the grout. Such scenario would also occur if the packer does not stay in the grout holes or the packer leaks.

The tunnel in the conceptual model was excavated 20 m under the groundwater level in Swedish granite with few major fractures. A consistent fracture perpendicular to the pre-grouting boreholes with an aperture of 0.2 mm was assumed in this analysis. This fracture was close to the tunnel face. The pre-grouting has been completed for borehole #1, it resulted in a radial penetration length, I , of 4 meters. The control hole, borehole #2, was drilled 2 meters below borehole #1 and intersected the grouted fracture. The pressure gradient, i , in the grout was thus 10 m/m. The cement-based grout was assumed to behave as a Herschel-Bulkley fluid (Shamu 2021) whose rheological model is defined as

$$\tau = \tau_0 + k\dot{\gamma}^n, \quad (2)$$

where τ (Pa) is the shear stress in the grout, k is the consistency coefficient, n is the flow index and $\dot{\gamma}$ (1/s) is the shear rate. In this study, the rheological model of the grout was simplified with $n=1$ (also called Bingham model) and thus k becoming the dynamic viscosity of the grout μ_g (Pa·s). The rheological properties of different alternatives of the cement-based grout varies in the analysis following Table 1.

The same tunnel was used for the conceptual model of post-grouting condition as illustrated in Figure 1. A fracture with an aperture of 0.2 mm opened up after the excavation and leakage into the tunnel appears. Post-grouting was thus performed in this fracture to stop the leakage. This fracture was assumed to be surrounded by unconductive rock or grouted areas, thus having closed boundaries. After the fracture was sealed as suggested in Figure 1, a pressure gradient starts to build up in the 2-meter long grout due to the pressure difference between the tunnel and groundwater. The pressure gradient in such case was also 10 m/m. In the conceptual model for post-grouting conditions, the alternatives of the grout also varied in its rheological properties following Table 1.

Based on the criterion in Eq (1), it was not expected that viscous fingering would occur in grout B4 and B5, while viscous fingering to a varying degree were expected in all other grouts in Table 1.

2.3 CFD analysis

Ansys Fluent was used in this study for the CFD analysis. The interaction between groundwater and cement-based grout was achieved by involving two phases of fluids, phase 1 being water and phase 2 being the cement-based grout.

In Ansys Fluent, the multiphase flow simulations are performed by solving transport equations of two types of scalars: within the phase and the mixture between phases (ANSYS Inc. 2009). Within phase- j and for an arbitrary k scalar φ_j^k , the software solves the transport equation in the volume which is occupied by the respective phase:

$$\frac{\partial \alpha_j \rho_j \varphi_j^k}{\partial t} + \nabla \cdot (\alpha_j \rho_j \vec{u}_j \varphi_j^k - \alpha_j \Gamma_j^k \nabla \varphi_j^k) = S_j^k \quad (3)$$

$$k = 1, \dots, N,$$

where α_j is the volume fraction, ρ_j is the physical density, \vec{u}_j is the velocity of phase- j . Γ_j^k is the diffusion coefficient, S_j^k is the source term. The mass flux for phase- j , F_j , is calculated as

$$F_j = \int_S \alpha_j \rho_j \vec{u}_j \cdot d\vec{S}. \quad (4)$$

When the scalar φ^k is associated with the mixture of the phases, the transport equation to be solved is

$$\frac{\partial \rho_m \varphi^k}{\partial t} + \nabla \cdot (\rho_m \vec{u}_m \varphi^k - \Gamma_m^k \nabla \varphi^k) = S_m^k \quad (5)$$

$$k = 1, \dots, N,$$

Table 1. Rheological properties of different cement-based grouts for conceptual models and for analysis.

Grout number	0 (Basis)	A1	A2	A3	A4	A5	B1	B2	B3	B4	B5
τ_0 [Pa]	3	3	3	3	3	3	1	5	8	10	12
k [Pa·s]	0.05	0.01	0.03	0.07	0.09	0.11	0.05	0.05	0.05	0.05	0.05

Figure 2. Dimensions and boundary conditions of the models for CFD analysis: (a) Post-grouting conditions; (b) Pre-grouting conditions. Both models are 0.2 mm in the third dimension (fracture aperture).

where the mixture density, ρ_m , can be calculated as

$$\rho_m = \sum_j \alpha_j \rho_j. \quad (6)$$

The mixture velocity, \vec{u}_m , can be calculated as

$$\rho_m \vec{u}_m = \sum_j \alpha_j \rho_j \vec{u}_j. \quad (7)$$

The mass flux of the mixture, F_m , is calculated as

$$F_m = \int_S \rho_m \vec{u}_m \cdot d\vec{S}. \quad (8)$$

The mixture diffusion coefficient, Γ_m^k , is calculated as

$$\Gamma_m^k = \sum_j \alpha_j \Gamma_j^k. \quad (9)$$

Lastly, the source term, S_m^k is calculated as

$$S_m^k = \sum_j S_j^k. \quad (10)$$

For this study, two 3D models were designed to simulate the rock fractures of interest, as shown in Figure 2. In order to reduce computational time and to increase accuracy, down-scaling was performed based on Eq (1). This equation has indicated that the pressure gradient $\partial P/\partial x$, the yield stress of the grout τ_0 and the fracture aperture b are the controlling parameters. These parameters should thus be the same as in the conceptual models and the other parameters can be scaled down. Therefore, the dimension of the rock fracture was reduced to

0.13 m x 0.13 m for the pre-grouting model (1/4 of the grout disc) and 0.18 m x 0.1 m (length x width) for the post-grouting model, with the unchanged aperture $b=0.2$ mm.

For the pre-grouting model, the upper and lower boundaries of the fracture models were modelled as no-slip walls while the walls in the aperture direction were modelled as slip walls. On the other hand, all the walls for the post-grouting model was no-slip walls due to that the fracture has closed boundaries. At the initial stage for both models, grout occupied 0.12 m of the fracture and the pressure gradient was achieved by applying the inlet groundwater pressure P_{in} from the inlet edges, which was calculated from the outlet pressure P_{out} and the pressure gradient i :

$$P_{in} = P_{out} + i \cdot 0.12 \text{ m}. \quad (11)$$

In this study, $P_{out}=0$ Pa and $i=10$ m/m or 100 kPa/m, which resulted in $P_{in}=12$ kPa. With a constant inlet and outlet pressure, the flow time in the simulations lasted for 10 s. The behavior of viscous fingering phenomena was recorded during this flow time.

3 RESULTS

The analysis results for both models with all the listed cement-based grouts are summarized in Table 2. In the table, if the grout is washed out after 10 s, the key moment showing typical viscous fingers with their respective time stamps is shown. For the rest of the analyses, the interfaces at 10 s of flow time are shown. All the results are followed by description over: if the grout is pushed back, if the interface is stable, if the viscous fingers are observed.

By comparing the results for post-grouting conditions from Grout 0 and A1-A5, having the same yield stresses, higher viscosity delayed the formation of viscous fingers in post-grouting conditions although it failed to avoid interface instability. It suggests that viscous fingers may still occur after 10 s of flow time for Grouts A3, A4 and A5. For pre-grouting

Figure 3. Bingham rheological models of all the grouts in the analyses.

conditions with Grout 0 and A1-A5, the difference made by higher viscosity is not clear apart from Grout A1 which has very low viscosity. No dominant viscous fingers appeared with Grout 0 and A2-A5. Instead, multiple smaller fingers appeared and then

disappeared. The possible explanation for such phenomena could be that the small grout outlet limited the flow rate of the grout thus limited shear rate of the grout and the progression of viscous fingers.

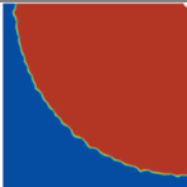

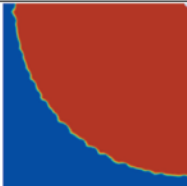

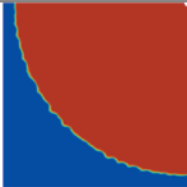

Among Grout 0 and B1-B5, the results show that higher yield stress will bring better resistance against grout pushed back and viscous fingering. Especially for Grout B4 and B5, the results coincides with the expectation that viscous fingering will not occur in both cases. Even though the interface is not stable in the pre-grouting conditions, the grout is not pushed back so viscous fingering is not likely to develop further. Compared to the increase of the viscosity, the increase of the yield stress appears to be more effective in preventing the viscous fingering from occurring.

The rheological models of all the cement-based grouts are plotted in Figure 3. All of the lines of the different grout rheological properties start at zero shear rate and end at the approximated shear rate (at 10 s) of each simulation. The highlighted areas between them provide indications on the sufficient grout property to maintain interface stability. The green area suggests that grout is stable (not pushed back and no viscous fingering) while the red area suggests unstable grout. In the specific case shown in Figure 1, the cement-based grout needs to have at least 10 Pa of yield stress to avoid viscous fingering from occurring.

Table 2. Analysis results with different cement-based grouts.

Grout	Post-grouting conditions		Pre-grouting conditions	
0		Grout pushed back, unstable interface with viscous fingers (10 s)		Grout pushed back, unstable interface with viscous fingers (10 s)
A1		Grout pushed back, unstable interface with viscous fingers (3s, washed out at 10 s)		Grout pushed back, unstable interface with viscous fingers (10 s)
A2		Grout pushed back, unstable interface with viscous fingers (10 s)		Grout pushed back, unstable interface with viscous fingers (10 s)
A3		Grout pushed back, unstable interface with no clear fingers (10 s)		Grout pushed back, unstable interface with viscous fingers (10 s)

4 DISCUSSIONS

4.1 Risk for viscous fingering in pre-grouting

The results indicate that the disturbance from viscous fingering was generally less serious in pre-grouting conditions than in post-grouting conditions. The reason for this difference could be that the relatively small open borehole creates

a threshold effect of outflow in the pre-grouting analyses, which limit the flow rate of the grout. For pre-grouting conditions, the risk lies in the backflow of the grout into the borehole, this would reduce the grouted area and thus compromise the overall grout results. Water leakage through the open borehole caused by penetrating viscous fingers presents lower risk than anticipated in the case of the conceptual model.

However, significant back flow with viscous fingering would still occur if the viscosity is lower than 0.01 Pa·s.

4.2 Risk for viscous fingering in post-grouting

Comparing the pre- and post-grouting conditions with the same type of grout, the post-grouting conditions present higher risk with respect to viscous fingering. The grout is more prone to have viscous fingering because the grout is exposed to a wider outlet, which is the entire cross-section between the fracture and the tunnel wall. In post-grouting conditions, the analyses showed the serious disturbance regimes of wash away (A1) and penetrating fingers (A2, B1). If the grout is completely washed away, the excessive leakage into the tunnel will likely to resume to its original level after a certain time; it means that the post-grouting is failed and changes of grouting plan or grout is required. Compared to be washed away, the penetrating fingers may actually cause more problems in the long term since it may easily lead to misjudgment of the grouting results. From the observations in the tunnel, seepage has indeed been reduced. However, until the grout has gained sufficient strength against erosion, seepage water will continuously erode the grout and expand the seepage channel even though viscous fingering has stopped. Although a few studies have been done previously (e.g. Axelsson 2009), the mechanism of grout erosion has not been fully understood. The exact time window before erosion stops is uncertain. The time delay before the worsening seepage is observed can cause extra operations and thus extra costs.

4.3 Strategy to reduce the risk of viscous fingering

One can conclude from the results in Table 2 and Figure 3 that higher viscosity and higher yield stress of the grout are beneficial with respect to delay or prevent viscous fingering. Between the two rheological properties, yield stress appears to play a more important role to prevent the viscous fingering from occurring than the viscosity. On the other hand, the viscosity helps delaying the occurrence of viscous fingering. In the particular case of the conceptual model, the yield stress of the grout is preferably higher than 10 Pa to maintain a stable water-grout interface.

High initial viscosity and initial yield stress, however, would compromise the penetrability of the grout, making it harder and slower to be injected. Therefore, it is more reasonable to use ordinary mixes of grout (w:c ratio between 0.6-1.0 in Swedish practice) and to hold the grouting pressure beyond the time needed to seal the fracture. The pressure during the holding time does not need to be as high as during the injection. A pressure that

is close to the groundwater pressure would be sufficient. Although this holding time would not give longer penetration length, it would allow the grout to develop strength without being displaced by the flowing water. No displacement indicates no viscous fingering. The exact pressure holding time depends on the actual recipe of the grout. For example, a low w:c ratio and accelerator can shorten the holding time while a high w:c ratio will prolong it. In a real project, pretesting on the grout's strength development over time is thus highly recommended to provide reference to the actual pressure holding time required.

Figure 4. Rheological properties directly from rheometer test and after Bingham fitting.

4.4 Uncertainties in grout properties

An important simplification in this study is that the cement-based grout behaves as an ideal Bingham fluid ($n=1$ in Eq (2)). It, however, may not represent the realistic rheological properties of cement-based grout in reality. As illustrated in Figure 4, the result of a typical rheometer measurement on the grout's properties does not strictly follow the linear Bingham model. Instead, the measured shear stress at low shear rate is much lower than the yield stress with Bingham curve fitting. This fact suggests that the risk of viscous fingering could be underestimated if the Bingham model is used to describe the grout properties.

5 CONCLUSIONS

From the performed numerical analyses in this study, the main conclusions are summarized as follows:

- Viscous fingering poses a risk for both pre-grouting and post grouting conditions in rock tunnel construction. In a worst case scenario, the injected grout can be washed away quickly from the fracture.

- The risk of viscous fingering is higher in post-grouting conditions compared to pre-grouting conditions.
- Higher yield stress can effectively reduce or avoid viscous fingering according to the limit state by Eq (1). In the specific case of the conceptual model, a yield stress of 10 Pa can prevent viscous fingering. Compared to high yield stress, higher viscosity may contribute less in preventing viscous fingering but can delay it.
- A practical suggestion for the grouting design in post-grouting conditions is that the grouting pressure should not be relieved before the grout has gained adequately high yield stress. The exact holding time varies depending on the grout mix. Pretests on the cement-based grout on the development of yield stress is recommended.

ABSTRACT: Cement grouting is widely used in rock tunnelling to control groundwater inflow by sealing rock fractures. Accurately predicting grout propagation in rock fractures is crucial for the design, execution, and monitoring of rock grouting in engineering applications. Current methods rely on theoretical models, such as the real-time grouting control (RTGC) method, which is derived based on simplified fracture geometries like smooth parallel plates/disks. However, real rock fractures consist of rough surfaces with variable apertures. In this study, we present a computational model for theoretically predicting the propagation of non-Newtonian cement grout in variable fracture apertures. This model is validated with laboratory test data on grout propagation in a one-dimensional varying aperture long slot (VALS). We also analysed the impact of varying aperture on cement grout propagation processes. Our findings demonstrate that the presented computational model predicts the grout propagation process in this geometry with good accuracy. Moreover, we observed that varying aperture significantly affects the grout propagation process in fractures. The insights provided by our model and analysis results are potentially useful in rock tunnelling projects, specifically for the theoretical analysis of cement grout propagation in rock fractures.

Keywords: Cement grout, Rock grouting, Varying aperture fracture, Real-time grouting control, Propagation length, Two-phase flow

1 INTRODUCTION

Cement grouting serves as a pivotal technique extensively applied in rock engineering projects, encompassing the construction and maintenance of rock tunnels, dams, and underground infrastructures built in or on rock. Modelling of cement grout propagation within rock fractures plays a pivotal role in the holistic approach to designing, implementing, and monitoring rock grouting processes (Stille 2015).

