Abstract

The first fluidized bed thermogravimetric analyzer (FBTGA) has been developed. The proof of concept of the FBTGA has been carried out on the thermal decomposition of calcium hydroxide. The kinetics and modeling of coal pyrolysis and gasification were investigated in the FBTGA. The obtained activation energies for the individual gases that are produced from coal pyrolysis are 19 to 21% lower than those found for similar coals in the literature. This decrease in the activation energies is explained by a temperature gradient of 185 to 209°C. For the CO shift reaction, the resulting activation energy is 46.6 kcal/mol, increasing by 20% from the one used in the literature. The second reactor presented in this work is a TGA powered by electromagnetic irradiation. As an application for this reactor, a novel kinetic model based on a dual attempt to predict not only the yield but also the composition of bio-oil is presented. The validation of the developed models demonstrated an excellent capability of predicting the yield and quality of the produced oil. The third reactor is a saddle reactor, which consists of two V-shaped pairs of arms and minimizes the impact of the heat and mass transfer limitation on chemical reactions.

Keywords: fluidized bed TGA, microwave TGA, saddle reactor, kinetics, gas-solid reactions

1. Introduction

Due to environmental constraints and a lack of access to natural resources, the feedstocks of several industrial sectors are changing, which is one reason why many industrial applications use new fuel sources and blends of feedstocks, including biomass, lignin, coal, and petcoke. The intrinsic variability in feedstock makes it challenging to design, operate, and optimize a chemical process, where detailed information regarding hydrodynamics, transport phenomena, and reaction kinetics among other subjects, is essential.

The gasification of coal technology also faces many issues, including low efficiency, the presence of tar, high capital, and operating costs. Furthermore, power efficiency of gasification decreases by the presence of ash in coal, which is also a major constituent of air pollutants.

One of the main problems in a low-grade coal gasification process is the formation of deposits, which can prevent gas flow and heat transfer, thereby obstructing the operation of the process. High-process efficiency could be theoretically and thermodynamically obtained with low-rank coal by using better solid-gas contacting systems and catalysts.

The common problem of all gasification technologies is building an appropriate apparatus to develop reliable kinetics. Since the gasifier is at the heart of a coal gasification plant, the overall performance of the plant can be successfully analyzed based on the reliability of the reactor modeling. The design of a gasifier is based on the reliability of the kinetics used for this purpose.

During the last few decades, a limited effort has been made to investigate these topics when a complex feedstock is being processed. In addition, a few microreactors have been invented to overcome the issues and limitations associated with the conventional instruments used to investigate the abovementioned topics. Microreactors are used in the field of chemical engineering for their advantages over reactors of traditional sizes. The microreactors are more powerful due to their small size so the gravitational force can be neglected. The surface forces will therefore be greater and the mass and energy transfer to the reactor will be higher.

Different experimental techniques can be applied to help define some reactions, for instance, solid fuel pyrolysis, combustion, gasification and thermal decomposition of polymers. Thermogravimetric analysis, differential thermal analysis, and differential scanning calorimetry are three experimental techniques used to determine the kinetics and the mechanism of gas-solid reactions that are thermally activated. There are some limitations with the thermogravimetric technique due to non-uniform temperatures, non-homogeneity of the distribution of gas-solid and solid-solid materials, low heating rates, not enough solid samples to represent the homogeneity of it, and the bulk, interparticle, and intraparticle diffusion control. This led to the invention of the first fluidized bed thermogravimetric analyzer that has the potential to decrease and eliminate these limitations [1, 4].

One of the advantages of the FBTGA due to fluidization is good mixing for a better distribution of solid and gas particles. It is therefore possible using the fluidized bed reaction chamber to achieve uniformity in the sample temperature, eliminate bulk and interparticle diffusion controls, have an acceptable quantity of solid sample, and obtain a higher heating rate. The main benefit is the new FBTGA that can be used to test and define catalytic gas-solid reactions on a smaller scale to gain a better overall view on an industrial scale.