In rock grouting practice, cement grouts are often injected through boreholes, which propagate through connected rock fractures. The cement grouts applied for rock grouting are typically non-Newtonian fluids with yield stress, which are often assumed as Bingham fluids (Håkansson 1993). The rheological properties of cement grouts are important parameters in rock grouting design. It is found that the rheological parameters of cement grouts i.e. yield stress and

plastic viscosity, significantly affect propagation lengths in single fractures (Zou et al. 2018).

In the literature, a few analytical and numerical models have been developed to analyse non-Newtonian cement grouts propagation in single rock fractures (Hässler et al 1992; Stille 2015; Zou et al. 2018, 2019, 2020a, 2020b). For simplicity, the fractures are typically assumed as a pair of parallel plates with constant apertures in previous studies. However, all natural rock fractures inherently feature rough surfaces, which causes variable aperture structures. Many studies have shown that fracture surface roughness and variable aperture structures can significantly affect fluid flow and mass transport in rock fractures (e.g., Zou et al 2018, 2019). In particular, Ghafar (2017) conducted grout tests in a variable aperture long slot (VALS) and compared the test results with the analytical solution of the real time grouting control (RTGC) method. It is found that the

*Corresponding author: lzo@kth.se

RTGC method using either the mean mechanical aperture or the hydraulic aperture can overestimate the grout propagation length. However, varying apertures caused by surface roughness have not been considered in previous theoretical and numerical studies on rock grouting and the impact of varying apertures on cement grouts propagation has not been comprehensively analysed.

In this work, we present a two-phase flow model to analyse Bingham cement grout propagation in fractures with variable apertures. This model is validated against a set of laboratory test data conducted by Ghafar (2017), for the first time. The validated model could be helpful for analysing cement grout propagation in natural rock fractures required in design for rock grouting in practice.

2 THEORY AND METHOD

The rheological properties of cement grouts are greatly dependent on water and cement ratios. In practice, the water and cement ratio are between 0.6 and 0.8, where the cement grouts behave as yield-stress fluids, often approximated by the Bingham model, expressed as

$$\begin{cases} \tau = \tau_0 + \mu_g \dot{\gamma}, & |\tau| > \tau_0 \\ \dot{\gamma} = 0 & \text{otherwise} \end{cases} \quad (1)$$

where τ is shear stress, τ_0 is the yield stress, μ_g is the plastic viscosity and $\dot{\gamma}$ is the shear rate.

Assuming that the cement grouts and groundwater are immiscible and incompressible fluids, a two-phase flow model for grout propagation into water-saturated fractures has been developed in previous work (Zou et al 2018; 2019), expressed as

$$\frac{\partial}{\partial x} T(C) \frac{\partial P}{\partial x} = 0 \quad (2)$$

$$u = \frac{T(C)}{2B} \frac{\partial P}{\partial x} \quad (3)$$

$$\frac{\partial C}{\partial t} + u \frac{\partial C}{\partial x} = 0 \quad (4)$$

where C is a phase function (i.e., $C = 1$ denotes the grout phase and $C = 0$ denotes the water phase), t is time, P is pressure, u is velocity, and $T(C)$ is the transmissivity, which is a function of C . For groundwater, i.e., $C = 0$, the transmissivity is given by the cubic law,

$$T(C = 0) = -\frac{2WB^3}{3\mu_w} \quad (5)$$

where B is the half of the fracture aperture, W is the fracture width and μ_w is the viscosity of groundwater. For the Bingham grout, its transmissivity can be determined by the analytical solution of the flow-rate for single-phase flow between smooth parallel plates, expressed as (Zou et al. 2018)

$$T(C = 1) = -\frac{WB^3}{3\mu_g} \left(1 - \frac{z_p'}{B}\right)^2 \left(2 + \frac{z_p'}{B}\right) \quad (6)$$

where z_p' is half of the plug flow region in the grout phase, which is a function of yield stress and the pressure gradient between the injection inlet and grout propagation front $I(t)$ (Zou et al., 2018)

$$z_p' = \min\left(\frac{\tau_0 I(t)}{P_1 - P_{I(t)}}, B\right) \quad (7)$$

where $P_{I(t)}$ is the pressure at the interface. Illustration of the plug flow region for yield stress fluid flow in homogeneous fractures is available in Zou et al. (2018).

The mathematical model for the two-phase flow of cement grout propagation in water-saturated fractures is a set of nonlinear partial differential equations, since the transmissivity for the Bingham grouts is naturally nonlinear. For modeling of grout propagation in fractures with variable aperture structures, the mathematical model is solved numerically by iteration at each time step. In order to track the propagation interface, a novel algorithm by introducing a moving node in each fracture has been developed in Zou et al. (2018). The detailed algorithm of the solution for the two-phase flow of grout propagation in saturated fracture networks and its advantages compared to traditional methods can be found in Zou et al. (2018).

3 RESULTS

3.1 Laboratory grouting test

A set of laboratory grouting tests in a varying aperture long slot (VALS) has been performed and presented in Ghafar (2017). We adopt this set of data to validate our computational model presented in Section 2. For completeness, the tests are briefly introduced here; more detailed information can be found in Ghafar (2017).

A long slot with varying apertures is manufactured to conduct the tests. The aperture structure of the varying aperture long slot is shown in Figure 1, where the slot aperture changes from 220 μm to 40 μm with chambers of 500 μm in between. The total length from the inlet to the outlet is 2.88 m. The detailed information on design of the VALS and the monitoring system is available in Ghafar (2017).

The adopted data contain two tests with two types of oil samples, named as SAE20 and SAE50, and four tests with two recipes of cement grouts, named as R1 and R2. The water-to-cement (w/c) ratio is 0.8 for both types of grouts; however, different concentrations of the super-plasticizer were added in the two recipes of cement grouts, i.e., 0.5% and 0.18% by volume in recipes R1 and R2, respectively. The rheological properties of the oil samples and cement grouts are summarized in Table 1.

A constant injection pressure of 15 bar was applied for all tests. The outlet boundary condition is zero pressure (i.e., open to air). Pressure sensors were installed at different locations in the slot. In each test, the grout front was monitored by recording the time interval when each pressure sensor began to rise. All tests were conducted in dry condition, which means that the involved two phases are the oil/grout and air.

Figure 1. The aperture structure of the varying aperture long slot (VALS).

Table 1. Material properties (Ghafar 2017).

Materials	Density (kg/m)	Plastic viscosity (Pa s)	Yield stress (Pa)
Oil SAE20	880	142.1e-3	0.14
Oil SAE50	950	754.6e-3	0.55
Grout R1	1610	8.3e-3	0.08
Grout R2	1600	5.7e-3	1.01

3.2 Comparison with laboratory grouting test data

Using the proposed two-phase flow model, we simulated the grouts propagation in the varying aperture long slot based on the test conditions and using the specific rheological properties. The simulated results of grout propagation with time are compared with the laboratory grouting test data.

Figures 2-5 present comparison of simulated grout propagation over time with test data. In general, the simulated results of propagation length over time match well with the results from the tests, for all cases.

The differences between the repeated tests for the adopted two recipes of cement grouts illustrates the uncertainty in the tests, which could be caused by complexity of rheological properties for cement grouts with additives of super-plasticizers, and filtration of cement particles that are not considered in the presented computational model.

The relatively good agreement between the simulated results and test data indicates that the presented two-phase flow model can reliably predict cement grouts propagation process in fractures with varying apertures.

Figure 2. Comparison between the simulated and tested grout propagation over time for oil SAE20.

Figure 3. Comparison between the simulated and tested grout propagation over time for oil SAE50.

Figure 4. Comparison between the simulated and tested grout propagation over time for grout R1.

Figure 5. Comparison between the simulated and tested grout propagation over time for grout R2.

4 GROUTS PROPAGATION IN RANDOM FRACTURES

After validation, we aim to use the two-phase flow model to analyse cement grouts propagation in heterogeneous fractures with varying apertures. In the literature, the apertures of rock fractures are often assumed following lognormal distributions based on observation from laboratory and field tests (e.g., Zou et al. 2020). In this work, we randomly generate rough-walled fractures with lognormal distributed apertures, for a generic analysis.

4.1 Random generation of varying fracture apertures

We consider 1D fractures with the length of 3m. The lognormal distributed fracture apertures are gener-

ated based on correlated Gaussian field, expressed as,

$$\log(b) = \sigma MG(0, 1, \lambda) \quad (8)$$

where b is the fracture field, σ is the standard deviation of a lognormal field, MG is a Gaussian field with mean 0 and standard deviation 1, and λ is the correlation length. Our previous studies showed that the correlation length has limited impacts on fluid flow and solute transport in fractures compared to the variance. Therefore, in this work we adopt a constant value for the correlation length, $\lambda = 0.15m$, and focus on the impact of variance.

Specifically, we randomly generated varying fracture apertures following lognormal distributions with three values of log-variances, that is, For the case $\sigma^2 = 0$, the aperture is constant, which is considered here as a reference case. For the cases of $\sigma^2 = 0.1$ and 0.5 , we simulated 50 realizations for each case to obtain a stable statistical analysis. The number of realizations is adopted based on our previous studies using lognormal distributed apertures, which showed that around 20 realizations are adequate to achieve a stable statistical analysis (Zou and Cvetkovic 2020; Zou et al., 2023).

Figure 6 illustrates the assembled cumulative distribution function (CDF) of generated varying apertures for different cases, showing the increasing variation when σ^2 increased from 0.1 to 0.5. Figure 7 illustrates an example of generated aperture geometry for each case.

Figure 6. The cumulative distribution function (CDF) for different cases, i.e., $\sigma^2 = 0$ (constant), 0.1 and 0.5.

Figure 7. Exemplified randomly generated varying fracture apertures for different cases, i.e., $\sigma^2 = 0$ (constant), 0.1 and 0.5.

4.2 Evolution of propagation length over time

The cement grouts propagation in all generated realizations of varying apertures are simulated using the validated two-phase flow model. The rheological parameters for Grout R2 shown in Table 1 are adopted in all simulations.

For a statistical comparison, the median values of propagation lengths for the 50 realizations are presented in Figure 8. The result shows that cement grouts generally propagate slower in varying fracture apertures. In particular, the propagation time is increased over 4 times for the case of $\sigma^2 = 0.5$, compared to the cases of $\sigma^2 = 0$ (constant) and 0.1.

This finding is consistent with previous studies on fluid flow in rough-walled rock fractures (e.g., Zou et al., 2015). The main reason is that the varying fracture apertures can reduce the effective transmissivity and cause additional pressure drop during the cement grout propagation process. This result also indicates that characterization of fracture aperture distributions is important in rock grouting analysis and ignoring the features of varying apertures could overestimate the propagation lengths in practice.

5 DISCUSSIONS AND CONCLUSIONS

In this work, we presented a two-phase flow model for predicting non-Newtonian cement grouts propagation in 1D fractures with varying apertures. This model is validated against a set of laboratory grouting tests in a varying aperture long slot. The validated model is used to analyse the impact of varying aperture on cement grouts propagation in 1D fractures with lognormal distributed apertures.

The results show that the presented two-phase flow model is reliable and can predict cement grouts

propagation in more realistic rock fractures with varying apertures. The varying apertures, quantified by variance, can significantly affect the cement grouts propagation process, and ignoring the varying apertures could generally overestimate propagation lengths. Therefore, it is recommended to consider the more realistic apertures structures in fracture characterization for rock grouting analysis in practice.

Figure 8. The median propagation lengths for different cases, i.e., $\sigma^2 = 0$ (constant), 0.1 and 0.5.

Although the presented two-phase flow model can be readily used to predict cement grouts propagation in fractures with varying apertures, accurate characterization of fracture apertures remains a challenge. In practice, the distributions of fracture aperture can be obtained from the fracture traces of rock cores or outcrop mapping. The obtained fracture aperture distributions can be used as the input information for the presented two-phase flow model to perform stochastic analysis, as presented in Section 4. Furthermore, the illustrated impact of varying aperture on cement grout propagation length can be potentially used to correct the analytical models with constant apertures, which could be an important topic for the future study.

ACKNOWLEDGMENTS

We sincerely thank the Swedish Rock Engineering Research Foundation (BeFo) for providing the funding for this study.

ABSTRACT: The space between the primary support and secondary lining of tunnel supporting structures is usually backfilled by grouting concrete slurry. Grouting quality significantly affects integrity of supporting structures, and therefore, the safety of tunnels. Several tunnel lining failure accidents have demonstrated that insufficient grouting and grouting defects may cause serious collapse disasters. As such, many non-destructive evaluation techniques have been developed to detect grouting defects, such as ground penetrating radar (GPR). However, these techniques cannot perform a real-time in-construction-process grouting defects and voids evaluation. Therefore, this study aims to develop a novel equipment based on a Raspberry Pi, which can evaluate grouting quality during construction process. This equipment can automatically detect concrete backfill quality by monitoring the conductivity of backfill. Then, the Raspberry Pi connects to the internet and uploads evaluation results in real time. A smartphone application is developed, which can visualize the grouting quality detection results by Raspberry Pi.

Keywords: tunnel second lining, raspberry pi, smart detection, smart construction, internet of things

1 INTRODUCTION

Tunnel second lining refers to the tunnel has been the case of initial support, the use of reinforced concrete and other materials to build the second lining structure of the tunnel, to achieve the role of support and reinforcement, anti-drainage, in order to meet the normal use of tunnels and the requirements of safe operation. When the back of the tunnel lining structure appeared hollow, will cause the second lining for the surrounding rock and supporting structures can not play a protective role, so that the overall rigidity of the tunnel lining and the force state changes, resulting in the stability of the tunnel structure, safety reduction, the lack of internal stability prone to safety accidents, in the external environment, the occurrence of the hollow will be with the cracks, the structure of vibration, the structure of freezing, and the lining itself insufficient thickness and other factors. Insufficient thickness of the lining itself and other factors to occur coupled with the disease, the structure of the

overall damage, and ultimately have a significant impact on the safety of the project.[1]. In general, the secondary lining of tunnels is monitored by means of pre-hole grouting, tapping or geo-radar buried in the ground. [2]. Eventually, grouting backfill, anchor reinforcement, liner arch reinforcement, surface part of the reinforcement and other treatment measures will be taken to deal with. The appeal of all the detection methods have a large demand for labor, monitoring is more complex, need to spend a lot of manpower and material resources to carry out, and monitoring has a periodicity, can not always understand the state of the two lining structure and timely safety measures to prevent the occurrence of safety problems and so on.

In order to improve the quality of tunnel engineering and avoid safety accidents. Combine the secondary lining cavity monitoring with sensors to realize the detection of the cavity in the back of the secondary lining of the tunnel, and then transmit it through the Raspberry Pi microcomputer[3],

*Corresponding author: 470065016@qq.com

Processing inspection data, and ultimately uploaded to the cloud, and then through the cloud and mobile data writing and reading through the cell phone or website to view the data, to realize the monitoring of the informationization and real-time, anytime and anywhere to open the app to view the current tunnel lining conditions, as well as real-time grouting situation analysis [4]. When a problem arises, it is possible to notify the relevant personnel in a timely manner to take immediate action to deal with it, prevent accidents from occurring, and minimize safety risks.

2 HARDWARE DESIGN

Figure 1. Detection instrument.

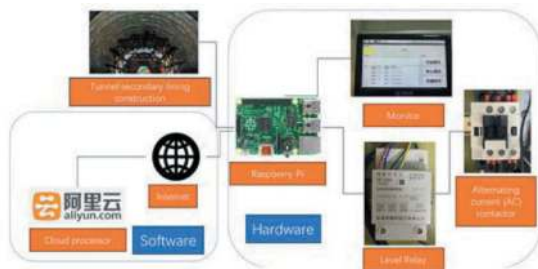

Figure 2. General design of the instrument.

Figure 3. Raspberry Pi GPIO coding.

2.1 Introduction to the Raspberry Pi platform and GPIOs

Using the Raspberry Pi platform for the latest release of the fourth generation of products Raspberry Pi 4 B, its performance and the Raspberry Pi 3B + compared to both processor speed, multimedia and memory have been significantly improved[5]. The Raspberry Pi 4B has desktop performance comparable to entry-level x86 PC systems.

The Raspberry Pi 4B features a 64-bit quad-core processor running at 1.5Ghz, up to 4GB of RAM (1GB, 2GB, 4GB, 8GB depending on model), 2.4/5.0 Ghz dual-band wireless LAN, Bluetooth 5.0/BLE, Gigabit Ethernet, USB 3.0, and PoE capability [6]. These configurations provide hardware support for the computerization of secondary lining cavity monitoring. As shown in Figure 2 is a schematic of the Raspberry Pi modules.

The choice to use Raspberry Pi as the main control platform is due to the fact that the Raspberry Pi system has the most powerful GPIO (General-Purpose Input/Output) with 40 pins. As shown in Figure 3 below [7]. GPIO: General Purpose Input/Output Port, through some of its above pins output high level or low level or read out the current state of the pin is high level or low level. Can be through the current state of the high and low levels and computer-related software. Eventually realize the purpose of data interaction, control software and hardware work, read the working status signal of software and hardware. Through the GPIO pin external wires to realize the current circuit to determine whether the successful connection, and ultimately realize the current state of the tunnel secondary lining of the back of the judgment of whether there is a hole [8]. Figure 3 below shows the 40 pins of the GPIO and the code of each pin [9].

The 40 pins of the GPIO is the BCM (Binary Coded Matrix) coded 17 pin GPIO.5 3.3v writing Pi coded 0 number of pins and ground pins for the operation of external wires.

2.2 Composition of testing instruments

It adopts a three-level rainproof distribution box, which is equipped with a buzzer alarm, signal light, test button, switch knob, and other devices[10]. Its functions are:

- 1) When the slurry is full of squeeze signal probe, through the signal probe to the relay action signal, buzzer flash, and alarm signal[11].
- 2) All components voltage selection DC24V (relay, buzzer, signal lamp), power supply from AC220V through the power converter into DC24V low voltage, to ensure the personal safety of construction workers.
- 3) A signal probe installed in the vault waterproofing board on the inside, to tower style is appropriate, to ensure good signal contact and normal feedback,

each board has two lining lengths of 12m, along the longitudinal direction of the vault and is equally spaced sequentially laid 6 groups, signal acquisition probe as a monitoring point, 6 groups of signal lines to lead to the distribution box terminals[12]. Terminal order: (11, 12) for the first group, (21, 22) for the second group, (31, 32) for the third group, (41, 42) for the fourth group, (51, 52) for the fifth group, (61, 62) for the sixth group.

- 4) 6 groups of monitoring point signal probes are connected in series to ensure that all 6 monitoring points are filled with relay action, the distribution box operating panel flash buzzer at the same time issues a warning signal[13].
- 5) Distribution box operation panel is equipped with a hand/automatic knob switch, automatic response from the probe, relay absorption issued by the warning sound, and manual position only for the role of the test sound warning device.

The selected AC contactor for this study is the Schneider LC1-D25 series, designed for use in AC circuits with a frequency of 50Hz or 60Hz and a voltage of 220V. Primarily intended for long-distance circuit connection or interruption, it can be combined with a thermal relay of corresponding specifications to form a magnetic starter, providing overload protection to the circuit. The operational principle involves the passage of current through the contact coil when the circuit is energized, generating a magnetic field. This magnetic field induces electromagnetic suction in the static iron core, attracting the movement of the dynamic iron core. Consequently, the AC contactor points are set in motion, leading to the disconnection of normally closed contacts and the closure of normally open contacts, creating a synchronized action between the two.

When the coil is disconnected, the electromagnetic suction vanishes, and the armature, released by the release spring, restores the contact point. This action leads to the disconnection of the normally open contact and the closure of the normally closed contact. By controlling the open and closed states of normally open contacts, the main AC circuit can be rapidly interrupted, allowing frequent switching of the high-current control circuit. Contactors find extensive application in controlling electric motors, factory equipment, electric heaters, workhorses, and various power units. Beyond circuit connectivity, contactors also offer low-voltage release protection. Their robust control capacity makes them suitable for frequent operations and long-distance control, rendering them indispensable components in automatic control systems. The main purpose of the electronic display is to serve as an external screen for the Raspberry Pi, allowing the user to program or operate the Raspberry Pi computer by directly connecting the mouse and keyboard to write and enter programs. It also allows the user to observe the results of the operation in real-time and to find out the results of previous measurements on the display. Electronic display through the HDMI interface wire and the Raspberry Pi on the high-definition multimedia interface HDMI

interface connection can display the contents of the Raspberry Pi computer, combined with the Bluetooth connection of the mouse and keyboard, the user can be in the Raspberry Pi to carry out a series of operations. Figure 4 below shows the hardware schematic of the instrument.

Figure 4. Schematic diagram of the instrument hardware.

3 SOFTWARE AND PROGRAM WRITING

The primary implementation of this program is in Python, focusing on developing and running the test page, including page loading and the transmission process. The procedure begins by entering the test point number and name to initiate testing. Upon circuit access, a returned value signifies a connected circuit, indicating the absence of voids behind the lining. The results are then stored in a designated folder.

In the case of an open circuit, where the circuit is not connected, the program conducts 20 tests at 0.1s intervals. If the internal access test matches the first case, or if the circuit remains unconnected, the program returns the corresponding information, storing pile number, pile name, etc. The test results are dichotomously stored and uploaded to the cloud.

Upon opening the program, historical data is automatically retrieved and displayed on the start page. The latest data is used for monitoring, and the monitoring data is seamlessly uploaded to the cloud for real-time accessibility on mobile devices.

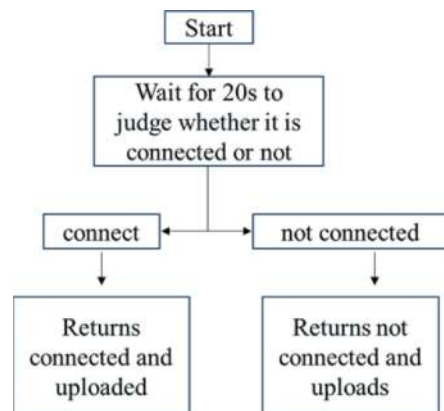

Figure 5. Judgment flowchart.

Page Design For the UI page design, the content to be included in the entry page of the program includes the page size, cover design, loading animation settings, and the running of the program needs to include the start and end key settings, the historical data list, and the latest data table (including the description of the pile number, the pile name, and whether it is full or not).

Utilizing the Tinder statement for UI design, the Label component is employed to exhibit information. Historical and latest data forms are constructed through direct definitions of height, width, and image parameters. The UI interface is crafted to showcase the word “Gansu Tunnel” and tunnel images upon program entry. As the loading figure progresses from 0% to 100%, the word “Gansu Tunnel” is displayed beneath it.

The left section of the UI features a historical data table presenting pile number, pile name, and connection status. On the right, the UI displays the current pile number, pile name for testing, and a start test button, requiring user input. Upon clicking, the program transitions to the operational interface.

4 CLOUD STORAGE OF DATA

To ensure the safety and integrity of the massive data generated during the monitoring of the tunnel’s secondary lining, crucial for project safety, effective data management is imperative. Key considerations include data storage integrity, security, readability, easy retrieval, disaster recovery readiness, and timely synchronization, all pivotal for the smooth functioning of the detection system.

Opting for cloud storage presents notable advantages. It allows seamless storage and retrieval, ensuring data security and implementing emergency measures to avert potential data loss and its associated severe consequences. Given the substantial data volume, utilizing traditional storage methods like U disks, CF cards, SM cards, TF cards, and flash memory sticks is cumbersome. Therefore, the study has wisely chosen cloud storage as the preferred method for data storage.

Utilizing an AliCloud server for data storage, the research group invested in this solution to ensure efficient data transmission and retrieval. The choice of AliCloud is advantageous due to its strong endorsement by a major Internet enterprise, ensuring mature technology and robust protection against data disruptions caused by external factors. This server proves effective in safeguarding data privacy. Additionally, it offers convenience and fulfills various requirements essential for this study. The data transfer to the cloud and subsequent retrieval are executed through Python statements, inputted into the

Raspberry Pi for seamless storage and access in the cloud.

The data presented in the mobile app’s display section showcases historical operational data from testing and commissioning. This historical data, stored both on the Raspberry Pi computer and in the cloud, ensures convenient and timely access via the mobile app. Users can utilize the WeChat mini-program “Crafted Tunnel” to gain real-time insights into various piles within the tunnel, allowing them to understand the current status of the tunnel lining. This approach enables continuous, real-time monitoring of the cavity behind the tunnel lining. Users have the capability to monitor the secondary tunnel lining status in real-time through the software and website, providing a proactive measure against potential hazards.

Front-end and backend development in Java involve a separated approach. In front-end development, we utilized the Element UI component library, Vue framework, and Echarts library. These tools offer high efficiency, flexibility, and ease of expansion. Element UI, based on Vue library’s desktop components, allows individual component introduction, reducing the impact on project volume. However, it may require manual code entry, which is manageable for this project due to its simplicity. Echarts, an open-source JavaScript chart library from Baidu, offers rich icon content, compatibility with most browsers, and the flexibility for users to create their charts. It is a valuable asset for chart drawing on the site.

The back end incorporates Spring Boot, MyBatis data interface, and Redis for data caching. Spring Boot facilitates seamless data exchange between the front and back end. MyBatis data interface encapsulates complex SQL database operations, mapping them through Java objects and SQL statements, simplifying the execution of SQL statements in code. This eliminates the need for manual processes like registering the driver, creating a connection, and setting up parameters.

MyBatis connects to the database through a configuration file, enhancing maintainability by avoiding hard-coding issues. SQL statement execution in MyBatis is configured separately from Java code, providing flexibility. MyBatis manages connection pooling and caching, optimizing database interactions for efficiency.

Redis primarily serves as a data cache for temporary storage, crucial for handling the large amount of data generated during the monitoring process in this study. The data is temporarily cached in Redis before being stored in the MySQL database hosted on Alibaba Cloud. MySQL is chosen for its advantages of small size, speed, low cost, and open-source nature. The overall interaction process between the front end, back end, and the cloud is depicted in Figure 6.

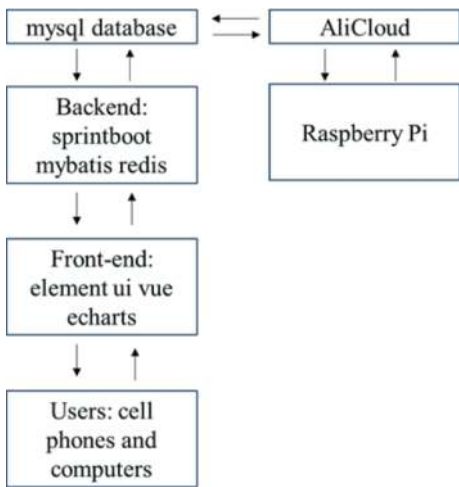

Figure 6. Front and back-end data as well as a cloud interaction process.

5 CONCLUSION

This paper introduces an Internet of Things (IoT) based system for detecting cavities in the secondary lining of tunnels. Leveraging the conductivity of reinforced concrete, the system forms a closed circuit at the connection points, allowing for the assessment of the tunnel lining's condition. If the secondary lining is full without any cavities, the concrete's conductivity maintains a normal circuit, triggering the indicator light, and storing the message "no cavity in the back of this secondary lining section" in the system, subsequently uploading it to the cloud.

Conversely, if there is a cavity in the back of the tunnel's secondary lining, the lack of conductivity in the air interrupts the circuit, preventing the indicator light from illuminating. This absence of a circuit connection indicates the presence of a cavity, prompting the system to store the information "there is a cavity in the back of this secondary lining section" in the Raspberry Pi system. This data is then transferred to the cloud and integrated into the app, allowing users to check the current status of the tunnel's secondary lining at their convenience through the app or web client.

This system design aligns with the current trends in civil engineering and the trajectory of intelligent construction. It not only addresses a wide market but also holds practical significance and social value.

ABSTRACT: Asset Management involves meeting the underground infrastructure's current operational demands while moving from being reactive to more proactive. This reduces the dollars spent on crises management by investing in preventing emergencies. This is accomplished by developing an accurate and complete record and understanding of the current state of the underground's assets which include developing an asset registry, condition assessment and developing a plan to maximize the assets' service life. A report which was prepared as part of National Cooperative Highway Research Program Project (NCHRP) 20-07/Task 276, (Development of Guidelines for Rehabilitation of Existing Highway and Rail Transit Tunnels) indicates that water leakage through the tunnel lining has been the majority of the problems. The main reason for tunnel inspections is to identify structural condition by locating and prioritizing structure defects to assure the safety of public traveling in tunnels and protect property. Historically, visual and manual procedures for tunnel inspection have been widely used. Since these procedures are time-consuming and subjective to human error, alternative automated techniques to increase efficiency and reliability in tunnel inspection are needed. This session will review the state-of-the-art of tunnel inspection technologies toward tunnel condition assessment and discuss case studies.

Keywords: Tunnel inspection, Asset management, Photogrammetry

1 INTRODUCTION

Based on the 2020-2021 International Tunnelling and Underground Space Association (ITA) Activity Report, the worldwide tunneling market has an estimated value of around \$135 billion annually, growing at a rate of 9 percent per year. This growth rate is significantly higher, approximately 2.5 times, compared to the overall construction market. Furthermore, the passage of the Infrastructure Investment and Jobs Act (IIJA) of 2021 is providing a much-needed financial boost to tunneling projects, which have historically faced significant funding obstacles. This legislation allocates \$66 billion over a span of five years to support rail initiatives, with \$8 billion

specifically designated for the Gateway program. Additionally, funding is being allocated for water and wastewater projects, including those related to combined sewer overflow (CSO) programs.

As tunneling projects continue to grow in length, size, depth, and complexity, there arises an increasing need for thorough and reliable tunnel inspection processes. These inspections play a crucial role in ensuring the safety, integrity, and functionality of the tunnels over their operational lifespan. Regular and comprehensive tunnel inspections are vital for identifying early signs of damage, assessing structural stability, and detecting potential issues that may compromise the tunnels' functionality and safety. The repair cost of tunnels will increase if

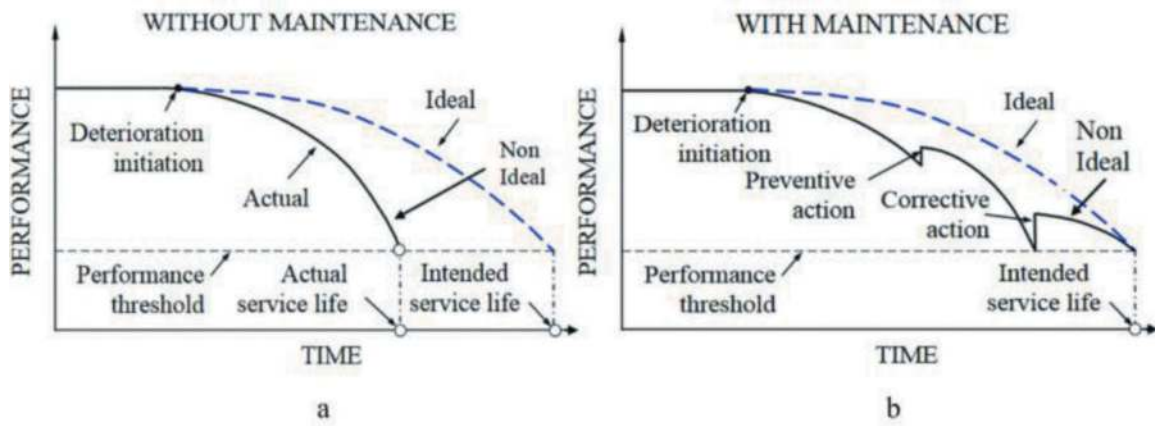

Figure 1. Deterioration curves without (a) and with (b) proper structures maintenance (Chaiyasarn, 2011).

maintenance of tunnels is not satisfactory and timely. Figure 1 illustrates an example of using Level of Service (LOS) in the asset management plan. Figure 1(a) illustrates a deterioration curve without asset renewal activities and the difference between it and the ideal service life of the asset. However, as shown in Figure 1(b), to restore the asset's condition and extend its service life, rehabilitation is needed at specific times to ensure that the asset's condition remains above the desired LOS. With proper structures maintenance, the service life of an asset can be extended to its intended service life.