The second novel system presented in this work is a TGA powered by microwave heating (MWH). The dominant mechanism of MWH, which relies on the direct volumetric energy conversion within the irradiated material, has established MWH in a significant number of industrial applications. Superseding the superficial heat transfer of conventional heating (CH) with that of MWH avoids most of the problems associated with CH, the most paramount being the temperature gradient inside and outside the heated materials that prompt

the undesirable secondary reactions. Based on the dielectric properties of the irradiated materials, MWH can dramatically diminish operating costs and the potential of a thermal hazard since it only interacts with particular types of materials. This aspect would lead to producing materials with a novel microstructure and/or initiate reactions that cannot be initiated when CH is applied. Also, it can perform the existing reactions under conditions that are entirely different from that of CH. The main reason behind these unique merits is the ability to concentrate the generated heat energy at a particular component among others, which might affect the reaction kinetics. The high precision and safety of the microwave heating technology offer a greater level of control that, consequently, presides over the target end in a delegated manner. As microwave irradiation is easily and rapidly initiated and terminated, such a mechanism would lead to reducing the undesirable intermediate thermal steps and, in turn, enhance the production rate. Indeed, these unique advantages and others help in the fundamental understanding of the energy conversion mechanism of MWH and how it impacts the chemical reaction engineering, especially when a non-conventional feedstock is processed.

The main objective of this chapter is to demonstrate two of the up-to-date systems developed for a better understanding of the chemical reactions behind the processing of complex feedstocks. To do so, the abundance and characteristics of low-grade feedstocks are debated. The common problems associated with the processing of such non-conventional materials are presented. The novel microreactors that have recently been developed in academia, including the fluidized bed thermogravimetric analyzer and the microwave thermogravimetric analyzer that was developed in the PEARL group, are elucidated. PEARL stands for process engineering advanced research lab [5].

2. Experiments

2.1. Material

2.1.1. Experiments in the fluidized bed TGA

The materials that were used for the fluidized bed TGA are the Western Canadian lignite coal (WLC) and ash free coal. The ash free coal was produced by the Department of Chemical and Materials Engineering, University of Alberta, Canada. It was produced by solvent extraction [2, 3, 6, 7]. The proximate and the ultimate analyses are presented in **Table 1**. Furthermore, K_2TiO_3 was the commercial catalyst that was used for the catalytic ash free coal gasification experiments.

2.1.2. Materials for the experiments in the microwave thermogravimetric analyzer

The virgin material processed in the developed MW-TGA was softwood kraft lignin that precipitated from a Canadian kraft mill using the LignoForce System™, a patent pending process. The CHNS of lignin are C=63.27%, H=5.79%, N=0.07%, and S=1.56%, and the approximate analyses are fixed: carbon=37%, volatiles=62%, and ash=1%. Further analysis of the processed material can be found in the references [8–12].

	Canadian lignite coal	Ash free coal

2.2. Apparatus description

2.2.1. Fluidized bed TGA

A schematic of the first microreactor presented in this book chapter is shown in **Figure 1**. This apparatus represents the first fluidized bed thermogravimetric analyzer (FB-TGA) in the world. It comprises a quartz reactor that can operate at temperatures from 25 to 1200°C, furnace and measuring instruments, such as thermocouples, two mass flow controllers, pressure transducers and load cell. The FBTGA is connected to a data acquisition system. The fluidization is set to the minimum rate for any temperature using specific software. The quartz operates at atmospheric pressure with a wide range of solid samples, with a maximum amount of 50 g.

2.2.2. Microwave thermogravimetric analyzer

Two significant modifications were performed to make a traditional microwave oven work as a TGA. To accurately measure the weight loss of the payload during exposure to microwaves, the carrier reactor was directly connected to a scale fixed on the top of the oven through two opposing side-holes, as shown in **Figure 2**. To measure the transient mean temperature of the payload during the exposure to microwaves, an innovative thermometer called an “air-thermometer” was designed and made. That thermometer’s theory is mainly based on the direct relationship between the pressure and temperature of a constant volume of gas. As soon as the temperature of the thermometer probe increases, the pressure of the gas that is inside the probe increases as well. The measured increase in the gas pressure is, then, translated to find the temperature of the payload. It is worth mentioning that the thermometer probe is made of

Figure 1. Fluidized bed TGA. Reproduced from reference [1].