2 BACKGROUND OF TUNNEL INSPECTION

Throughout history, the assessment of tunnels has predominantly hinged upon visual inspections conducted manually. These long-standing practices, although prevalent, come with inherent drawbacks, notably their laborious nature and susceptibility to human mistakes. Consequently, there exists an urgent requirement for the introduction of cutting-edge automated methodologies capable of not only expediting the inspection process but also elevating the overall dependability of tunnel evaluations. As of the 2020 report by the National Tunnel Inspection Program, the United States boasts a grand total of 526 tunnels. These tunnels can be predominantly categorized into two distinct eras of construction: the initial wave occurred during the 1930s and 1940s, while the second surge coincided with the development of the Interstate Highway System throughout the 1950s and 1960s. Figure 2 provides a visual representation of the top five states in the United States, which collectively house more than 270 tunnels.

Due to easy access, durability, and lower cost pre-cast concrete liners and cast-in-place concrete liner are frequently used as permanent final lining systems in highway tunnels (FHWA, 2015). Figure 3 lists some common concrete defects.

In Specifications for the National Tunnel Inventory manual, which was published by the FHAW in

Figure 2. Top five states with majority of tunnels in the US.

2015, four different condition states for tunnel liners have been described and quantified based on the severity of defects. Figure 4 shows these four condition states. Tables 1 describes the definitions of four different condition states for precast concrete tunnel liner (FHWA, 2015).

In tunnel inspection process, detecting and measuring cracks in tunnel lining is vital as cracks are the initial signs of damages to the tunnel structure. It is an arduous task for tunnel inspectors to visually detect and measure cracks in tunnel liners as it is a time-consuming task and subjected to human error. Also, to decrease the downtime during tunnel inspection, monitoring and inspection of tunnel structure usually is conducted during the night time. With advanced inspection technologies and methodologies, engineers and inspectors can closely monitor the condition of the tunnels and implement timely maintenance and repair actions. Additionally, considering the extensive

Figure 3. Some common concrete defects.

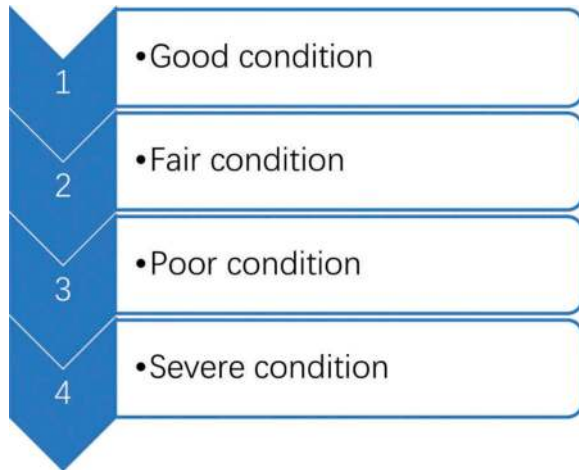

Figure 4. Tunnel liner condition states.

capital investments involved in tunnel construction, conducting regular inspections is a cost-effective approach to preventing major failures that could result in expensive repairs or even partial or complete shutdowns. As the demand for tunnels continues to rise, and as they become more challenging to construct and inspect, investing in state-of-the-art inspection techniques becomes paramount. Traditional tunnel inspections often involve manual and time-consuming methods, requiring a substantial workforce and significant financial investment. However, the process of tunnel inspection can be significantly optimized by leveraging advanced tunnel scanning technologies, such as laser scanners, thermography, and photogrammetry systems (Behbahani et al., 2023). These state-of-the-art systems offer numerous benefits, including cost reduction, time savings, and decreased personnel requirements, making the

inspection process more efficient and accurate. By proactively addressing potential issues through regular inspections and adopting cutting-edge inspection techniques, tunnel owners and operators can ensure the long-term performance, safety, and sustainability of these critical infrastructural assets.

3 3D TUNNEL SCANNING SYSTEM

3D Tunnel scanning opens up possibilities to create a digital twin of tunnel tubes with a surface resolution of up to 1 x 1 mm per pixel and a geometric resolution of up to 5 mm. The Altira scanning system, an ultra-light and compact hybrid scanning system developed by Dibit Measuring Technique, records 3D measurements of tunnels. It is a hybrid device equipped with a LiDAR (Light Detection And Ranging) scanner, a photo unit, and an optional thermal unit (also known as infrared or IR cameras). The laser scanner enables precise measurements of the tunnel geometry (Mett et al., 2019). The measurement unit can be mounted on a trolley that is highly adaptable to various settings and can be used in water tunnels, railroad tunnels, and road tunnels. Figure 5 shows the Altira System in subway tunnels on the left and in a water tunnel on the right.

The measurement trolley is manually pushed through the tunnel, allowing the operator to achieve a recording speed of approximately 2-3 mph (Steinkühler et al., 2022). During recording, the operator monitors the measurements on a computer that displays a live cross-section of the tunnel surface. The use of the Altira mobile scanning device can reduce inspection time spent in the tunnel by up to 75%. The raw data will be processed and referenced in Dibit's proprietary software, Dibit-8. This software is specifically designed for processing and analyzing 3D data captured in cylindrical structures such as tunnels (Steinkühler et al., 2022). Dibit-8 is capable of handling large volumes of data and can quickly and seamlessly visualize the 3D scan data in both 3D and 2D views (see Figure 6).

The database "dibit-TIS" (Tunnel Information System) is a core component of the software. In combination with the dibit-Viewer 3D, tunnel data is analyzed and visualized (Steinkühler et al., 2022). The high-resolution data provides inspection engineers with the capability to measure and map cracks with a width as small as 0.3 mm. In fact, all defect locations can be mapped as planes, lines, or points in the software and are actively visible in the viewers. Furthermore, they can be exported to open data formats such as Excel spreadsheets, ASCII point clouds, and AutoCAD scripts (see Figure 7).

Each digital tunnel assessment provides a snapshot of the tunnel's conditions. By comparing the measured data with future scans, changes can be detected (Steinkühler et al., 2022). For follow-up scans, Dibit-8 can display both datasets in parallel within the viewers. This enables users to compare areas of interest, such as

Table 1. Condition state definitions for precast concrete tunnel liner (FHWA, 2015).

Defect	Condition State 1	Condition State 2	Condition State 3	Condition State 4
Delamination/ Spall/Patched area	None	Delaminated. Spall 1 in. or less deep or 6 in. or less diameter. Patched area that is sound.	Spall greater than 1 in. deep or greater than 6 in. diameter. Patched area that is unsound or showing distress. Does not warrant structural review.	The condition warrants a structural review to determine the effect on strength or serviceability of the element or tunnel, OR a structural review has been completed and the defects impact strength and serviceability of the element or tunnel
Exposed Rebar	None	Present without measurable section loss.	Present with measurable section loss, but does not warrant structural review.	
Efflorescence/ Rust Staining	None	Surface white without build-up or leaching without rust staining.	Heavy build-up with rust staining.	
Cracking (Liners)	Width less than 0.012 in. or spacing greater than 5.0 ft.	Width 0.012 - 0.10 in. below spring line or spacing of 1.0 - 5.0 ft.	Width greater than 0.10 in. below spring line or greater than 0.012 in. above spring line or spacing of less than 1 ft.	
Distortion	None	Distortion has received structural review and has been mitigated.	Distortion has received structural review and does not require mitigation.	
Leakage	Dry Surface	Saturated surface indicating seepage may be present or evidence of past seepage.	Fully saturated surface with seepage.	Seepage could range from dripping to flowing.

Figure 5. Altira System in subway tunnels on the left and in a water tunnel on the right. The measuring system is supported by a robust aluminum construction with a specially designed rail/wheel cart. Altira consists of an LED flash-lighting unit (white), cameras, and the LiDAR scanner (gray puck).

cracks and spalls, over time (see Figure 8). Inspection engineers can now observe and objectively describe and map changes on the tunnel surfaces.

Automated interpretation of tunnel lining inspections represents a burgeoning area of research within the fields of deep learning and artificial intelligence. Numerous automated video interpretation systems for sewer pipelines have already been developed, employing Convolutional Neural Networks (CNNs) for tasks such as classification, localization, and object segmentation. However, based on the literature search and interviews with industry experts, it becomes apparent that relatively few studies have focused on the

automated interpretation of tunnel lining inspections. To achieve real-time object classification and localization, several advanced models, including You Only Look Once (YOLO), Faster Region-based Convolutional Neural Network (Faster R-CNN), and Mask R-CNN, have been developed. Currently, the authors are actively researching ways to harness recent breakthroughs in deep learning to enhance the accuracy and speed of defect detection in tunnel inspections. Figure 9 provides a glimpse of this ongoing work, showcasing examples of crack detection utilizing YOLOv8, a cutting-edge computer vision model developed by Ultralytics.

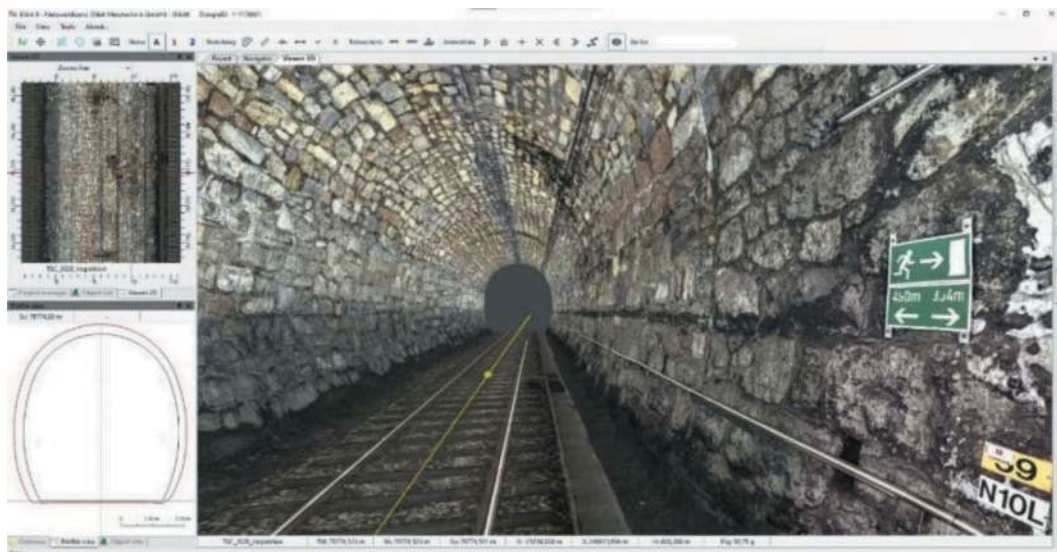

Figure 6. A 3D-view of a railroad tunnel in the DIBIT-8 software (center), along with the 2D-view and profile-view at the same location in the tunnel (left).

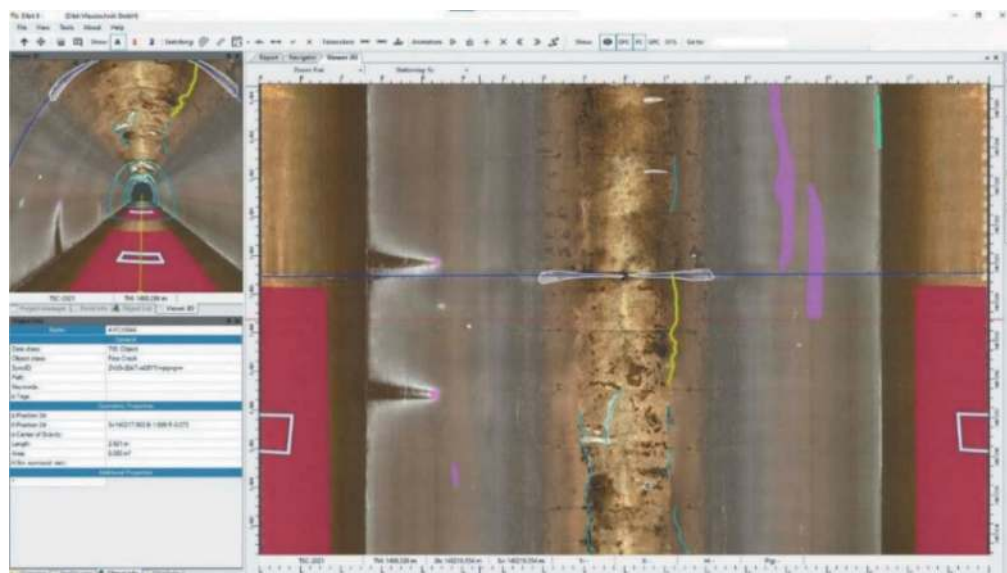

Figure 7. A 2D view of a water tunnel in the DIBIT-8 software (center), along with the 3D view and the database (left). Every object mapped in the software is visible in the viewers.

4 CONCLUSIONS

Proactive and comprehensive tunnel inspections are indispensable for safeguarding the longevity and effectiveness of these vital underground infrastructures in an era of unprecedented growth and investment. Neglecting tunnel maintenance can lead to escalating repair costs. The field of tunnel inspections is undergoing a rapid transformation with the integration of advanced scanning technologies such as laser scanners, thermography, and photogrammetry systems. These cutting-edge systems offer a multitude of benefits, including cost savings, time efficiency, and a reduced need

for manpower, effectively streamlining the inspection process and elevating its precision to new heights. The adoption of these state-of-the-art inspection techniques enables tunnel owners and operators to proactively address potential issues through routine assessments, thereby ensuring the sustained performance, safety, and long-term sustainability of these vital infrastructural assets. By embracing these innovations, not only do they enhance the efficiency of the inspection process, but they also fortify the overall resilience and dependability of tunnel systems, a crucial consideration in today's ever-evolving and demanding operational environment.

Ground movement due to shaft construction and dewatering at Bengeworth road for the London Power Tunnels 2 scheme

Oliver Brown*, Anna Simic & Joseph Ellis
AECOM, Croydon, UK

ABSTRACT: London Power Tunnels (LPT) Phase 2 is a new purpose-built cable tunnel system which will replace the existing buried cable network in the south of London. This £1 billion National Grid (NG) scheme comprises 32.5km of 3m internal diameter deep underground tunnels and 8 shafts which will help keep Londoners connected to safe and reliable electricity supplies. The tunnels extend from Wimbledon in the West to Crayford in the East, reaching depths of up to 50m below ground level. At Bengeworth Road, a 15m diameter, 30m deep shaft has been constructed to provide a connection to UK Power Network's (UKPN) existing high-voltage electricity transmission network, whilst also providing permanent access and ventilation to the tunnels.