Figure 2. Microwave thermogravimetric analyzer.

quartz and the working gas is air. This means that almost no interactions between the applied electromagnetic waves and the materials mentioned above have taken place. This aspect ensures that the innovated thermometer does not suffer from the drawbacks of traditional thermometers. A manifold that consists of seven ports is connected at the outlet of the reactor to enable splitting the gas/vapor product at different times/temperatures for kinetics and other purposes. Farag and his co-authors have called the developed system the MW-TGA, which, at the time, was the first MW-TGA developed in the literature. For further details, kindly refer to [9, 10, 13, 14].

2.2.3. Saddle reactor

In the chemical reaction where a gas phase is one of the leading products, using a fluidized gas to overcome the heat and mass transfer limitations creates an issue. This issue is mainly related to the dilution of the produced gas. To overcome this problem, a novel reactor—called “saddle reactor”—has been designed and built in PEARL labs. As shown in **Figure 3**, the saddle reactor consists of two V-shaped pairs of arms connected at their bottoms by a small chamber. One of these two V-shaped is twisted by 90°; it is the optimum angle for the best mixing efficiency—which has been proofed in our previous publications. A set of heating elements is distributed in each arm to reach the needed temperature of performing the reaction. The power of those heaters was calculated and chosen to provide the heat energy required to achieve a particular end. Four built-in thermocouples are employed to control the input power to the heating elements and avoid reaching their melting points. A fifth thermocouple is fixed in the middle of the chamber that combines all the heating elements. This thermocouple controls the whole system based on the temperature of the payload. This means that the five measured temperatures are used to control the heating power of the system. The outlet of the saddle reactor is connected to two analytical techniques, GC and FTIR, to analyze the gas product.

2.3. Experimental procedures

2.3.1. Coal pyrolysis and gasification in the FB-TGA: the first application

The experiments for this first application of the FB-TGA were carried out in three steps: coal pyrolysis, partial oxidation of char, and coal gasification. The pyrolysis was performed in a nitrogen atmosphere. The heating rate was 40°C/min up to a maximum temperature of 700°C. The reactional system stabilized at 700°C for more than three hours. Novel kinetic parameters were developed for coal pyrolysis reactions from the collected data during the whole experiment time. During the second step, a specific gas mix of 5% oxygen-balance nitrogen was used to partially oxidize the produced char from the first step. The same heating rate and program were used. The experimental data were collected and used to derive kinetic parameters for the partial oxidation of the char. The third step in the FB-TGA was the coal gasification. During this third step, two different experiments were separately carried out under different conditions. The first one was at 650°C, while the second one was at 750°C. The two reactions were repeated three times. The method of collecting data was the same and the heating method was the same as the one that was used for the first two steps. The product gases, such as CO, CO₂, H₂, CH₄ and H₂O, were measured by a system of gas chromatography (GC)/Fourier-transform

infrared spectroscopy (FT-IR). For the three steps, the condensed tar at the exit of the reactor was burned off at 750°C.

2.3.2. Catalytic ash free coal gasification in FB-TGA: the second application

For this second application, about 5 g of lignite coal and ash free coals >500 µm and <600 µm in size were fluidized with 40 g of olivine sand, >180 µm and <212 µm in size. The experiments of coal gasification were carried out in a gas mixture of 5% oxygen-balance nitrogen (N₂), whereas those for ash free coal gasification were established in a gas mixture of 3% oxygen-balance nitrogen. The heating rate was 40 °C/min and the particle density for the olivine sand was 3290 kg·m⁻³. The gas flow rate was changed, based on the strategy developed for the fluidized bed TGA, depending on the temperature to maintain the bed at the minimum fluidization regime [1].

To test the stability of the catalyst K₂TiO₃, 20 g of the commercial catalyst was fluidized and heated up to 800 °C under air atmosphere for 5 h. The results from the weight loss measurement and gas analysis demonstrated and confirmed that the commercial catalyst was stable. In all of the experiments, the K/C weight ratio was 10%, where K and C represent the amount of K and C that are contained in K₂TiO₃ and coal respectively.

2.3.3. Microwave thermogravimetric analyzer (MW-TGA)

Strategic procedures were performed to enable investigating the product yield and composition obtained from the microwave thermal cracking of lignin. The freezing zone that was used to collect the liquid product was kept at -18°C and the entire tubing barrier to the condensation system was kept at 200°C to prevent any condensation before the freezing zone. Then, the reactor was filled with the raw material and connected as shown in **Figure 2**. Subsequently, the signal cables and the air thermometer were installed, and an inert environment was created by purging the system with N₂.

When the reaction started, all the valves of the product manifold were closed, except one that was used for collecting the product. Afterward, at a certain temperature/time, the opened port was switched off, and the closed one was switched on to start receiving the product during another interval temperature/time. Once the reaction was eventually completed, the obtained liquids and the solid product were cold to the ambient temperature. The liquid product was separated into the oil phase, which has the most organic chemicals, and the aqueous phase, which is lower in density than the oil phase and mostly water and sent for analysis.

3. Results and discussion

3.1. Proof of the concept of the fluidized bed TGA

The proof of the concept of the fluidized bed TGA was carried out with the thermal decomposition of the calcium hydroxide. The results for the fluidized bed and conventional TGAs are shown in **Figure 3**. For the conventional TGA, three different amounts of calcium hydroxide (10, 25, and 140 mg) were tested, while 4 g of calcium hydroxide were used in the FB-TGA.

Figure 3. Saddle reactor.

For the first temperature interval, the results with 25 mg from the conventional TGA were similar to the ones for the FB-TGA with 4 g of calcium hydroxide. The conventional TGA results for 10 and 25 mg are similar, but they are different from those obtained for 140 mg. Two different parts can be distinguished in **Figure 4**. For 10 and 25 mg, the first part can be defined from 370°C to 470°C, whereas this first part is from 395°C to 565°C for 140 mg [1].

For the first part, the heat transfer limitation and/or the temperature gradient are responsible for the difference between the results obtained for 10, 25, and 140 mg. The intraparticle and the external diffusions of the produced water through a small layer of CaO that was formed around the Ca(OH)_2 became the rate-controlling step of the thermal decomposition during the second step [1].

Only for the first step, the results for 25 mg of Ca(OH)_2 in the conventional TGA agree with those for 4 g in the fluidized bed TGA. Indeed, the thermal decomposition of Ca(OH)_2 in the FB-TGA was carried out in one stage, from 360°C to 540°C. Thus, a better heat transfer and mass transfer of water vapor was obtained with the use of the FB-TGA and no diffusion control was observed.

3.2. Coal pyrolysis and gasification in the fluidized bed TGA

The experiments of coal pyrolysis and gasification were carried out in the fluidized bed TGA. These experiments were used to derive novel kinetic parameters from the fluidized bed TGA.

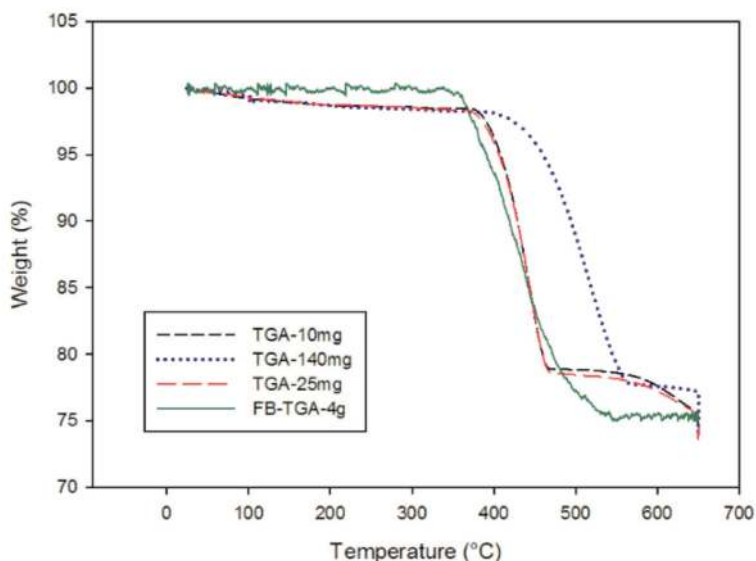

Figure 4. $\text{Ca}(\text{OH})_2$ decomposition: comparison between conventional and fluidized bed TGAs. Reproduced from reference [1].