This paper presents the ground surface settlement monitoring data recorded during shaft construction, which is compared against the existing industry standard empirical relationship by New & Bowers (1994), and numerical analysis methods, to evaluate potential risk to adjacent assets. Finite element (FE)/ finite difference (FD) analysis was undertaken to predict ground movements due to the excavation of the circular shaft and associated dewatering within the Lambeth Group and Thanet Sand Formation. Analysis of groundwater drawdown was carried out using MODFLOW and analysis of ground movements due to shaft construction was carried out using PLAXIS, considering the anticipated range of input parameters, e.g. groundwater level and the coefficient of earth pressure at rest (K₀). The monitoring data and analysis indicates some variation from the empirical relationship by New & Bowers (1994) and highlights the importance of considering the shaft construction method, site-specific ground conditions and dewatering when making ground movement predictions, particularly when in close proximity to sensitive third-party assets.

Keywords: Tunnelling, Numerical analysis, Simulation, Monitoring

1 INTRODUCTION

London Power Tunnels (LPT) Phase 2 is a new purpose-built cable tunnel system which will replace the existing buried cable network in the south of London. This £1 billion National Grid (NG) project comprises 32.5km of 3m internal diameter deep underground tunnels and 8 shafts which will help keep Londoners connected to safe and reliable electricity supplies. The project will replace three existing high voltage transmission cable circuits from Wimbledon to New Cross, New Cross to Hurst and Hurst to Crayford. The new tunnels extend from Wimbledon in the West to Crayford in the East, constructed by tunnel boring machines (TBMs) in 5 tunnel drives with a precast concrete segmental lining and reaching depths of up to 60m below ground level. Shaft diameters vary between 9m and 15m and are constructed by a variety of techniques including caisson sinking and underpinning with precast concrete segmental

lining, sprayed concrete lining and secant piling. The shafts will later be covered by headhouses to provide access and ventilation for the tunnels. The project is currently under construction and due to be completed in 2027. HOCHTIEF-MURPHY Joint Venture (HMJV) are contracted to deliver the Package 2 Tunnels & Shafts and Package 5 Headhouses & M&E contracts on the scheme, and appointed AECOM as permanent works design partner.

At Bengeworth Road, in the London Borough of Lambeth, a 15m internal diameter, 30m deep circular shaft has been constructed to provide a connection to UK Power Network's (UKPN) existing high-voltage electricity transmission network, whilst also providing permanent access and ventilation to the tunnels.

During construction of the shaft, ground movements exceeded predictions. Numerical analysis was carried out to investigate and better understand this behaviour and to estimate final settlements to evaluate potential risk to adjacent assets.

This paper presents the ground surface settlement monitoring data recorded during shaft construction, which is compared against the existing industry standard empirical relationship by New & Bowers (1994), and numerical analysis methods. Finite element (FE)/ finite difference (FD) analysis was undertaken to predict ground movements due to the excavation of the shaft and associated dewatering within the Lambeth Group and Thanet Sand Formation. Analysis of groundwater drawdown was carried out using MODFLOW and analysis of ground movements due to shaft construction was carried out using PLAXIS, considering the anticipated range of input parameters, e.g. groundwater level and the coefficient of earth pressure at rest (K_0).

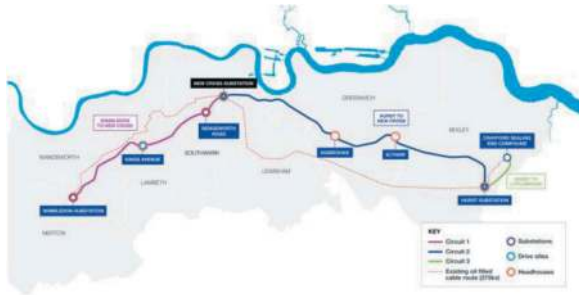

Figure 1. Scheme overview.

2 GROUND CONDITIONS

The Bengeworth Road site is located approximately 1.2km northeast of Brixton, in the London Borough of Lambeth. The ground conditions at the site are typical London Basin strata, comprising Made Ground overlying London Clay Formation, Harwich Formation, Lambeth Group, Thanet Formation and Chalk.

The assumed ground profile at the location of the shaft based on interpretation of historical and recent ground investigation at the site is given in Table 1.

3 GROUNDWATER CONDITIONS

Based on groundwater monitoring data, it was evident that multiple groundwater bodies would be encountered below the Bengeworth Road site. Shallow/ perched groundwater is present in the Made Ground and shallow London Clay where infiltrating surface water becomes trapped on low permeability layers such as the London Clay. The London Clay Formation generally acts as an aquiclude, meaning perched water may also be present in isolated lenses and pockets but not in significant volumes. Perched water posed a risk of localised instability of shallow excavations, particularly in granular materials.

Groundwater is present within the underlying Harwich Formation and in granular horizons within the upper layers of the Lambeth Group (Woolwich and Reading Formations), confined under pressure by the

Table 1. Derived ground profile.

Stratum	Top of stratum m bgl	mOD	Thickness m
Made Ground – Cohesive (MG-C)	0	+16.5	3.5
London Clay (LC)	3.5	+13.0	19.8
Harwich Formation (HA)	23.3	-6.8	1.4
Woolwich Formation Upper Shelly Beds – Cohesive (LG-C1)	24.7	-8.2	1.4
Reading Formation Upper Mottled Beds – Cohesive (LG-C2)	26.1	-9.6	1.9
Woolwich Formation Laminated Beds – Cohesive (LG-C1)	28.0	-11.5	3.4
Woolwich Formation Lower Shelly Beds – Cohesive (LG-C1)	31.4	-14.9	0.3
Reading Formation Lower Mottled Beds – Cohesive (LG-C2)	31.7	-15.2	4.7
Reading Formation Lower Mottled Beds – Granular (LG-G2)	36.4	-19.9	1.4
Upnor Formation – Granular (LG-G2)	37.8	-21.3	1.9
Thanet Formation (TG)	39.7	-23.2	12.0
Chalk (CHK)	51.7	-35.2	Not proven

overlying London Clay. Together these strata are referred to as the “intermediate aquifer”. The thickness, lateral variation and inter-connectivity of the units in this aquifer varies significantly. Groundwater is also present in the Upnor Formation (the basal deposit of the Lambeth Group), Thanet Formation and Chalk, typically considered as one aquifer and referred to as the “lower aquifer”, which is the main water-bearing unit beneath the site.

The groundwater level in the lower aquifer is confined under pressure by the overlying lower permeability strata. Available data suggests the groundwater in the Upnor, Thanet and Chalk Formations are in hydraulic continuity. There is no evidence of hydraulic connectivity between the intermediate and the lower aquifers.

4 GEOTECHNICAL PARAMETERS

The following characteristic geotechnical parameters were derived for the strata present at the site.

Hardening soil model stiffness parameters (Schanz et al., 1999) for the London Clay were derived from oedometer test data available from the site-specific ground investigation.

Table 2. Characteristic geotechnical parameters.

Parameter	Units	MG-C	LC	HA-C	
Bulk unit weight, γ_{bulk}	kN/m ³	19	19.5	19.5	
Saturated unit weight, γ_{sat}	kN/m ³	20	20.5	20.5	
Poisson's ratio, ν	-	0.2	0.2	0.2	
Coefficient of lateral earth pressure at rest, K_0	-	0.58 - 0.62	0.7 - 1.5	0.9 - 1.5	
Undrained shear strength, c_u	kN/m ²	40	40 + 4.4z ¹	130	
Drained cohesion, c'	kN/m ²	0	0 - 5 ²	0 - 5 ²	
Friction angle (constant volume), ϕ_{cv}'	°	23	22	23	
Friction angle (peak), ϕ_p'	°	N/A	22	24	
Undrained stiffness, $E_u^{3,4}$	MPa	16	16 + 1.76z ¹	52	
Drained stiffness, $E^{3,4}$	MPa	12.8	12.8 + 1.41z ¹	42	

Parameter	Units	LG-C1	LG-C2	LG-G2	TG
Bulk unit weight, γ_{bulk}	kN/m ³	19.5	20	20	19
Saturated unit weight, γ_{sat}	kN/m ³	20.5	21	21	20
Poisson's ratio, ν	-	0.2	0.2	0.2	0.2
Coefficient of lateral earth pressure at rest, K_0	-	0.7 - 2.0	0.7 - 2.0	0.7 - 1.5	0.7 - 1.0
Undrained shear strength, c_u	kN/m ²	110	125	N/A	N/A
Drained cohesion, c'	kN/m ²	0	0	0	0
Friction angle (constant volume), ϕ_{cv}'	°	20	20	30	30
Friction angle (peak), ϕ_p'	°	20	20	32	32
Undrained stiffness, $E_u^{3,4}$	MPa	55	62	N/A	N/A
Drained stiffness, $E^{3,4}$	MPa	44	50	120	130

1. z = depth from the top of the London Clay, with $z = 0m$ at +13.0 mOD

2. Drained cohesion value assumed when peak parameters are appropriate. Cohesion of 0kN/m² applied for critical state/constant volume shearing.

3. Stiffness values for bedrock materials refer to horizontal stiffness. For London Clay, Harwich Formation and Lambeth Group cohesive, $E'h=1.5E'\nu$.

4. Stiffness values assume large strain (0.1% to 1.0% strain).

A summary of the hardening soil model parameters derived is provided in Table 3.

Table 3. Hardening soil parameters for London Clay.

Parameter	Units	Value
Tangent stiffness for primary oedometer loading, $E_{oed,ref}$	kN/m ²	12,000
Secant stiffness in standard drained triaxial test, $E_{50,ref}$	kN/m ²	14,000
Unloading/ reloading stiffness, $E_{ur,ref}$	kN/m ²	36,000
Power for stress-level dependency of stiffness, m	-	0.75
Reference stress for stiffnesses, p_{ref}	kN/m ²	200

For completeness, the in-situ stiffness profile obtained with the hardening soil model parameters was compared against the stiffness values derived from empirical correlations with undrained shear strength (c_u). The E_{ur} profile derived showed a good correlation with $E' = 400c_u$ which is consistent with relationships typically used for the proposed method of shaft construction and the anticipated unload-reload behaviour of the over consolidated London Clay.

5 THE BENGEWORTH ROAD SHAFT

The site comprises an area of land within the UKPN Bengeworth Road site where the new shaft has been constructed which incorporates a number of existing structures and utility services (see Figure 2).

Figure 2. Bengeworth road site.

NG are to provide a Grid Supply Point (GSP) to UKPN by developing a 400/132kV substation to feed new and existing 132kV transformers at

Bengeworth Road. The new NG 400kV Gas Insulation Substation (GIS) will be fed via Circuit 1, to be housed within the proposed LPT Phase 2 cable tunnel between New Cross and Wimbledon.

A schematic of the shaft is shown in Figure 3. At the top of the shaft (1m below ground level) is a 1m deep temporary reinforced concrete collar beam used to facilitate construction of a 15m internal diameter, 350mm thick precast concrete segmental shaft lining by the underpinning method. The shaft lining comprises 33 no. 1m deep rings, below which is a 2.2m thick reinforced concrete base slab with mass concrete infill above. The base slab is tapered to provide stability against uplift/ flotation and a temporary sprayed concrete lining (SCL) is used to provide temporary support to the side walls of the base slab excavation prior to casting the base slab.

Figure 3. Bengeworth road shaft schematic.

The underpinning method of shaft construction (see Figures 4 and 5) falls under the Support Before Excavation (SBE) construction category as defined by Faustin et al. (2018).

Figure 4. Bengeworth road shaft lining underpinning.

Figure 5. Bengeworth road shaft lining underpinning.

As part of a wider value engineering exercise, the LPT Phase 2 tunnel alignment was realigned to pass directly through the Bengeworth Road shaft (online shaft) and therefore the shaft incorporated an 8m high, 500mm thick reinforced concrete secondary lining with two portals to transfer forces around the openings. The shaft is then covered by a headhouse to provide access and ventilation for the tunnels.

The lowest excavation level of the shaft is at -19.66mOD which is within the Reading Formation Lower Mottled Beds (LG-C2). Checks of the temporary stability against uplift were carried out in accordance with Eurocode 7 and indicated that groundwater control would be required for both the lower aquifer and intermediate aquifer to control the basal heave risk during shaft excavation.

Groundwater control on site was carried out by HMJV's specialist supply chain partner WJ Groundwater and comprised an array of surface dewatering wells extended down to the Lambeth Group and Thanet Sand (see Figure 6), with provision for probe drilling at the base of the part excavated shaft within the Lambeth Group.

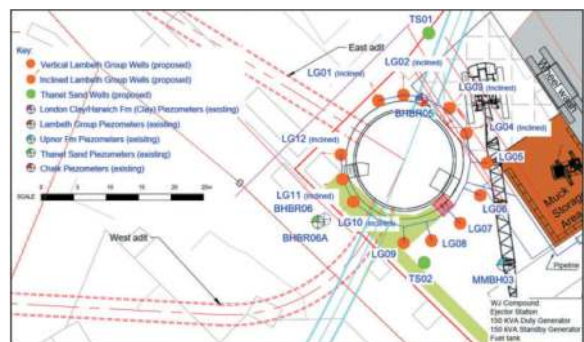

Figure 6. Dewatering well layout.

Throughout the shaft excavation process, HMJV instigated a permit process closely aligned with that

of SCL works, for the underpinning construction, i.e. a Required Excavation Support Sheet (RESS). As well as review of monitoring data, strength testing and survey results (steps, lips, ovality, alignment), regular face logging was undertaken prior to the construction of each ring. This regular review of ground conditions ensured design requirements were closely followed and mitigation measures undertaken if necessary.

6 EMPIRICAL GROUND MOVEMENT PREDICTION

Predicted ground movements due to shaft construction were initially based on the well-known empirical relationship by New & Bowers (1994) between distance from the shaft wall d and the settlement S_d , which has the following equation:

$$S_d = \alpha \cdot (H - d)^2 / H \quad (1)$$

Where, S_d is the settlement at distance d from the shaft wall in m; α is an empirical constant; H is the depth of the shaft excavation in m; and d is the distance from the shaft wall in m.

This is based on data analysed from an access shaft at Heathrow, near London, UK, constructed by caisson-sinking and then underpinning to 16 m depth, and then excavated in 1m steps and lined with shotcrete to 26 m below ground level. For the Bengeworth Road shaft, an α value of 0.0006 was adopted in line with industry practice and the maximum settlement predicted adjacent to the shaft was approximately 22mm.

It was accepted that this relationship would not account for potential dewatering impacts on settlement. Past experience suggested that whilst increasing total settlement values, differential settlements were unlikely to be significantly increased at the location of nearby assets. Monitoring of the shaft lining and nearby assets was carried out in order to review differential settlement in the daily review meetings.

7 ANALYSIS OF GROUND MOVEMENTS

During construction of the shaft, recorded ground movements exceeded the empirical prediction. The layout of monitoring points is shown in Figure 7.