The weight loss measurement and the quantity of gas produced showed general agreement, for both coal pyrolysis and gasification results.

Due to a 170–209°C temperature gradient, the obtained values of some activation energies are lower or higher than what was found in the literature. The obtained activation energy for the CO shift reaction was 195.0 kJ/mol. This value is 20% higher than the one in the literature. The obtained activation energies for coal pyrolysis reactions were 19–21% lower than the ones obtained in the literature for similar coals [2]. These new results confirm that there was a measurement error of the temperature in certain past studies. Such measurement error means that for the past studies, the reaction chamber temperature was not the one that is used to find kinetic parameters. Thus, there is a temperature gradient between the measured temperature by the thermocouple of the conventional thermogravimetric analyzer and the real one of the reaction. Such increase of 19–21% of the activation energy is the equivalent of 185–209°C temperature gradient of similar relatively exothermic reactions [2, 4, 15]. Finally, the results obtained were as expected and confirmed that the FB-TGA provides reliable kinetic parameters. More discussion and results are shown in our previous work [3, 4].

3.3. Catalytic ash-free coal gasification in a fluidized bed TGA

The second experiment that was carried out on the FB-TGA is about the catalytic ash free coal gasification. In this work, the effect of the catalyst on ash free coal gasification is included. A comparison of the total product gas yield and the weight loss is represented in **Figure 5**.

The two experimental results are in global agreement, and the slight difference is due to the produced tar from ash coal experiments.

A comparison of the carbon conversion results of coal, ash free coal and catalyst with ash free coal is illustrated in **Figure 6**. CatAFC, AFC, and coal, stand for the catalyst with ash free coal, ash free coal and coal gasification, respectively. The lowest carbon conversion is obtained from ash free coal for temperatures lower than 730°C, after which the coal

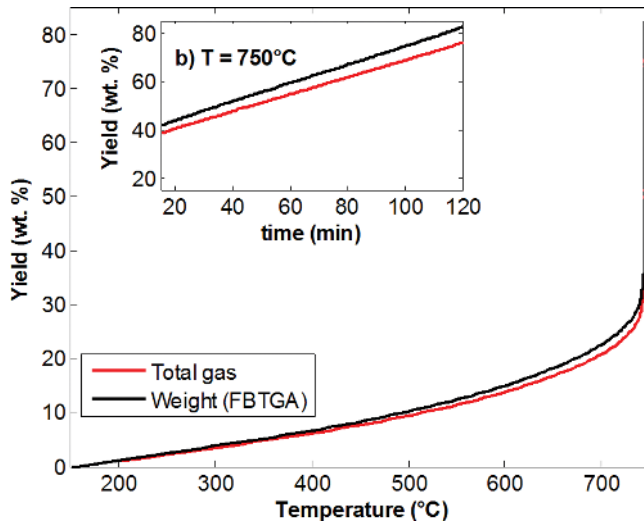

Figure 5. Catalytic ash free coal gasification in a fluidized bed TGA. Reproduced from reference [2].

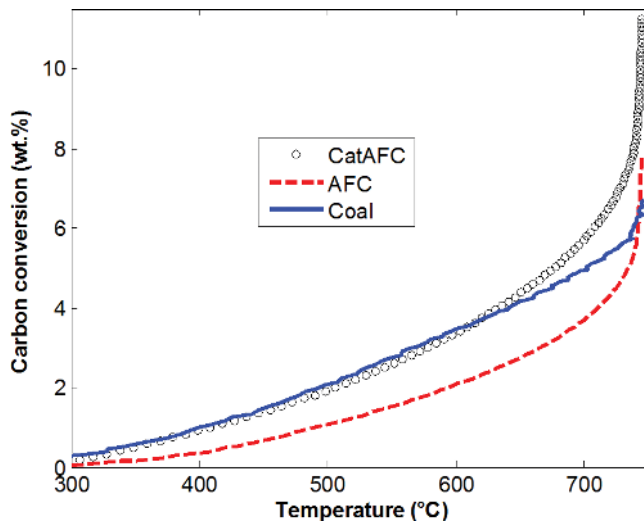

Figure 6. Temperature effect on carbon conversion. Reproduced from reference [2].

gasification had the lowest carbon conversion result. Thus, coal beneficiation has a negative affect on carbon conversion. Nevertheless, at 700°C, there is an increase of carbon conversion by 15.3 and 52.6%, for coal and ash free gasification. These values increased to 44.5 and 69.1% at 750°C [2].

Moreover, novel kinetic parameters are obtained form the FB-TGA experimental results for the reactions of partial oxidation, gas-water shift, and methane reforming. For char gasification, the results are similar to those found in literature [16]. For the gas-water shift and methane reforming reactions, the obtained activation energies were 56.5 and 77 kJ/mol, respectively. Compared to the values found in literature, these results are significantly lower. The lowest activation energy for the water-gas shift reaction was 70 kJ/mol [2, 17–19], which is 1.24 times higher than the one obtained in the fluidized bed TGA.

The lowest activation energy found in literature for the methane reforming reaction is 85 kJ/mol [2, 18], which is 10% higher than the one obtained with the fluidized bed TGA.

The values of the activation energies of the CO shift and the methane reforming reactions decreased by 56% and 33%, respectively, by using the catalyst. This catalyst was applied on other reactions in the literature and the activation energy was decreased by 43 to 75% [2, 20]. More results and discussions are given in our previous article [2].

3.4. Microwave thermogravimetric analyzer

Farag and his co-authors have employed the obtained experimental data from the developed MW-TGA, following the method presented in Section 2.3.3, to carry out a kinetic study based on the lumped approach. The established model in their work takes into consideration the chemical composition of the oil and aqueous products that are obtained from the microwave pyrolysis of lignin. As shown later, it considers that the virgin material converts into seven main products: remaining solid, phenolics, aromatic single ring and non-phenols (ASR-Non-Ph), aliphatics, heavy molecular weight compounds (HMWCs), water, and non-condensable gas, as shown later. The kinetic model demonstrated in Eq. (1) was used to estimate the kinetic parameters, activation energy, pre-exponential factor, and reaction order associated with every reaction toward producing these seven products.

$$\frac{dS}{dt} = -k_{o_s} \left(e^{-\frac{E_s}{RT}} \right) (S - S_{\infty})^{n_s} - k_{o_{ph}} \left(e^{-\frac{E_{ph}}{RT}} \right) (S - S_{\infty})^{n_{ph}} - k_{o_{ASR-Non-Ph}} \left(e^{-\frac{E_{ASR-Non-Ph}}{RT}} \right) (S - S_{\infty})^{n_{ASR-Non-Ph}} - k_{o_a} \left(e^{-\frac{E_a}{RT}} \right) (S - S_{\infty})^{n_a} - k_{o_{HMWC}} \left(e^{-\frac{E_{HMWC}}{RT}} \right) (S - S_{\infty})^{n_{HMWC}} - k_{o_w} \left(e^{-\frac{E_w}{RT}} \right) (S - S_{\infty})^{n_w} - k_{o_g} \left(e^{-\frac{E_g}{RT}} \right) (S - S_{\infty})^{n_g} \quad (1)$$

In Eq. (1), k_0 is the pre-exponential factor [time^{-1}], E_a is the apparent activation energy [J/mol K], T is the reaction temperature [K], and R is the universal gas constant [J/mol K]. The subscripts *s*, *ph*, *ASR-Non-ph*, *a*, *HMWC*, *g*, and *w* refer to solid, phenolic, aromatic single ring and non-phenolic, aliphatic, heavy molecular weight compound, gas and water products, respectively. **Figure 7**