After construction of the 11th segmental shaft ring (excavation depth of approximately 13m), the 3 no. monitoring points installed on the top of the shaft lining indicated between 24 and 42mm settlement compared to an empirical prediction of approximately 8mm maximum settlement for this stage. Whilst differential settlement triggers had not been exceeded, this significant difference prompted

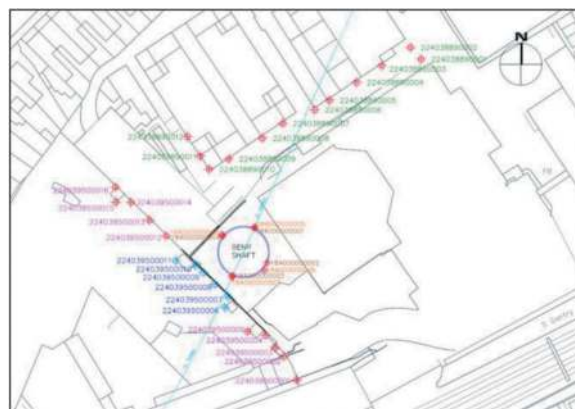

Figure 7. Location of monitoring points around the shaft.

numerical analysis to be carried out to investigate and better understand this behaviour and to estimate final settlements to evaluate potential risk to adjacent assets. The following sections describe the numerical analysis carried out to estimate settlements due to both dewatering and shaft construction and compare the results of the analysis with the empirical predictions and monitoring data.

7.1 Analysis of ground surface settlements due to dewatering of the Lambeth Group and Thanet sand formation

Finite difference software MODFLOW was used to analyse the groundwater drawdown profile due to depressurisation and dewatering of the Lambeth Group and Thanet Sand Formation. The drawdown estimates were based on the following method and assumptions:

- Hydraulic properties for Thanet Sand Formation and Lambeth Group based upon pumping tests undertaken by WJ Groundwater in 2021.
- MODFLOW model used to simulate the head distribution created by lowering of piezometric pressures in the Lambeth Group and Thanet Sand Formation for a pumping period of between 56 days and 120 days.
- Lambeth Group properties; hydraulic conductivity $k = 0.12$ m/d, aquifer thickness $b = 16.9$ m, transmissivity $T = 2\text{m}^2/\text{d}$, storativity $S = 3 \times 10^{-4}$, initial groundwater level = -6mOD, 12 no. surface well points assumed to lower pressure to -20mOD.
- Thanet Sand Formation properties; hydraulic conductivity $k = 4$ m/d, aquifer thickness $b = 11.5$ m, transmissivity $T = 46\text{m}^2/\text{d}$, storativity $S = 1 \times 10^{-2}$, initial groundwater level = -16mOD, 4 no. surface well points assumed to lower pressure to -22mOD, very low vertical hydraulic conductivity.
- All water is derived from storage (no boundary inflow or recharge).
- Confined system assumed.

Due to the vertical and lateral variability of the Lambeth Group material, and possible ‘pockets’ of groundwater not in continuity with the main aquifer, it is very difficult to predict the drawdown distribution with confidence. As a result, the drawdown results were an estimate only, and are presented in Figures 8 and 9 below.

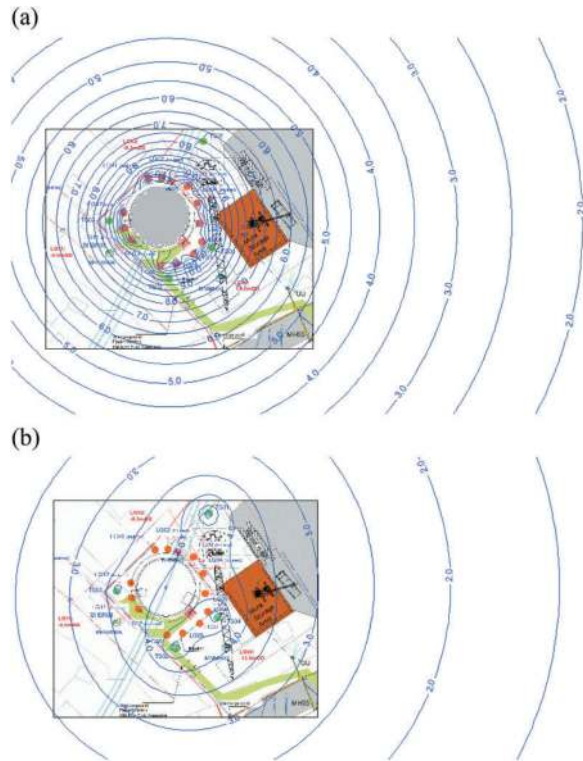

Figure 8. (a) Lambeth Group drawdown contour (metres) after 56 days pumping (b) Thanet Sand Formation drawdown (metres) contour after 56 days pumping.

Figure 9. Estimated drawdown after 56 days and 120 days pumping in the Lambeth Group (LG) and Thanet Sand (TS).

The ground surface settlements associated with the above predicted drawdowns were then calculated, based on the following method and assumptions:

- Groundwater drawdown results in a reduction in pore water pressure and hence an increase in effective stress in the ground.
- Settlement was calculated based on reduction of pore water pressure corresponding to predicted drawdown.
- Small strain stiffness (0.1 to 0.01% strain) was assumed.
- For Lambeth Group dewatering, it was assumed that drawdown occurs in the entire thickness of Lambeth Group and Harwich Formation strata and that cohesive strata become drained by the end of pumping. This is conservative but is a reasonable assumption given the permeability of the Lambeth Group and the presence of sand channels and granular lenses.

The settlement estimates are presented in Figure 10 below. The localised effects on groundwater drawdown and associated settlement in close proximity to the pumping wells is ignored for simplicity.

Figure 10. Estimated ground surface settlement after 56 days and 120 days pumping in the Lambeth Group (LG) and Thanet Sand (TS).

7.2 Analysis of ground surface settlements due to shaft construction

Finite element software PLAXIS was used to analyse the ground surface settlement due to shaft construction. A 2D axisymmetric model was used (see Figure 11) and considered the anticipated range of input parameters including groundwater level, the coefficient of earth pressure at rest (K_0), surface surcharge and undrained (A) or undrained (B) material models (for cohesive materials).

Soils have been modelled using the Mohr-Coulomb (MC) or Hardening Soil (HS) constitutive models (Schanz et al., 1999), depending on the level of ground investigation data available. The stiffness parameters were specified assuming a dominant strain level of between 0.1 and 1% for the underpinning method of shaft construction.

Granular materials were assumed to be drained and cohesive materials were assumed to be undrained in the short-term during shaft construction, which has been modelled using either the

Figure 11. PLAXIS 2D axisymmetric analysis of the shaft.

undrained (A) or Undrained (B) drainage types in PLAXIS. The undrained (A) drainage type uses an effective stress analysis with effective stiffness and effective strength parameters, whereas undrained (B) uses an effective stress analysis with effective stiffness and undrained strength parameters. A summary of the soil models and drainage types adopted for each stratum is as follows:

- MG-C, HA (cohesive) LG-C1 and LG-C2: Mohr Coulomb material model and either Undrained (A) or Undrained (B) parameters.
- LC (cohesive): Hardening soil material model and either Undrained (A) or Undrained (B) parameters.
- LG-G2 and TG: Mohr Coulomb material model with drained parameters.

The segmental lining was characterised by 350mm thick linear elastic two-dimensional plate elements with axial, shear and flexural resistances. The construction of the segmental lining by underpinning was modelled explicitly considering step by step excavation and installation of each 1m deep segmental lining ring. Full face excavation of the shaft was considered with an unsupported excavated depth of 1.5m prior to the installation of each ring. A pin connection between each segmental lining ring was modelled. The temporary reinforced concrete collar beam, permanent base slab and mass concrete infill were characterised by linear elastic non-porous volume elements. The temporary SCL support to the side walls of the base slab excavation were characterised by 100mm thick linear elastic two-dimensional plate elements and assigned isotropic stiffness according to Chang & Stille (1993) to reflect the time-dependent behaviour of the SCL properties, accounting for creep. Construction of the SCL sealing layer was modelled explicitly considering step by step excavation and installation of 1m deep rings, similar to the segmental lining.

It is worth noting that the rate of settlement of the top of the shaft lining was higher up to grouting of the second segmental shaft ring, which had settled by up to 21.9mm (see Figure 12) by this stage.

Figure 12. Recorded settlement of shaft top segmental ring.

This increased settlement may have been due to a low strength/ stiffness or more drained behaviour of the MG-C, e.g., a higher permeability/ granular material. It is also understood that there was a delay in grouting behind these rings, which may have caused additional settlement due to the excavated shaft face remaining unsupported for an extended period, partly because of constraints to permitted working time arrangements.

This behaviour was not replicated in the PLAXIS analyses because a reduced strength or stiffness of MG-C was not adopted in the analysis. Instead, in order to allow a more meaningful estimate and comparison of settlements, the maximum monitored settlement of the top of the shaft lining after grouting of the second segmental shaft ring (21.9mm) was used as a starting point (see Figure 13) and added to the PLAXIS analysis settlements for subsequent construction stages.

A comparison of the monitoring survey readings, empirical predicted settlement and PLAXIS 2D analysis settlements is presented in Figures 14-16.

Figure 13. Monitoring readings after grouting of ring no.2.

Figure 15 shows a comparison of the ground surface settlement after installation of permanent ring no. 18. This was the latest stage which did not include the influence of dewatering as it had not yet begun (dewatering settlement is analysed separately in Section 7.1). The analysis results which most closely matched the recorded movements were then used to provide an estimate of the future settlements due to shaft construction to evaluate potential risk to adjacent assets. Note that an extra point has been

Figure 14. Settlement of shaft top segmental ring (excluding dewatering settlement).

Figure 15. Ground surface settlement after ring no. 18 installation.

Figure 16. Ground surface settlement after base slab installed.

added to each of the curves to indicate the settlement of the shaft top segmental ring (plotted at the extrados of the shaft lining, i.e., distance from shaft centre = 7.85m) but this is the movement of the shaft lining itself and not the ground surface movement. Figure 15 indicates that for installation of permanent ring no. 18, the PLAXIS analysis case assuming minimum K_0 , minimum groundwater, no surcharge and undrained (B) material model was the closest match to the recorded movements, and results of this analysis were then combined with the estimated

settlements due to dewatering and used to evaluate potential risk to adjacent assets (see Section 7.3).

Figure 16 shows a similar comparison but for a later stage after the base slab was constructed. For this stage, the recorded movements more closely match multiple PLAXIS analysis cases which assume min K_0 , however, it should be noted that for this stage, the PLAXIS analysis results do not include dewatering settlements whereas the recorded movements will be influenced by dewatering and therefore a direct comparison cannot be made.

7.3 Combined estimate of ground surface settlements due to shaft construction and dewatering

Combined estimated ground surface settlements due to shaft construction and dewatering from numerical analysis are compared against recorded movements in Figure 17.

Figure 17. Combined ground surface settlement vs distance from shaft centre after base slab installed.

Estimated settlements due to shaft construction are from the PLAXIS analysis case assuming minimum K_0 , minimum groundwater, no surcharge and undrained (B) material model, and the estimated settlements due to dewatering are from the MODFLOW analysis for 56 days Thanet Sand pumping and 120 days Lambeth Group pumping.

These combined settlements were used to evaluate potential risk to adjacent assets by calculating settlements, rotation and angular distortion along the assets in close proximity to the shaft, i.e., 2 sets of cables, the UKPN substation perimeter wall to the north of the shaft and the wall to the south of the shaft. To simplify the assessment, it was assumed that the settlement along the assets is equal to the predicted ground surface settlement.

During shaft construction, ground surface settlements were monitored to check that the impact of shaft construction and dewatering were consistent with the above estimates.

Additional monitoring points were installed in proximity to the shaft, and frequency of monitoring was increased to closely align construction activities with recorded movements. Figure 17 shows that

estimated ground surface settlements due to shaft construction and dewatering from numerical analysis correlate well with recorded ground movements and have a similar profile shape but are slightly higher. Although the recorded ground movements significantly exceeded predictions based on the empirical relationship by New & Bowers (1994), a reasonably good match with recorded movements can be found by combining the empirical prediction with the estimated ground movements due to dewatering, except for approximately one shaft radius away from the shaft where there is a significant difference. However, the movement attributed to the separate activities of shaft construction and dewatering cannot be differentiated from the monitoring data with certainty as both activities were generally progressing concurrently.

8 DISCUSSION AND CONCLUSIONS

During construction of the shaft, recorded ground movements significantly exceeded predictions based on the empirical relationship by New & Bowers (1994). Numerical analysis was carried out to investigate and better understand this behaviour and to estimate final settlements due to both dewatering and shaft construction. The numerical analysis considered several cases covering the anticipated range of groundwater level, coefficient of earth pressure at rest (K_0), surface surcharge and undrained (A) or undrained (B) material models (for cohesive materials). Estimated ground movements from the numerical analysis were found to correlate reasonably well with the recorded movements, with the best match generally provided by the PLAXIS analysis cases assuming minimum K_0 and the undrained (B) material model.

A reasonably good match with recorded movements can be found by combining predictions based on the empirical relationship by New & Bowers (1994) with estimated ground movements due to dewatering, except for approximately one shaft radius away from the shaft.

The significant increase in settlement at the location of the shaft lining, particularly during construction of the initial lining rings, is thought to be due to a low strength/ stiffness or more drained behaviour of the MG-C, e.g., a higher permeability/ granular material. It is also understood that there was a delay in grouting behind these rings which may have caused additional settlement due to the excavated

shaft face remaining unsupported for an extended period.

Overall, the monitoring data and analysis indicates some variation from the empirical relationship by New & Bowers (1994) and highlights the importance of considering the shaft construction method, site-specific ground conditions and effects of dewatering when making ground movement predictions, particularly when near sensitive third-party assets.

Application of Acoustic signal to quantify the damage of the lesser Himalayan sandstone under unconfined compression loading and its implementation in the micromechanical damage-plasticity model

Aditya Singh

Assistant Professor, Indian Institute of Technology, Roorkee, India

ABSTRACT: Space scarcity and population growth are the two reasons for using underground space to improve the quality of human life. Currently, numerous rock tunnels are constructed in the Himalayan region of India. Due to the stress variation, microcracks are generated in the rock, leading to damage. The quantification of damage with the microcrack propagation is essential for the safety and health monitoring of the rock tunnels. The Acoustic Emission (AE) technique is a real-time Structural Health Monitoring (SHM) method. This technique records the micro-physical activities in terms of acoustic signals that occur during the loading of the rocks. The recorded AE signals contain valuable information about the damage and fracture mechanism. In this paper, we have experimented on the lesser Himalayan sandstone under unconfined compression loading to quantify the damage using real-time recorded AE signals. Further, we have implemented the AE-based damage variables to obtain the Himalayan sandstone's nonlinear constitutive behaviour. The present study results encourage utilization of the AE technique, i.e., the non-conventional experimental method for safety and health monitoring of rock tunnels in the Indian Himalayas.

Keywords: Acoustic Emission (AE), Himalayan Sandstone, Damage Quantification, Micromechanical Damage-Plasticity Model

1 INTRODUCTION

In the modern era, space scarcity and population growth are the two main reasons for using underground space to construct shallow and deep underground rock engineering structures. The major rock tunnel projects like subsurface roads, railways, and hydroelectric power projects are constructed in India's sub-Himalaya and lesser Himalaya. These tunnelling projects are the Udampur-Katra rail tunnel project, Uri hydroelectric project, Parbati stage-II hydroelectric project, Rohtang highway tunnel project, Maneri stage-I and II hydroelectric project, Tehri project, Rishikesh and Karanprayag rail link project, Subansiri hydroelectric project, Laktak project and many others, lies in the Himalayan states of Jammu and Kashmir, Himachal Pradesh, Uttarakhand, Assam, Arunachal Pradesh, and Manipur in India (Goel and Singh, 2017). During the construction and operation of tunnels, local stresses

are altered. Due to these changes in the stress state, microcracks are generated in the tunnel's surrounding rock or rock mass. In the case of a rockburst, the stored elastic strain energy that triggers the fracturing processes and damage to the tunnel is released. During the damage evolution, the release of stored elastic strain energy generates a high-frequency elastic wave called the Acoustic Emission (AE) signal (Ishida et al., 2017; Feng et al., 2019).