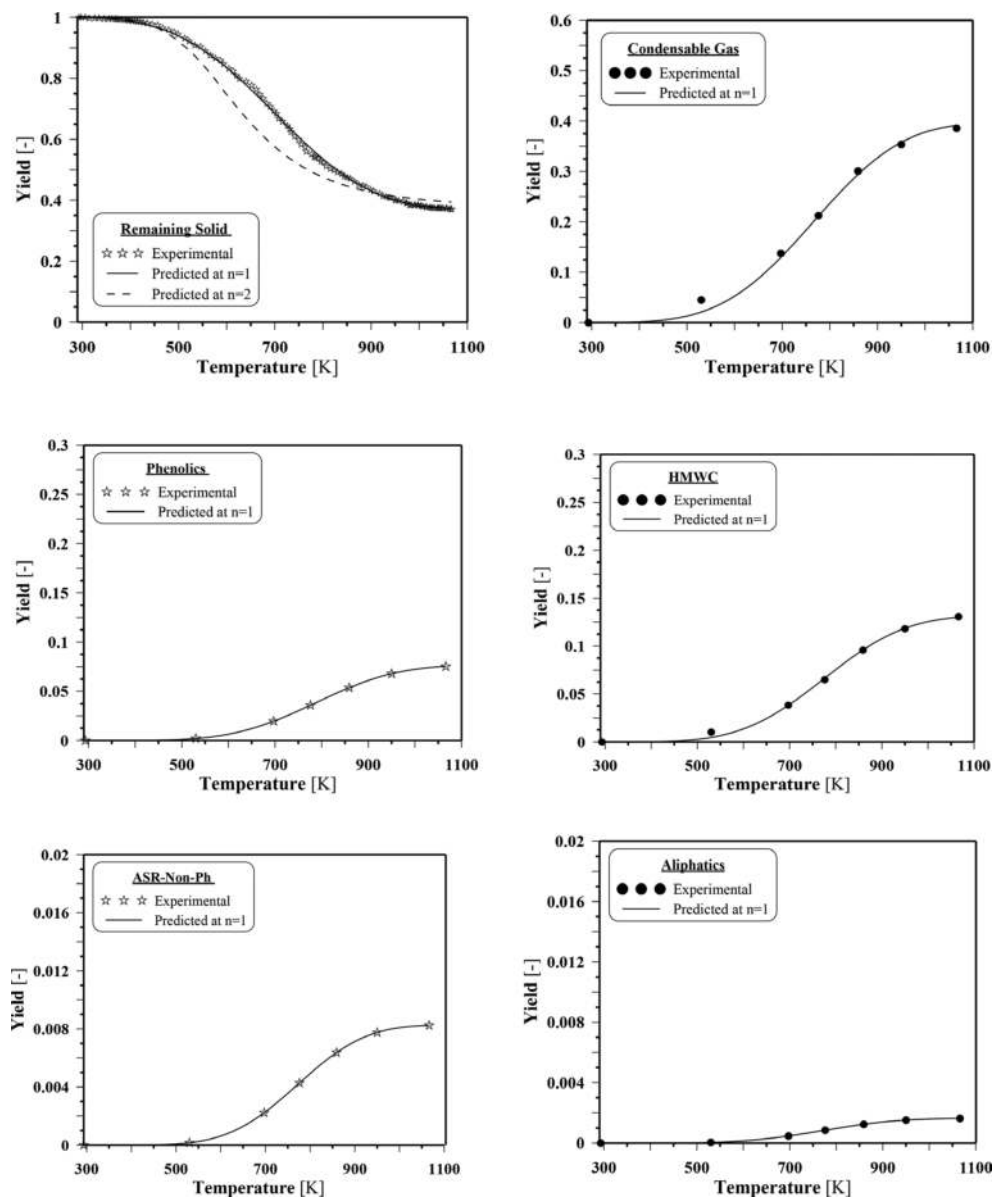

Figure 7. Experimental and predicted yields of lignin pyrolysis products. Reprinted with a permission form [5].

demonstrates the experimental and predicted yield of these products, except water, which can be calculated by subtracting the summation of these products from unity. **Table 2** shows that the estimated kinetic parameters of each single reaction lead to the production of each of these products. For the full details regarding how these parameters were determined, kindly refer to [10].