The AE technique records elastic vibrations in rocks or rock masses caused by the growth or generation of micro or meso cracks. The recorded AE signals contain valuable information about the microcrack generation and fracture processes and are related to the damage evolution of rock under external compressive loading (Shah and Labuz, 1995; Eberhardt et al., 1999; Kim et al., 2015; Du et al., 2020; Chajed and Singh, 2023a, b, c, d). The consequences of damage are inelastic deformation and deterioration of mechanical properties, which results

*Corresponding author: s_chajed@ce.iitr.ac.in

in a nonlinear stress-strain behaviour of rocks (Zhu et al., 2016; Zhu and Shao, 2017). The AE-based damage quantification and its use in constitutive modelling is an area that can be explored in the safety and health monitoring of rock tunnels.

In the current study, we have reported the monitored AE of the lesser Himalayan sandstone under unconfined compression loading for following two objectives: the first objective is to quantify the damage variable of the lesser Himalayan sandstone under unconfined compression loading using acoustic signals; the second objective is to implement the AE-based damage variable for obtaining the nonlinear constitutive behaviour of the lesser Himalayan sandstone using the micromechanical damage plasticity constitutive model.

2 EXPERIMENTAL METHODOLOGY

Experimental work includes the damage quantification of the lesser Himalayan sandstone under uniaxial compression loading using real-time AE monitoring. This section mentioned the rock material, the experimental setup with the AE monitoring system, and the AE-based damage quantification methodology.

2.1 Rock material

The Himalayan sandstone employed in the current study is the Devprayag sandstone collected from the Devprayag town of the Tehri Garhwal district, Uttarakhand, India. The Tehri Garhwal district lies in the outer lesser Himalayas.

2.2 Experimental setup with AE

The uniaxial compression tests were performed by the servo-hydraulic closed-loop static cum dynamic rock triaxial testing system at the Indian Institute of Technology, Roorkee. The loading capacity of the system is 2000 kN. The test specimens were loaded under displacement-controlled mode with a constant displacement rate of 0.2 mm/min. The load and strain data were recorded by the load cell and strain gauge, respectively, with a sampling rate of 1 Hz. At the same time, the acoustic signals induced by microcracks growth were recorded by an AE sensor with the data acquisition system. The AE sensor was placed at mid-height of the rock specimen. The sampling rate of the AE data acquisition system is 1 MHz. The total test duration was 6 minutes and 41 seconds, with 401 million data points. The schematic diagram of the laboratory AE monitoring system and the positioning of the AE sensor and strain gauge on the Devprayag sandstone specimen are shown in Figures 1 (a, b, and c), respectively. The recorded AE signal is processed using the developed MATLAB program. The processed AE signal is used to quantify the damage of the Devprayag sandstone under uniaxial compression loading.

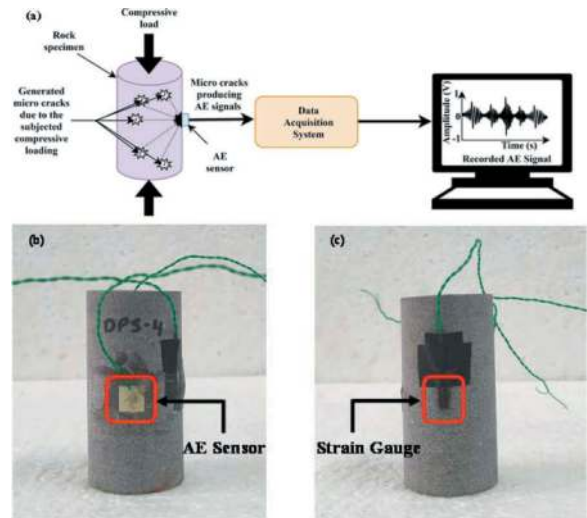

Figure 1. (a) Schematic diagram of the laboratory AE monitoring system, (b and c) positioning of an AE sensor and strain gauge on the Devprayag sandstone cylindrical specimen.

2.3 Methodology of AE-based damage quantification

First, we need to denoise the recorded AE signal and determine the different AE signal parameters to obtain the AE-based damage quantification. During the testing, the recorded AE signal will be interfered with by the noise signals from the surrounding environment, transmission media, and vibration induced by the testing machine. In the present study, we have denoised the recorded AE signals using the wavelet transform filtering algorithm based on the local time-frequency analysis method with multiscale wavelet coefficient processing (Yang et al., 2021). Morlet proposed this method in the 1980s. Afterward, the filtered AE signal was used to determine different AE signal parameters, i.e., AE event count, AE ringdown count, and AE event duration. Figure 2 graphically represents a typical AE signature's AE signal parameter. A reader can refer to Chajed and Singh's (2023a, b) articles for more details about determining different AE parameters from a typical AE signature. The obtained AE parameters are used to quantify the degree of rock damage. The AE-based damage variable (d_{AE}) is the ratio of the cumulative AE parameter under a certain stress level to the total cumulative AE parameter until the failure of the rock. In the present study, we have used AE event count (E_{AE}) as an AE parameter for damage quantification of the Devprayag sandstone under unconfined compression loading.

3 AE-BASED MICROMECHANICAL DAMAGE PLASTICITY MODEL

This section briefly presents the formulation of the AE-based micromechanical damage plasticity model proposed by Chajed and Singh (2023b). The proposed model utilized the AE-based damage variable to

Figure 2. Graphical representation of the AE signal parameters in a typical AE signature (red horizontal line represents the threshold line; blue and green dashed vertical lines are shown as the starting and ending point of an AE event, respectively).

predict the nonlinear stress-strain response of intact rock under Conventional Triaxial Compression (CTC) loading. The model is based on two main dissipation processes: the first one is the inelastic deformation due to friction sliding along the closed microcracks surface, and the second one is the damage due to the growth of microcracks. The friction and damage criteria are presented below based on these two dissipation processes.

3.1 Friction criterion

A linear Coulomb-type friction criterion is used to determine the friction-induced inelastic deformation along the closed microcrack surface, and it is given by Eq. (1) as:

$$f(\sigma^d) = \|q^d\| - \zeta p^d \leq 0 \quad (1)$$

where q^d and p^d are the local deviatoric and hydrostatic stress acting on the crack surfaces, respectively, and ζ is the apparent friction coefficient associated with the roughness of the crack surface.

3.2 Damage criterion

A strain-energy release rate-based damage criterion is used to determine the damage due to microcrack growth, and it is given by Eq. (2) as:

$$f^d(F^d, d) = F^d - R(d) \leq 0 \quad (2)$$

where F^d is the damage-deriving force associated with the internal damage variables (d), the $R(d)$ represents the resistance to damage evolution of material, and it is given by Eq. (3):

$$R(d) = R(d_{AE})_c \left[\frac{b_2 \eta}{(b_2 - 1 + \eta^{b_2})} \right] \quad (3)$$

where $\eta = d/(d_{AE})_c$ is defined as a dimensionless parameter, $(d_{AE})_c$ represents the AE-based critical

damage variable corresponding to the peak stress, $R(d_{AE})_c$ is the AE-based critical damage resistance of rock at $d = (d_{AE})_c$, and b_2 is the material parameter.

3.3 Yield function

Coupled the abovementioned two dissipation processes and obtained the final damage plasticity yield function, which is given by Eq. (4) as:

$$f(\sigma) = \|q\| - \zeta p - 2\sqrt{R(d)\kappa} \leq 0 \quad (4)$$

where q and p are the deviatoric and hydrostatic stress, and κ is a model parameter. Zhu et al. (2016) use a similar yield equation for penny-shaped microcracks. In the proposed model, the value of κ is obtained for arbitrarily shaped microcracks using the triaxial compression test and AE data. For arbitrarily shaped microcracks, the value of κ is given by the Eq. (5) as:

$$\kappa = \left[(\sigma_1)_p - \frac{(\sqrt{6} + 2\zeta)}{\sqrt{6} - \zeta} \sigma_3 \right] \left[\frac{(\sqrt{6} + 2\zeta)(d_{AE})_c M}{6(\varepsilon_1^i)_p} \right] \quad (5)$$

where $(\sigma_1)_p$ is the peak stress, $(\varepsilon_1^i)_p$ is the inelastic strain corresponding to the $(\sigma_1)_p$, σ_3 is the confining pressure, and M is given by Eq. (6) as:

$$M = \left(\frac{2}{\sqrt{6}} - \frac{\zeta}{3} \right) \quad (6)$$

3.4 Constitutive equations for unconfined compression loading ($\sigma_3 = 0$)

The final yield function can be written in the form of σ_1 and d , as given by Eq. (7), and the modelled axial strain component is determined by Eq. (8).

$$\sigma_1 = \frac{6\sqrt{R(d)\kappa}}{\sqrt{6} - \zeta} \quad (7)$$

$$\varepsilon_1 = \frac{\sigma_1}{E^s} + d \sqrt{\frac{R(d)}{\kappa}} \left(\frac{2}{\sqrt{6}} - \frac{\zeta}{3} \right) \quad (8)$$

where E^s is Young's modulus of elasticity of rock. A reader can refer to the Chajed and Singh (2023b) article for detailed information and formulation of the AE-based micromechanical coupled damage plasticity model. The experimental results and model validation are reported in the following section.

4 EXPERIMENTAL RESULTS, DISCUSSION AND MODEL VALIDATION

The AE-based damage quantification of the Devprayag sandstone under unconfined compression loading and its model validation results are presented here.

4.1 AE-based damage quantification of the Devprayag sandstone

The total 11572 AE event counts are identified within the Devprayag sandstone under uniaxial compression. Based on the normalized cumulative AE parameter concept, the AE event counts are used to quantify the rock's damage variable. Figure 3 shows the damage variable based on the AE event counts of the Devprayag sandstone under unconfined compression loading. The obtained value of the damage at peak stress is 0.0088. This damage is called the AE-based critical damage variable (d_{AEc}). After the peak stress, a sudden increase in the damage variable is observed. Physically, it signifies the generation of macro fractures within the rock. Therefore, we can use these AE-based damage quantification results for the safety and health monitoring of the rock tunnels. Correspondingly, we can implement these AE-based damage variable results for the constitutive modelling of tunnels surrounding rock material.

Figure 3. Deviatoric stress-time response of the Devprayag sandstone under unconfined compression loading with damage variable (d_{AE}) based on AE event counts (peak stress, and critical AE-based damage variable (d_{AEc}) is marked the by symbol star and triangle, respectively).

4.2 Model validation

The triaxial compression and AE data are used to determine the model parameters. Their values are presented in Table 1.

Table 1. Typical values of model parameters for the Devprayag Sandstone at 0 MPa confining pressure based on AE Event Counts (E_{AE}).

Model Parameters	Values
$(\epsilon_I^m)_p$ (%)	0.01
E^s (GPa)	54.13
ζ	0.935
$(d_{AE})_c$	0.0088
κ	1895.733
$R(d_{AE})_c$	0.479
b_2	1.45

We compared the modelled damage variable with the experimentally obtained AE event counts-based damage variable, and the result is presented in Figure 4. It is noticed that the magnitude of the damage variable obtained from the model is close to the experimental data in the pre-peak region. The obtained damage variable is used to get the nonlinear stress-strain response of the Devprayag sandstone under unconfined compression loading.

Figure 4. Comparison between the experimental and modelled damage variable-strain response based on the AE event counts for the Devprayag sandstone under unconfined compression loading.

Figure 5 compares the modelled stress-strain response with the experimental data. The model performance is verified by obtaining the class-II nonlinear stress-strain behaviour, similar to the experimentally obtained stress-strain response of the Devprayag sandstone under unconfined compression loading. The class-II stress-strain curve of rock undergoes self-sustaining fracturing and shows the rockburst condition (Akdag et al., 2019).

Figure 5. Comparison between the experimental and modelled stress-strain response of the Devprayag sandstone under unconfined compression loading.

5 CONCLUSIONS

In the present study, we performed the AE monitoring of the lesser Himalayan sandstone under unconfined compression loading and quantified the damage variable based on AE event counts. We have observed from the test results that a sudden increase in damage variable occurred after the peak stress. Physically, it signifies the generation of macro fractures within the rock. We have also implemented the experimentally obtained AE-based damage variable for simulating the nonlinear constitutive behaviour of the lesser Himalayan sandstone. The model performance is verified by obtaining the class-II nonlinear stress-strain behaviour of the Devprayag sandstone, similar to the experimentally obtained stress-strain response under unconfined compression loading. It is the first time such a study has been conducted on the Devprayag sandstone in the lesser Himalayan range of the Indian Himalayas. The present study results encourage utilization of the AE technique, i.e., the non-conventional experimental method for safety and health monitoring of rock tunnels in the Indian Himalayas.

ABSTRACT: Currently, most of the geometric element detection methods used in tunnel engineering still rely on traditional methods such as total stations and laser profile meters. These traditional sampling methods have potential risks and may ignore some data that constitute hazards. Terrestrial Laser Scanning (TLS) is a new remote sensing technology that provides high-precision and high-density active measurement data even in harsh, unlighted conditions, with lower requirements for the work environment than traditional measurement techniques. Based on TLS, this paper proposes a method for reorganizing tunnel point cloud data and studies tunnel detection (including clearance, smoothness, and lining steel bar installation) and deformation monitoring technology. The proposed method has advantages such as high automation, high precision, and high efficiency, and has been validated in practical engineering, which can improve the quality of tunnel construction. The holographic deformation monitoring method can capture the asymmetric and non-uniform deformation characteristics of the initial support structure and improve the safety of the construction.

Keywords: Terrestrial Laser Scanning, Monitoring, Inspection, Tunnel

1 INTRODUCTION

The detection and monitoring of geometric elements in tunnel sections are necessary and extremely important processes that directly affect the construction quality, progress, cost, and safety of tunnels. Traditional methods for tunnel section detection and monitoring include the use of total stations, cross-sectional detectors, etc. The former can measure the coordinates of any single point, and by comparing the position coordinates with the corresponding position of the designed section, it is possible to determine over-break and intrusion conditions. By monitoring different fixed points over time, the deformation situation of those points can be obtained. The latter method upgrades from one-dimensional single point measurement with a total station to two-dimensional cross-sectional measurement, but fundamentally, it is still a sampling detection method that cannot grasp the construction situation of various parts of the tunnel wall, and it often has a long working time inside the tunnel, which easily affects the normal progress of other processes. Terrestrial Laser Scanning (TLS) is a non-contact active technique for rapidly acquiring dense three-dimensional point cloud data of object surfaces (Cheng et al., 2019). It is considered as a technological revolution in the field of surveying and mapping after GPS technology. This

technology can obtain vector coordinates and reflectivity of tens of millions of points within a range of approximately 60 meters in about three minutes. Through post-processing software, including line data and design section initialization, point cloud cleaning, denoising, and registration, accurate results of overall over-break, intrusion, initial support flatness, and tunnel deformation can be obtained. It breaks through the traditional sampling measurement methods and has unique advantages such as high efficiency, high accuracy, and holistic information, as listed in Table 1.

Table 1. Traditional measurement vs TLS.

Items	Traditional measurement	TLS
Efficiency	3-5 mins per single cross-section	40-60 m per station within 3-5 mins
Results	Limited sample testing	Holistic detection
Presentation	2D cross-sections	3D as-built BIM

2 THE WORKING PRINCIPLE OF TLS

TLS technology uses the principle of laser ranging to quickly and extensively acquire the three-

*Corresponding author: by_sky@126.com

dimensional coordinate values, reflectivity, and color information of scanned tunnel arch walls and lining surfaces. The data acquisition speed can reach several tens of thousands to millions of points per second. The collected data is later processed on a computer to efficiently model tunnels. The data collected in the field can provide a basis for subsequent work as original measurement data resources.