Farag et al. believe that up to 725 K the condensable gas yield is slightly lower than that of the non-condensable gas, which could be the result of the swift split in lignin-side aliphatic hydroxyl groups [10]. Beyond 725 K, the total liquid yield continues increasing because of the decomposition of strong chemical bonds in the lignin network. Based on the estimated kinetic parameters, the reaction rate of the liquid products is lower than that of the solid product. The authors have claimed that the low secondary reactions under these conditions might be the reason for this result. The non-condensable gas product is mostly produced from the cracking of lignin-side chains, and the liquid product is produced from the breakdown of bonds between lignin aromatic rings. Therefore, the estimated activation energy of the non-condensable gas is lower than that of all oil products. Since the structure of the decomposed material's network is totally poly-aromatics, the reaction rate to produce phenolics and HMWC groups is much higher than that of ASR-Non-Ph. Accordingly, the estimated activation energy of aliphatics is greater than that of the other groups. The authors also think about the impact of microwave heating to decrease the probability of a secondary reaction when producing aliphatics.

In the scientific literature, an apparent contradiction to the interpretation of the influence of electromagnetic irradiation on reaction kinetics has been documented. Wang et al. 2013, Li et al. [26], Fukushima et al. 2013, Adnadjevic and Jovanovic [25], Sun et al. [22], Jovanović 2012, and a few other research groups believe that the reaction activation energy decreases under microwave irradiation [21–28]. On the other hand, Mazo et al. [28] and Yadav and Borkar [27] have reported that E_a is the same in both cases, MWH and CH [13, 29–31]. It is well known that the wavelength of microwaves is significantly longer than the intermolecular distance of the target, which ideally doubles the impact of MWH on the activation energy. However, this does not reject the probability of producing some intermediates that could

Product	ko [min ⁻¹]	Ea [kJ/mol]	n
Remaining solid	7	19	1
Water	9	27	1
Phenolics	21	38	1
HMWC	22	35	1
ASR-Non-Ph	1	40	1
Aliphatics	20	47	1
Condensable gas	22	29	1
Non-condensable gas	6	22	1

Table 2. The estimated kinetic parameters of the Farag et al. [5] model.

Figure 8. Effect of the speed mixing on the temperature profile in the saddle reactor.

have different behaviors than that of the starting material which would impact the activation energy. In such cases, the dielectric properties of the produced intermediates should be measured and investigated to understand the potential of having hot spots that affect the reaction kinetics locally [14, 32, 33]. Therefore, further investigations are required to discover the fact behind the reported effects on the activation energy and other reaction kinetic parameters.

3.5 Saddle reactor

As explained previously, the saddle reactor is mainly used to avoid the dilution of the product gas. Indeed, the solid sample can be very well mixed in the saddle reaction chamber without using a gas mixing agent. To prove this concept, different masses of silica sand—from 20 to 30 g—were mixed and heated up to 350°C in the reactor. The results shown in **Figure 8** are for different mixing speeds, ranging from 15 to 30 RPM. The similar temperature profiles confirm the good mixing in the developed reactor.

4. Conclusion

New microreactors for the gasification of low-grade feedstock have been developed. The fluidized bed TGA was applied to the coal and ash-free coal gasification. New values of activation energies are obtained. The values for coal pyrolysis are from 34.7 to 59.8 kcal/mol, whereas the one for the CO shift reaction is 46.6 kcal/mol. The use of the potassium catalyst is allowed to reduce the activation energies of the CO shift and the methane-reforming reactions

by 56 and 33%, respectively. A novel microwave-TGA equipped with an innovated air thermometer and a product manifold was built. The developed system was used to predict the product yield and the bio-oil composition from pyrolysis of kraft lignin using a lumping approach. The experimental data were employed to estimate the kinetic parameters of every reaction to produce the solid, water, aliphatics, phenols, aromatic with a single ring aromatic non-phenol, heavy molecular weight compounds, and gas product.

At a temperature below 725 K, the yield of the gas product was higher than that of the liquid products. This results from the swift split of the lignin chains that mainly produce water and/or gas products. The estimated kinetic parameters showed that the rate of thermal cracking of lignin is higher than that of the liquid product, which points out that the possibility of secondary reactions is low. The formation of the ASR-Non-pH and aliphatics families is lower than that of the HMWC, which could originate from the complex structure of the lining.

A saddle reactor is developed, and good mixing was observed for 20–30 g of silica sand and speed mixing of 15–30 RPM.