At present, to fully utilize the functions of a 3D laser scanner, control software and data processing software are also needed. The control software is built-in software in the scanner, primarily used for data acquisition and processing according to certain requirements. The data processing software is generally provided by other companies, specifically designed for data processing, such as TK-PCAS (Tunnelkey 3D Laser Point Cloud Processing and Analysis System) which has optimal processing speed, learning cost, and scene quantity.

The laser rangefinder uses active laser emission and measures distance based on the laser echo signal, which is the laser reflected from the surface of the tunnel's arch walls and linings. By calculating the corresponding changes in the emitted and received lasers, the distance is determined, and the spatial relative coordinates of the scanned points are obtained. If the coordinates of the survey station are known, data processing software can be used to convert the coordinates to absolute coordinates, i.e., coordinates in the measurement coordinate system. The 3D laser scanner's reflector mirror vertically reflects the laser beam onto the scanned object, and the vertical angle encoder simultaneously measures the vertical rotation angle β (vertical angle) of the mirror. The laser scanner can rotate horizontally 360° , and the horizontal angle encoder simultaneously measures the scanner's horizontal rotation angle α (horizontal angle), thereby obtaining the three-dimensional point cloud data. The scanner scans the target object in all directions through the motion of the transmission device, and a series of processing is conducted to obtain the point cloud data of the tunnel's arch walls and linings. The spatial position of the scanned points relative to the instrument is shown in Figure 1.

Figure 1. Single point spatial coordinate positioning.

The point cloud obtained above is in relative coordinates and needs to go through engineering coordinate registration in order to have practical engineering significance. After setting up the total station, the center of the prism ball is marked by points, obtaining the coordinates of the prism ball center. At the same time, the scanner scans the back of the prism ball and fits the virtual prism ball center. By using post-processing software, the coordinates from the total station are transferred to the point cloud, with a registration accuracy as high as 1mm.

3 OVER-BREAK AND CLEARANCE DETECTION

After excavation or blasting on the face of the tunnel and completion of debris removal, the excavation face is scanned. TLS technology, with its efficient and holographic features, can quickly obtain the coordinates of all points within the scanning range. The relative point cloud obtained by the 3D laser is converted into absolute point cloud coordinates using a total station, and placed in the corresponding positions of the designed tunnel. By comparing it with the design cross-section, the analysis results of over-break or under-break can be obtained (Cheng et al., 2016). Similarly, scanning detection at the appropriate time can yield results on the intrusion limits of the initial support and secondary lining.

The newly-built Lijiang to Shangri-La Railway (referred to as "LiXiang Railway") is located on the Yunnan-Guizhou Plateau, with a total length of 139.7 kilometers and over 20 tunnels. It starts from the Shangri-La Basin at an elevation of 2400 meters and climbs northwards to the Shangri-La Basin at an elevation of 3400 meters, passing through plateau snow mountains. The surrounding rock stress of the tunnels is complex, and some tunnels experience significant deformation in soft rock, up to the magnitude of meters.

To better understand the deformation of various parts of the tunnel in the circumferential direction, the construction unit used TLS technology to conduct holographic scans and inspections of the areas with significant deformations in the tunnel. Point cloud data was then processed to generate cross-sectional drawings, 2D unfolded drawings (Qiu and Cheng, 2017), and 3D chromatographic maps. Among them, the 3D model provides the most intuitive display (Duan et al., 2021), differentiating over-break and under-break using warm and cool colors, and indicating the extent of over-break and under-break with varying shades of color. The results allow for a comprehensive understanding of the overall tunnel conditions, providing strong data support for experts in formulating response plans in the next steps.

4 SMOOTHNESS DETECTION

The smoothness index of the initial support of a tunnel refers to the level of unevenness on the

Figure 2. On-site view and three-dimensional laser results of a tunnel on the LiXiang Railway.

surface of the initial support concrete lining. It is an important criterion for tunnel engineering quality acceptance. The smoothness of the initial support directly affects the laying of waterproof membranes, the quality of the second phase lining, and the safety of the tunnel engineering. Excessive smoothness of the initial support surface can cause a decline in the construction quality of the waterproof membranes and the second phase lining, indirectly affecting the water permeability of the tunnel surface and the compactness of the secondary lining, making the tunnel surface more prone to water leakage and the quality of the secondary lining fails to meet the standards.

The traditional method of smoothness detection in railway tunnels involves using a 1-meter or 2-meter ruler to randomly sample different parts of the initial support. If the ratio of depth to length (D/L_t) is greater than 0.05, it is considered to exceed the smoothness standard. This detection method has low accuracy due to the randomness of the selected measurement points, and it is slow and inefficient. When using a total station to measure the smoothness of the initial support surface, the prism mode can greatly affect the measurement accuracy, resulting in a significant deviation between the fitted plane and the actual wall surface. Consequently, the precise smoothness of the initial support cannot be obtained. In addition, the subjective selection of measurement points on the arch wall of the tunnel cannot fully and accurately reflect the condition of the surface of the initial support.

Figure 3. Computing the ratio of depth to length.

By using the achievements of TLS holography, the initial support of the tunnel can be scanned and analyzed for smoothness using the “virtual standard ruler” in the system. Two-dimensional reports and three-dimensional walkthroughs can be generated, and they can be displayed in the section quality inspection module. By setting a threshold, the thermal distribution of the tunnel surface can be displayed, allowing clear identification of abnormal

locations and values of smoothness. This provides a comprehensive overview of the smoothness of the initial support, indirectly avoiding quality issues such as lining voids.

To verify the accuracy and efficiency of the three-dimensional laser smoothness detection technology, the Z+F5016 three-dimensional laser scanner was used at the entrance construction site of the Sangyuan Tunnel on the Xi'an to Shiyuan High-Speed Railway. The initial support in the section from DK40+671 to DK40+709 was scanned, and more comprehensive smoothness results were obtained by importing the data into post-processing software.

Figure 4. The on-site operation of the Z+F5016 three-dimensional laser scanner.

Figure 5. The thermal map of the simulated smoothness calculation results using the virtual ruler method (with the color scale and distribution chart on the right).

The blue region represents a smoothness depth-to-length ratio parameter between 0 and 0.05, the orange region represents a smoothness depth-to-length ratio parameter between 0.05 and 0.1, and the red region indicates that the smoothness parameter exceeds 0.1. The on-site construction personnel can locate the areas of potholes based on the mileage and planar coordinates and carry out corrective measures accordingly, as shown in the Figure 6.

5 REBAR INSPECTION

Before pouring the secondary lining concrete in the tunnel, it is necessary to conduct acceptance

Figure 6. The focused presentation of the areas with potholes.

inspection of the reinforcement in the initial support. The inspection of the geometric elements of the reinforcement includes the diameter, quantity, spacing, etc (Cheng et al., 2023). Due to the tight coordination of tunnel construction processes, inadequate time coordination often leads to the omission of acceptance of this hidden engineering process. However, a three-dimensional laser scanner can scan millions of points in just three minutes. The panoramic point cloud data of the reinforcement can be stored on a computer, and the diameter, spacing, and lap length of the reinforcement can be directly measured from the point cloud data.

To quickly analyze the quality of the reinforcement construction, the software can automatically extract and build a three-dimensional model of the reinforcement based on the characteristics of the lining reinforcement data. The modeling results are shown, and the reinforcement in both circumferential and longitudinal directions of the secondary lining is clearly visible. It makes hidden engineering no longer hidden.

Figure 7. The three-dimensional laser walkthrough of the reinforcement.

Ground Penetrating Radar (GPR) for reinforcement detection is affected by factors such as concrete compaction, antenna fit, and multiple reflections from double-layer reinforcements, resulting in reduced accuracy of radar detection. On the other hand, TLS technology provides intuitive, accurate, and holographic features.

Figure 8. The thickness of the protective layer (left) and spacing between surface reinforcements (right).

6 HOLOGRAPHIC DEFORMATION MONITORING

Deformation monitoring of surrounding rocks in railway tunnels has always been primarily done using total stations. After setting up the total station, the coordinates of the installed reflectors need to be surveyed and collected. Multiple monitoring of the reflectors on the arch can provide information about settlement near the arch. Monitoring the symmetrical reflectors on the arch waist can provide convergence information on both sides of the arch waist. However, traditional methods have several unavoidable limitations due to technological constraints:

- 1) Difficult to install and protect monitoring points
- 2) Inaccurate initial values
- 3) Dust accumulation and re-spraying affecting measurement
- 4) Influence of light sources
- 5) Large spacing between monitoring points, poor representativeness
- 6) Overall deformation and uneven deformation
- 7) Authenticity of early warning

TLS technology, unlike traditional single-point monitoring, can holographically extract three-dimensional coordinates of various parts of the tunnel. The collected point cloud is compared with the corresponding design section in software to obtain the results of the first scanning phase. Multiple 3D laser scans are performed at different times within the same interval. With the deformation of the tunnel, the deformation of the tunnel can be observed in the multi-phase 3D laser model. This technology allows us to understand the deformation of various positions in the tunnel, avoiding the drawbacks of traditional sampling monitoring. Compared to total station measurements, TLS has the following irreplaceable advantages in deformation monitoring:

- 1) No need to install reflectors, preventing false alarms

- 2) High scanning efficiency, fast speed, and no impact on other processes
- 3) Holistic monitoring and precise control of deformation in various parts
- 4) Absolute deformation measurement for the tunnel, monitoring overall deformation
- 5) Evaluation of regional point clouds, providing more accurate information

The Shanenshan Tunnel of the China-Laos Railway has a maximum burial depth of 200m and a total length of 2090 meters. The tunnel site belongs to a tectonic erosion high mountain landform and is affected by the Shanenshan Fault #2 and the Shara-bassi Fault, with large undulations in terrain. The strata crossed by the tunnel mainly consist of Carboniferous shales, sandstones, and mudstones. Due to the influence of the Laos-Burma suture zone and regional fault structures, the rock layers are distorted, folded, and fragmented, resulting in uneven deformation of the tunnel. Traditional total stations cannot assess the deformation outside the reflector area. However, using TLS for deformation monitoring can perfectly overcome this limitation.

After the initial shotcrete of the tunnel, the first TLS of the initial support section within the measurement range is conducted. The field scanning should comply with the following requirements:

- 1) In the deformation monitoring of the clearance, the range of the 3D laser scanner is limited to within 10m in front and back or within one times the diameter of the tunnel (whichever is smaller).
- 2) In the deformation monitoring of the clearance, the angular resolution should be set to be better than 0.036° . Each station measurement must be registered with a total station and cannot be spliced with targets.
- 3) The scanning frequency for clearance deformation monitoring needs to be determined based on the distance from the excavation face.
- 4) Setting up the station for TLS requires the cooperation of a total station. The control points used by the total station are set up on the arch or sidewall closer to the scanning section and on the arch with a longer construction time and almost stable deformation, for verification of the total station's control points.

From August 30th to September 22nd, the monitoring instrument used was the Faro S150 scanner, and a total of 17 scans were conducted. All scans were post-processed using resection method, with two known points observed in the backsight during station setup, resulting in small standard deviations. The holographic settlement and convergence cloud map for the section from DK21+942 to DK21+962 are shown in Figures 9 and 10, displaying the overall settlement and convergence in that section.

To verify whether the accuracy of the TLS in tunnel deformation monitoring meets the standards set by the construction company, deformation

Figure 9. Settlement color map (only showing the final displacement map).

Figure 10. Horizontal convergence displacement color map (only showing the final displacement map).

monitoring was carried out on the sections of K210+946 and K210+956. In the holographic deformation monitoring dataset, the monitoring data from the same mileages at the arch crown and arch waist were selected for comparative analysis. As of

September 22nd, for the K210+946 section, the maximum cumulative settlement at the arch crown was 65.8mm, while the scanner measured 70mm. The average deviation and mean error between the scanner and total station monitoring data were 2.0 and 5.1, respectively. The maximum cumulative convergence at the arch waist was 199.2mm, while the scanner measured 203.8mm. The average deviation and mean error between the scanner and total station monitoring data were -0.4 and 5.8, respectively. For the K210+956 section, the maximum cumulative settlement at the arch crown was 31.9mm, while the scanner measured 35.3mm. The average deviation and mean error between the scanner and total station monitoring data were -2.6 and 6.8, respectively. The maximum cumulative convergence at the arch waist was 102.8mm, while the scanner measured 112.5mm. The average deviation and mean error between the scanner and total station monitoring data were 1.3 and 8.5, respectively.

7 CONCLUSION

With the widespread application of TLS technology in railway tunnel construction, the use of this technology for detection and monitoring has become increasingly common in the tunnel industry. It has expanded from its initial applications in identifying encroachments and excessive under-excavation to include areas such as initial support alignment, rebar inspection, and holographic deformation monitoring. From the various scenarios and feedback, the following conclusions can be drawn:

- 1) Ensuring safety: From traditional limited cross-section sampling to holographic deformation monitoring, TLS technology can comprehensively cover all parts of the tunnel and accurately control the overall deformation. When there is non-uniform deformation in the tunnel, holographic area determination can better understand the differential deformations, promptly identify geological hazards, and provide effective data support for changes in construction methods.
- 2) Quality improvement: Through holographic detection, we ensure that the under-excavation, initial support clearance and smoothness, second lining clearance, and other aspects meet the design requirements before proceeding to the next construction step. By guaranteeing that each process meets the necessary standards, we ensure that the results of each phase during construction meet the design requirements. Compared to traditional total stations, TLS can provide a more comprehensive understanding of the under-excavation and encroachment conditions of excavation, initial support, and lining, while meeting the design requirements. This improves construction quality and speeds up the progress.

- 3) Cost control: According to statistics, excessive excavation results in concrete wastage of over 3000 cubic meters per kilometer. Through timely holographic detection using TLS, effective data support is provided for concrete preparation, actual consumption statistics, and optimization of drilling and blasting construction processes. This allows for precise concrete preparation and eliminates excessive concrete consumption. Additionally, the three-dimensional laser can accurately determine the precise location and value of the maximum settlement in a specific section. By comparing and summarizing the maximum settlement of continuous sections, the true deformation of the tunnel can be determined, allowing for dynamic adjustments to the reserved deformation allowance in the design. This helps ensure safety and save concrete costs.
- 4) Efficiency improvement: Three-dimensional laser on-site data collection only takes less than 3 minutes to obtain 40-60 meters of valid point cloud data, which is more than 7 times faster than a total station. This significantly improves on-site detection efficiency. The tunnel quality can be visually displayed through a three-dimensional model and color zoning, enhancing the efficiency of detection. Mid-process control can be implemented for defective areas, saving rework time in the later stages of construction and accelerating the construction progress.

ABSTRACT: Bored tunnels normally consist of rings assembled from segments that are bolted together in the tunnel boring machine. Until now the measurement of rings for position, attitude, and rotation has been limited to point-by-point collection by total station or manual extraction from scanned point clouds. The lack of an automatic calculation has limited the application of simple-to-use scanners for bored tunnel measurements to help service the drive-in real time. Furthermore, the value of mapping the segments for the purposes of planning a systemwide installation for new tunnels has been limited by the burden of manually extracting the segment edges from the scanning. The authors will propose and demonstrate that it is now possible to standardize the automatic extraction of quality-controlled segment edge information from a certain density of registered scan cloud using state-of-the-art processing software and by inputting a series of relatively simple-to-define engineering parameters.
